## DAMSELS IN DISTRESS: WIDESPREAD DISEASE IN GALAPAGOS REEF FISHES (Abstract ID: 29968)

Emergent disease is one of the less understood but potentially devastating impacts of climate change. Warmer waters have been associated with increased disease and population decline in benthic invertebrates, but less is known of the effects on fish communities. We observed an outbreak of fish disease during the onset of the 2015-2016 El Niño event in the Galapagos Islands, Ecuador. The disease presents initially as discoloration of the skin followed by progressive whitening, loss of scales, and epithelial deterioration. Advanced cases have severe loss of structural integrity and limb function. Infected individuals show abnormal behavior including distressed swimming, lethargy, increased opercular ventilation rates, and aggressive solicitation of cleaner fish. Pathogen isolation is in progress. To date, 16 infected species have been recorded to a depth of 15m on several islands. Prevalence rates vary, but the four most heavily infected species at Cuatro Hermanos Island are the ring-tailed damselfish Stegastes beebei (49.1%), the giant damselfish Microspathodon dorsalis (28.6%), the Panamic soldierfish Myripristis leiognathos (26.0%), and the king angelfish Holacanthus passer (19.6%). Prevalence rates are probably under-estimated as fish with advanced disease likely fall prey quickly to predators. The wide geographic extent (>73 km), high prevalence rates, range of species from vastly different phylogenetic backgrounds affected, and progressive symptoms of the disease present an alarming situation for this diverse and productive fish assemblage with high rates of endemism.

## CAPACITY DEVELOPMENT FOR PROTECTED AREA MANAGEMENT IN THE PACIFIC (Abstract ID: 27790)

The Pacific Islands Managed and Protected Area Community (PIMPAC) was established in 2005 as a long term capacity development program and social network of site based managers, non-governmental organizations, local communities, federal, state, and territorial agencies, and other stakeholders working together to collectively enhance the effective area-based management in the US Pacific Flag Islands and Freely Associated States of Micronesia. To do this PIMPAC supports capacity building for ecosystem-based management approaches, which integrate land and sea connections as well as human dimensions into management planning and activities. Examples of this scope include ridge to reef management, marine and/or terrestrial protected areas, and community based locally managed areas. PIMPAC's three main goals include: 1) develop model sites that are effectively planned, monitored, evaluated, and managed adaptively, 2) develop jurisdictional teams with core competencies to carry out effective management, and 3) institutionalize trainings in the region to support long term access to skills building for current and future area based managers. PIMPAC uses four types of activities to reach its goals: 1) Training and Technical Support, 2) Learning Exchanges, 3) Partnership Building, and 4) Communications/ Information Sharing. When implementing these activities, PIMPAC focuses on: adaptive management planning, biological monitoring and socio-economic monitoring enforcement, climate change adaptation and watershed management.

## MACRO AND MICRO-SCALE SPATIAL VARIATION IN THE ACOUSTIC ACTIVITY OF SNAPPING SHRIMP ON CORAL REEFS IN THE PACIFIC (Abstract ID: 29218)

Coral reef soundscapes are increasingly becoming recognized as critical factors in the study of reef dynamics, from the role they play in larval recruitment to the assessment of coral reef biodiversity and ecosystem stability. Snapping shrimp produce the predominant source of sound on most coral reefs at frequencies between 2 and 20 kHz. Their activity is influenced by a variety of abiotic factors, including light levels, temperature, and weather. As such, coral reef soundscapes are prone to considerable flux and variation. However, this variation is still poorly understood on a variety of spatial and temporal scales, making it difficult to draw meaningful comparisons between the soundscapes of different reefs. We report on an effort to quantify the acoustic activity of snapping shrimp across twelve coral reef sites in the Pacific Ocean separated by distances ranging from hundreds of meters to thousands of kilometers, including reefs across the Hawaiian archipelago, the Northern Mariana Islands, and American Samoa. We use data obtained from long-term, bottom-moored acoustic recorders to document the variability in snapping shrimp activity observed on multiple temporal scales, ranging from days to seasons, and examine factors correlated with this variability at each location.

## INTEGRATING ECHO-SOUNDER AND UNDERWATER VIDEO DATA FOR DEMERSAL FISH ASSESSMENT (Abstract ID: 29303)

Effective management of demersal fish species requires accurate, spatially explicit assessments of their abundance and distribution. Non-invasive techniques such as echo-sounders and visual census are of particular importance in no-take marine reserves where direct sampling is restricted. This study is investigating the use of echo-sounders and stereo Baited Remote Underwater Videos (stereo-BRUVS) in demersal fish assessment. Echo-sounders have the advantage of covering nearly the entire watercolumn and being able to cover vast areas in a relatively short period. However, "ground-truth" data is usually needed to produce species-specific identification and sampling the area close to the seafloor is problematic, requiring investigation, particularly for demersal species in complex topography. Whereas, underwater video techniques allow identification to species level in most cases, but in a particular location. The combination of co-located bathymetric and habitat maps, with quantifiable acoustic backscatter and species-specific visually groundtruthed abundance, holds potential to significantly further these studies and provide a more cost- and labour-efficient sampling regime. This study provides a preliminary investigation into the relationship between active acoustic and stereo-BRUV derived biomass maps acquired in Western Australia's shallow water reefs and compares the results across various depth strata, bathymetry and habitat.

FLESHY MACROALGAE SHARE DOMINANCE WITH OTHER ORGANISMS ON DEGRADED CORAL REEFS (Abstract ID: 29985 | Poster ID: 583)

Based on an analysis of 482 Caribbean area sites surveyed by AGRRA in 2011-2013, fleshy macroalgae (FMA) cover exceeded that of all other benthic organisms. Yet FMA dominance (defined as occupying 25% or more of the substratum) was only observed in 60% of the sites. When the cover of calcareous macroalgae is added to FMA, macroalgal (MA) dominance increased to 77% of the sites. Turf algal sediment (TAS) mats, which displace corals and prevent recruitment of coral larvae, were present in 77% of the sites, but only displayed dominance at 10% of sites, mainly at shallower depths (6 vs.12 m) and on patch reefs. Live coral cover only averaged 13% across all sites. The average cover for crustose corallines and sparse turf algae, both ideal coral recruitment surfaces, averaged 20%. Invertebrates that overgrow corals (certain sponges, octocorals, zoanthids, tunicates) were present in most (81%) surveys. Our results support the observation that, organisms promoting reef construction are losing the competition for substratum space on most of these Atlantic reefs. Large-sized herbivorous fishes offer one of the only natural ways to remove MA holdfasts but will avoid TAS mats. While bans on harvesting parrotfish are a sensible component of biologically-based management, recovery or restoration of sea urchins may be more important. In heavily fished reefs, physical removal of MA, and/or reduced nutrient and sediment inputs to nearshore reefs might also be needed to discourage the growth of undesirable benthic algae.

EVIDENCE OF THREE LEVEL TROPHIC CASCADES WITHIN REEF FISH ASSEMBLAGES FROM BODY-SIZE DISTRIBUTIONS (Abstract ID: 29367)

Assemblage body-size distributions can provide information on the ecological processes that structure ecosystems. Fishing can restructure marine ecosystems by directly removing large individuals, thereby indirectly reducing predation pressure on medium bodied individuals (prey of larger bodied species) and increasing their density. We compared assemblage body-size distributions sampled using baited underwater stereo-video inside and outside areas closed to line fishing at the Houtman Abrolhos Islands off Western Australia over three years. Both spline based Functional Data Analysis and multivariate analysis of size bins found significantly lower proportions of large and small body-size species and a greater abundance of medium body-size species at fished sites relative to those closed to fishing. Within this study, metrics based on body-size appear to be much more sensitive to the effects of fishing than metrics based on abundance or biomass of particular species. Obtaining reliable body-size information is an important consideration in studies investigating the effects of fishing on reef fish assemblages.

GUAM'S STAGHORN ACROPORA POPULATIONS REQUIRE MANAGING FOR RESILIENCE (Abstract ID: 29488 | Poster ID: 169)

Guam's coral reefs were severely impacted from back-to-back bleaching episodes in 2013 and 2014. Surveys in 2015 estimated that 47% (+/- 10%) of Guam's staghorn Acropora were lost to bleaching-related mortality within 12 months. This constitutes the loss of over 18 ha of coral dominated by four species: Acropora muricata, A. aspera, A. c.f. intermedia, and A. c.f. pulchra. Staghorn Acropora were found at 21 sites and half of these sites lost ≥75% of their cover; others have been reduced to small, scattered clumps. Efforts to manage for future resilience have begun. The reproductive biology of this group has not previously been studied in Guam and this is the current focus of these efforts. Preliminary results suggest that, in 2015, A. c.f. intermedia spawned in April, A. cf. pulchra and A. muricata spawned in May, and A. aspera spawned in September. Genetic analysis is in progress to examine connectivity between remaining staghorn populations. Additional current management efforts include culturing of asexual fragments from surviving communities and reintroducing them to decimated areas. Understanding the reproductive biology, genetic structure of remaining populations, and the relative roles of both asexually- and sexually-produced colonies in natural populations are all critical to effectively managing and re-establishing Guam's staghorns.

CORAL RECRUITS ON PALMYRA ATOLL EXHIBITING 'STRANGER DANGER' (Abstract ID: 28745)

Corals are sessile animals that form some of the most biodiverse regions in the world. Since these animals are usually found growing on a piece of hard substrate, they search for cues before settlement as planktonic larvae. These animals have been known to show density dependent recruitment, and one species *Montastrea faveolata* shows a Janzen-Connell effect where young individuals do not mix with adults to escape bacterial and other conspecific related diseases. This information thus spurs the question do coral recruits show density and distance dependent recruitment towards other recruits? In order to answer this question photomosaic analyzing techniques were used to find average distances between all known coral recruit genera at three sites on Palmyra Atoll. It was found that each genera has their own specific bias, showing clustering when compared to certain species but over-dispersion towards others. These findings are also heavily skewed by population size since the genera compared were found at vastly different densities. In the future including studies of adult distances to juveniles conspecifically would potentially provide information on possible Janzen-Connell effects.

A TALE OF TWO OCEANS: ARE DEEP-SEA BAMBOO CORALS FUSSY ABOUT THEIR NEIGHBORS? (Abstract ID: 27823)

Bamboo corals (Family Isididae) are a widely distributed group of gorgonian octocorals, with the subfamily Keratoisidinae commonly found in the deep sea below 200 m. High-definition in situ images, video footage, literature, and collected specimens were used to characterize the benthic megafauna communities on seamounts off Tasmania in the South Pacific and on the New England and Corner Rise Seamount chains in the Northwest Atlantic. The overall benthic community structure is strikingly different between the two locations. However, a detailed taxonomic analysis of the bamboo corals collected suggests that a few of the species present on Tasmanian seamounts are very closely related to, and perhaps the same species, as specimens collected from the Northwest Atlantic seamounts. These results support the individualist theory of ecology and imply that the environmental conditions in these two regions, although in two different oceans and on opposite sides of the globe, are favorable for the settlement and growth of these particular species of bamboo corals, independent of their surrounding neighbors.

MODELLING CORAL PHOTO-PHYSIOLOGY AND GROWTH POTENTIAL UNDER VARYING TURBIDITY REGIMES (Abstract ID: 28292)

Management of dredging typically relies on suspended sediment thresholds. When sediment thresholds are exceeded, the risk of damage to corals is elevated and dredging activities are suspended. Yet, most threshold values are based on limited biological data, are not site specific, and are typically linked to coral mortality not stress. To provide more effective management of reefs vulnerable to high sediment loads, a numeric model was developed based on site-specific biological (photosynthetic yield, P-I curves) and physical data (light attenuation, turbidity). The model quantifies zooxanthellae and coral growth potential (mass carbon) under varying light-turbidity regimes, and incorporates coral acclimation to low light over time following increases in zooxanthellae biomass. A high growth potential indicates a non-stressed coral with energy for essential functions (e.g. feeding, reproduction). The model (2D FM model with ECO Lab; MIKE, DHI 2012) was run for two weeks under four light-turbidity regimes (< 5, <20, <45, >100 mg/l) for Platygrya sinesis, a common clear and turbid water coral. The model output indicates that at <20 mg/l, both zooxanthellae (100-150%) and coral (18-50%) growth potential is high. However at >45 mg/l low light availability results in a negative scope for growth with no photo-acclimation occurring at the highest turbidities. Our study provides a critical step towards a comprehensive model that, together with site specific data, can be used as a quantitative tool to both track and forecast the potential effects of high sediment loads on corals.

CARIBBEAN OCTOCORAL COMMUNITY DYNAMICS: REGIME CHANGE, STABLE STATES OR JUST THE LAST COLONY LEFT STANDING? (Abstract ID: 29089)

Descriptions of the transition of tropical reefs from dominantly scleractinian cover to other taxa have overwhelmingly focused on the well documented loss of scleractinians in favor of macroalgae. However, reports from both Caribbean and Indo-Pacific reefs have documented cases of increased abundances of taxa such as sponges, zoanthids, corallimorpharians, or octocorals. In most cases, the basis for these transitions is unknown, but it is clear that the trajectories of other macro-invertebrate populations, when known, are different from those of both scleractinians and macroalgae. Focusing

on Caribbean octocorals we explore 3 classes of hypotheses for why some non-scleractinian taxa have increased in abundance. 1, Scleractinians and octocorals compete for space and the competitive balance has changed; 2, Octocorals are more resistant to environmental challenges than scleractinians; or 3, Octocoral populations are more resilient than scleractinians, which can be subdivided to 3a, octocoral populations recover more rapidly and preempt scleractinian recovery, and 3b, octocorals are less affected by, and benefit from, feedbacks between community change and recruitment that have limited the resilience of scleractinians. Data to rigorously test these hypotheses are not available but decadal scale data from two Caribbean locations suggest that the resilience of octocoral populations may be a key component of observed changes in abundance.

THE RELATIONSHIP BETWEEN BEHAVIOURAL AND PHYSIOLOGICAL TOLERANCE TO ELEVATED CO2 IN CORAL REEF FISH (Abstract ID: 29351)

Reef fish exhibit individual variation in both behavioural and physiological sensitivity to elevated CO2. Those individuals that are most tolerant provide hope for future populations to adapt to changing environmental conditions. Yet whether there is an interaction between behavioural and physiological tolerance is unknown. We seek to understand this relationship, as well as how elevated temperature might alter it. Juvenile Acanthachromis polyacanthus will be reared in one of four temperature x CO2 treatments: control, elevated temperature, elevated CO2, or elevated temperature and CO2. After 40 days individuals from each treatment will be tested for their behavioural and physiological tolerance to elevated CO2. Behavioural tolerance will be measured as response to chemical alarm cue in a two-choice flume tunnel. Physiological tolerance will be measured as aerobic scope in a respirometer. We predict that a tradeoff will exist between behavioural and physiological tolerance to CO2, where individuals with a high behavioural tolerance will have a low physiological tolerance, and vice versa. This indicates that at the population level, selection towards highly tolerant individuals will act orthogonally to the direction of the most genetic variation, and so future adaptation to high CO2 conditions will be constrained. Furthermore, we predict that elevated temperature and CO2 together will have a multiplicative effect on physiological tolerance. This will increase the importance of behavioural tolerance, and thus push future populations towards an increased behavioural tolerance.

FINDING A BIOLOGICAL UPPER LIMIT FOR THE MESOPHOTIC ZONE (Abstract ID: 28599)

The lower boundary of the mesophotic zone on coral reefs is largely accepted as coinciding with the last photosynthetic hard corals. The upper limit is set at 30m. These two boundaries are fundamentally different in character. The lower bound is capable of moving, accommodating changes between sites in water clarity and local species capabilities. Such a mobile boundary allows the logical comparison of mesophotic reefs from different sites based on their biology. The upper bound, as currently defined, is a more limiting concept. Generally there is greater environmental variability in the shallows than at depth. This variability could cause the upper limit to vary from site to site. A fixed upper limit may lead to illogical comparisons between sites across reef zones. Here it is argued that we should try to reach a consensus on an upper limit of the mesophotic zone, rooted in biology, allowing the easy identification of mesophotic reefs by researchers. Potential defining characters may include irradiance levels, changes in physiology or taxonomic indicators. Here we propose using benthic community composition. Coral presence or absence as a signal integrates many environmental variables which may reveal the boundaries of mesophotic reefs. Identifying corals visually may also be faster and require less specialist equipment than other approaches. Data from Honduras is used to show vertical reef structure if we take a lead from community data. An in progress follow up project employing a systematic review to capture the global picture will also be explained.

GROUPER CATCH TRENDS (1950S TO 2014) IN FIVE MARINE KEY BIODIVERSITY AREAS INFERRED FROM FISHERS' KNOWLEDGE USING LINEAR MIXED METHODS (Abstract ID: 28046 | Poster ID: 10)

We analyzed fishers' knowledge data(n=1245) on ten groupers species from 1950s to 2014 in 5 marine key biodiversity areas(mKBA) in the Philippines, including Lanuza Bay, Danajon Bank, Verde Island Passage, Polillo Islands and Honda Bay using Generalized Linear Mixed Modelling to determine the catch per unit effort(CPUE) declines of each grouper species throughout the decades. Fixed effects included effort variables such age, gear, horsepower and hours fishing, while random effects included the interviewee, age and mKBA. Life history metrics such as maximum total length, growth coefficient, and age at maturity were also modeled to determine which were better predictors of CPUE. Dispersion and Akaike Information Criterion were the criteria for model selection. Groupers including *Epinephelus lanceolatus*, *Plectropomus leopardus* and *Epinephelus polyphekadion*, among others exhibited 34-74% CPUE decline accompanied by a 29-73% decline in the size of fish caught since the 1950s, with *E.lanceolatus* exhibiting the highest CPUE decline.Life history analysis showed that groupers with lower growth coefficient appear to be preferred by fishers. This provides evidence on catch declines throughout the decades and its possible drivers of depletion which may be useful in reassessing local and national policies on small scale grouper fisheries, which includes updating the National Biodiversity Strategy and Action Plan 2016-2028. Marine protected area networks should also be strengthened to encompass the ontogenetic habitats of species,specifically groupers.

RESPONDING TO WIDESPREAD REEF FINFISH EXTIRPATIONS IN THE PHILIPPINES INFERRED FROM ORAL HISTORY AND FISHERS' KNOWLEDGE USING LINEAR MIXED MODELS (Abstract ID: 27938)

While the Philippines is known to have the globally greatest number of shorefish species with very high fishing pressure, yet no long-term reef fisheries data are available to explore species-level changes that may have occurred widely. Through oral history with 2655 face-to-face interviews, we studied fishers' recall of past catch rates of reef-associated finfish species from Lanuza Bay, Danajon Bank, Verde Island Passage, Polillo Islands and Honda Bay. We modeled temporal trends in catch per unit effort (CPUE) based on fishers' reports of typical good days' catches. Sixty-five different finfishes were reported by fishers to have disappeared from catches between the 1950s and 2014. The five species common to all sites with the greatest number of fishers targeting or opportunistically catching them and reporting zero catches, and with greatest species intrinsic vulnerability index values, were *Bolbometopon muricatum*, *Cheilinus undulatus*, *Alectis ciliaris*, *Epinephelus lanceolatus* and *Lutjanus argentimaculatus*. Our models show that between the 1950s and 2014, the perceived CPUE of bumphead parrotfish declined by 88%, that of humphead wrasse by 82%, African pompano by 66%, giant grouper by 74% and mangrove red snapper by 64%. Using fishers' knowledge and oral history in this data-poor setting, we identify reef fish species vulnerable to local extinction. Among the country's responses to prevent such species loss includes updating the National Biodiversity Strategy and Action Plan 2016-2028 and strengthening of marine protected area networks in marine key biodiversity areas.

THE ROLE OF NUSA PENIDA MPA IN MANTA RAYS CONSERVATION AND TOURISM WITHIN THE LESSER SUNDA ECOREGION (Abstract ID: 27781)

Nusa Penida Marine Protected Area (20,057.2 ha) is located in southeastern Bali Island of Indonesia. It is one of the most dense marine resource users in the southwest corner of the 'Coral Triangle' by welcoming 200,000 visitors annually. Nusa Penida waters encompass critical habitats for unique marine species such as manta rays and sunfishes. Manta rays (Manta birostris and M. alfredi) have been assessed as vulnerable species according to IUCN Red List, and recently have been protected under Indonesian government law since 2014. The economic value created through visitors in Nusa Penida spend their money nearly USD 2 million annually. However, manta tourism has to become more sustainable in terms of manta life span and their habitats, as well as economic

value to the people. Based on the photo identification, 512 individuals of manta rays have been counted within the Nusa Penida MPA since 2012. Some of them even have been sighted 450 km away, in Komodo National Park. Major threats that need to be addressed include illegal fishing and bycatch, marine debris and massive tourism on manta sighting. This means connecting MPAs in order to protect their migration habitats plays an important role in manta conservation, and a MPA network based on marine connectivity studies is needed. Therefore, it is necessary to link Nusa Penida MPA and some MPAs along the south coast of the Lesser Sunda Islands as one cluster of MPAs network. This paper attempts to describe manta ray issues and the role of Nusa Penida MPA to support manta ray protection within the Lesser Sunda Ecoregion.

### HIGH PCO2 AND WARMING ARE THREATS FOR THE PEARL OYSTER PINCTADA MARGARITIFERA AND THE PEARL FARMING. (Abstract ID: 28220)

The pearl culture is one of the most lucrative aquacultures worldwide. In South Pacific area, it depends on the exploitation of the pearl oyster Pinctada margaritifera and relies on the environmental conditions of lagoons. It is fundamental to assess climatic stressors, such as ocean acidification and the warming on the functionality of the resource. The impact of pCO2 (3540, 1338 and 541µatm) was evaluated twice on pearl oysters exposed for 100 days on shells by optical and electronic microscopy, and at molecular level by measuring the expression of mantle genes involved in the formation of calcite and aragonite. The impact of temperature (22, 26, 30 and 34°C) was studied on the metabolic capabilities biomineralization on pearl oysters exposed 10 days. High pCO2 (3540 µatm) significantly slowed down the shell deposit rate at the ventral side andthe expression level of Pmarg-PUSP6 gene. SEM observations found chemical dissolution signs. Thirty degree Celsius was the temperature where energy metabolism and, hence, the scope for growth, wasmaximizedthen dramatically fell at 34°C. Biomineralization examined through the expression measurement of mantle genes showed significant changes of Pmarg-NacreinA1, Pmarg-MRNP34, Pmarg-Prismalin14 and Pmarg-Aspein. These changes showed that expression of these genes was maximum at 26°C and minimum at 34°C. The responses to high pCO2 and high temperatures, according to the Intergovernmental Panel on Climate Change (IPCC) projections, highlighted that pearl oyster stocks and cultures would be severely threatened in the next decades.

### QUALITY OVER QUANTITY: HABITAT CONDITION IS A STRONGER DRIVER OF FISH BIOMASS ON CORAL REEFS THAN HABITAT SPATIAL EXTENT AND CONNECTEDNESS IN THE PHILIPPINES (Abstract ID: 28973)

There is increasing research emphasis on optimising the placement of no-take marine reserves (NTMRs) to maximise their conservation and fisheries benefits. Recently, spatial analysis tools have been used to demonstrate that spatial characteristics such as the extent, proximity, and connectedness of key reef and non-reef habitats can be important drivers of reef fish abundance. In this study, we used a combination of in situ assessment of benthic habitat condition and remote sensing of habitat spatial characteristics to identify the most important drivers of the presence and biomass of six key foodfish groups both inside and outside NTMRs in the central Philippines. We found that spatial variables such as the extent of coral reef, the extent of seagrass beds, and the connectedness of sites with mangrove stands were rarely significant drivers of fish presence or biomass, regardless of the fish group's known habitat uses. Instead, measures of benthic habitat condition or suitability such as depth and percent cover of benthic components specifically required by each fish group were consistently better predictors of both foodfish presence and biomass. NTMR status was also a key predictor of foodfish biomass for 5 of 6 fish groups, and a key predictor of foodfish presence for 3 of 6 fish groups. Our results highlight the value of NTMRs in this system, and underscore the importance of placing NTMRs in high-quality benthic habitats to ensure their conservation and fisheries objectives can be achieved.

### ECOSYSTEM VULNERABILITY AND CUMULATIVE IMPACTS ON HAWAIIAN REEFS (Abstract ID: 29168 | Poster ID: 596)

The nearshore reef environment in Hawai'i is impacted by a wide range of human activities. As a result of these anthropogenic drivers, economic and sociocultural benefits to communities in Hawai'i have diminished over time. Understanding the spatial distribution, intensity, overlap, and cumulative impact of human activities is essential for effective marine management and protection of ecosystem services generated by coral reefs. Currently, this kind of information is not readily available to resource managers and policy makers in Hawai'i. This research uses existing data and novel approaches to produce maps for some of the most important anthropogenic drivers of coral reefs in Hawai'i. To accomplish this, we compiled a comprehensive database, synthesized a suite of spatial datasets into a unified framework, and devised geospatial methodologies to produce statewide maps of anthropogenic drivers including: fishing pressure, land-based pollution, habitat modification, and invasive species. Expert knowledge surveys were conducted to assess the vulnerability of different habitat types to anthropogenic drivers. The resulting vulnerability weighting factors for stressor-habitat pairs were used to produce continuous maps of cumulative impacts across the Main Hawaiian Islands. These maps directly benefit management by identifying what places and habitat types are most impacted, which drivers should be of greatest concern in different areas, and where different management strategies (e.g. regulations, restoration, enforcement, or increased monitoring) should be prioritized.

### CELL PROLIFERATION AND TURNOVER IN EARLY LIFE STAGES OF A SYMBIOTIC SCLERACTINIAN CORAL (Abstract ID: 28687)

Cellular dynamics underlying scleractinian coral metamorphosis and growth of the primary polyp remain largely unknown, limiting our understanding of this critical phase in the life cycle. In this study, we investigated coral and endosymbiont cell proliferation while simultaneously recording TUNEL-positive apoptotic cells in four life stages (planula, early metamorphosis, primary polyp and adult colony) of Stylophora pistillata (Esper, 1797). The fate of BrdU-labeled cells was monitored in the developing primary polyp over a 3 d period. The highest proliferation activity was localized in the pharynx area. During the chase period, BrdU-labeled cells accumulated in the surface pseudostratified epithelium and the skeletogenic calicoderm of the primary polyp. Surprisingly, the lowest cell turnover was always recorded in the calicoderm, despite active, ongoing skeletal deposition following settlement. Furthermore despite a constant symbiont to host cell ratio, the dinoflagellates had much higher DNA synthesis rates compared to the coral gastroderm cells, especially during planula and early metamorphosis stages. Apoptosis in the symbiont population shifted from low rates in the larval stages to high rates in the developing primary polyp. These results highlight an ontogenic succession of post-mitotic control mechanisms by the host of its endosymbiotic Symbiodinium sp. population.

### PROPAGATION OF SEDIMENT IMPACTS IN AN ECOLOGICALLY IMPAIRED REEF SYSTEM (Abstract ID: 28572)

Suspended sediment and sedimentation are some of the greatest threats to coral reefs, and these are expected to worsen with increasing land use and growth of coastal populations. Conditions of high suspended sediment concentration and sedimentation significantly alter the physical structure of coral reefs. Coral distribution becomes vertically truncated with light attenuation, often with the replacement of reef slope habitats with silts, and rugosity is further reduced with loss of topographically complex sensitive taxa. This severely reduces ecological function of coral reefs, especially impairing physical processes such as energy attenuation and in turn affecting sediment transport. Using a combination of acoustic and optical instruments, the sediment transport characteristics in complex flow around reefs are described. We demonstrate that low complexity, silted reefs in Singapore, typically considered as ecological receptors in impact assessments for activities such as dredging, can also function as a novel source of sediments to other habitats. Recursive settlement, resuspension and transport sets up a stepping-stone effect, propagating sediments in space- and time far beyond typical expectations of

point sources in an accumulatively exacerbated manner. This potential roll-on effect from levels of reef impairment that might be within environmental quality objectives of stakeholders in the EIA process emphasizes the importance of considering the fate of transport characteristics of sediment.

INFLUENCE OF CLIMATE VARIATIONS ON CORAL REEF (CHUUK ATOLL) ACIDIFICATION IN THE WESTERN PACIFIC OCEAN (Abstract ID: 27944)

The primary goal of the present study was to explore the effects of large-scale climate variations on the physical and biological processes that determine carbonate chemistry of reef waters. The 7-year weekly records of carbonate chemistry conditions in the Chuuk lagoon, located in the coral-rich western Pacific Ocean, showed that during weak intrusion of ambient seawater from the surrounding open ocean two internal biological processes (calcification and respiration) reinforced each other and collectively lowered the pH of the reef water for extended periods, ranging from a few to several months. Our study indicates that periods of low wind speeds weaken the intrusion of ambient water, resulting in a longer residence time of reef water so that respiration and calcification increase its acidification. This finding is not an isolated phenomenon, but may be widespread in the coral-rich western Pacific Ocean, which contains 50% of global coral reefs and in which the degree of ambient water intrusion was found to be closely associated with the El Niño Southern Oscillation-induced wind speed change.

THE ROLE OF THE SEA CUCUMBER HOLOTHURIA SCABRA AS A CORAL REEF ECOSYSTEM ENGINEER IN FIJI (Abstract ID: 28153)

A substantial amount of organic matter (OM) on coral reefs is mineralized in permeable sands. Bioturbation through reef ecosystem engineers such as sea cucumbers can potentially enhance recycling of OM in reef sands. However growing demand from Asian markets has driven the overexploitation of sea cucumbers globally. Thus there is a pressing need to understand the consequences their removal has on reef ecosystems. Densities of Holothuria scabra were manipulated in enclosures in situ on a reef flat in Natuvu, Fiji, to simulate different fishing intensities. Three treatments (n=4 treatment-1) were used; High (350g m-2), Natural (60g m-2), and Low (0 g m-2) density of H. scabra, and Cage controls. Sedimentary oxygen consumption (SOC), organic carbon turnover, grain size distribution, porosity, and O2 penetration depth were recorded. Additionally feeding rate, burrowing rate, and sediment reworked were quantified in relation to H. scabra size class, microhabitat, tidal cycles, and diurnal cycles. All parameters are combined to provide a more comprehensive view of the ecosystem role of H. scabra. Preliminary results show that natural density enclosures and cage controls were similar. SOC rates were consistently higher in low-density than high-density enclosures. This indicates that bioturbation by sea cucumbers plays a significant role in the capacity of reef sediments to recycle OM. Overfishing of sea cucumbers may thus lead to a reduced ability of reef sands to process OM pulses caused by land-derived eutrophication and thereby decrease the overall resilience of local reefs.

CARIBBEAN CORAL REEF BASELINES FROM AN ARCHAEOLOGICAL PERSPECTIVE: PROSPECTS AND CHALLENGES FOR INTERDISCIPLINARY STUDIES AND CONSERVATION EFFORTS (Abstract ID: 29996)

Within the interdisciplinary study of marine historical ecology, practitioners have argued for the importance of historical baselines to inform coral reef conservation efforts throughout the world. Research has demonstrated the great temporal depth of anthropogenic and environmentally-derived changes among coral reef habitats, and has provided chronological context to current coral reef conditions and projected futures. However, in many cases, the full potential of historical coral reef baselines is yet to be realized in terms of collaborations that present multi-dataset perspectives of coral reef deep history. In this presentation, we discuss some of the challenges of constructing critical temporal baselines from an archaeological perspective, focusing on the Caribbean Antilles. Drawing on illustrative case studies, we summarize archaeological evidence of coastal resource utilization and examine the potential and limits of archaeological data for constructing baselines. Considerations include analytic scale, chronological control, sampling, and cross-disciplinary dataset integration with historical, paleontological, and modern data. We argue greater emphasis needs to be placed on interdisciplinary studies that parse anthropogenic from environmental change in coral reef ecosystems through time, while recognizing such changes are not necessarily mutually exclusive. Increased interdisciplinary collaborations of this nature in the Caribbean region will better serve conservation efforts.

INFLUENCE OF FUNCTIONAL TRAITS ON THE PERCEPTION OF CORAL REEF FISH BIODIVERSITY PATTERNS. (Abstract ID: 28077 | Poster ID: 503)

An increasing body of literature suggests that functional diversity enhances ecosystem functions such as productivity, resilience to disturbances or invasions and regulation in the flux of matter. Numerous indices are now commonly used for assessing functional biodiversity. They are mainly based on the values of functional traits taken by the species in the community studied. However, the impact of functional traits on the assessment of functional indices, and thus on our perception of functional diversity patterns, is still poorly known. Here, we presented the first study strictly focused on the sensitivity of the most used functional indices to the variation of the number and the nature of functional traits. We used data on coral reef fish's communities collected by underwater visual census in Tuamotu Archipelago (French Polynesia) to raise this issue. We found not only that the number and the nature of functional traits may strongly alter the estimation of the indices considered but it may also lead to counter-intuitive results. Moreover, we showed that the extent and profile of the sensitivity of functional indices to the number of functional traits strongly vary from one index to another. In fine our results highlight that the properties of functional traits may have huge consequences on functional diversity assessments and management decisions.

THE DYNAMIC CHANGES OF REEF CORALS IN THE XUWEN CORAL REEF RESERVE AREA DURING THE PAST TEN YEARS (Abstract ID: 29213 | Poster ID: 63)

Xuwen coral reef was the only largest fringing reef in the mainland China. The status of the coral reef in Xuwen coral reef reserved area was investigated from 2004 to 2014, and the total recorded species number was 62 in 11 families and 29 genera. Over the past 10 years, the coral community in the reserved areas showed a great trend of degradation, and the main type of coral species were massive, while branching coral species becoming increasingly rare since 2004. The total recorded number of reef coral species in the area decrease from the highest of 54 to recent of 20, and the average living coral coverage dropped from 28.9% to about 10%. The factors impact on this coral reef reserved area were very complex, among which the human fishery activities and intensive aquaculture being the most important factors. We suggested that the ecological status of coral reefs in the whole reserved area will be better if the long-term ecological monitoring and human activities management were strengthened.

SUPPORTING THE HOLOGENOME THEORY OF EVOLUTION: BROADCAST SPAWNER CORAL HAS DIFFERENT STRATEGIES TO TRANSFER THEIR BACTERIA AND ZOOXANTHELLAE (Abstract ID: 29405)

The Hologenome Theory of Evolution (HTE) proposes that host and microbiota genomes are adapted and evolved together as a unit of natural selection. In this case, the microbiome can be transmitted from one generation to the next and, thus, may also influence the evolution of the holobiont. Strong evidence of microbial vertical transmission (VT) in brooding corals was reported in early larval stages of brooder corals and one broadcast spawner. To explore the VT hypothesis, colonies of the broadcast spawner species, *Mussismilia hispida*, were kept in nurseries until spawning. Gamete bundles, larvae and adult corals were analyzed to identify their microorganisms' composition and location. The ultra-thin section transmission electron microscopy showed *Symbiodinium* cells in oocytes but no bacterial profiles were detected, indicating that only the zooxanthellae were transmitted directly from parental to the offspring. In addition, this community was able to change, since parental colonies and oocytes had*Symbiodinium* clades A, B and C, but only clade B was found in the larva. The core bacterial communities found in the bundles, larva, and parental colonies were *Burkholderia, Pseudomonas, Acinetobacter, Ralstonia, Inquilinus and Bacillus*, suggesting that these communities could be vertically transferred through the mucus. These data confirmed the vertical transmission assumption stated in the HTE, also pointing at groups most likely related to coral larvae and adult development, opening the discussion on its potential role in coral resilience.

IMAGING THE UPTAKE OF NITROGEN-FIXING BACTERIA INTO LARVAE OF THE CORAL ACROPORA MILLEPORA (Abstract ID: 27873)

Diazotrophic bacteria are instrumental in generating biologically-usable forms of nitrogen by converting abundant dinitrogen gas (N2) into available forms, such as ammonium. While nitrogen is crucial for coral growth, direct observation of associations between diazotrophs and corals has previously been elusive. We applied fluorescence in situ hybridization (FISH) and nanoscale secondary ion mass spectrometry (NanoSIMS) to observe the uptake of 15N-enriched diazotrophic Vibrio sp. isolated from Acropora millepora into conspecific coral larvae. Incorporation of Vibrio sp. cells was observed in coral larvae after 4-hour incubation with enriched bacteria. Uptake was restricted to the aboral epidermis of larvae, where Vibrio cells clustered in elongated aggregations. Other bacterial associates were also observed in epidermal areas in FISH analyses. Although the fate and role of these bacteria requires additional investigation, this study describes a powerful approach to further explore cell associations and nutritional pathways in the early life stages of the coral holobiont.

SEAHARMONY: AN INNOVATIVE FORUM FOR COLLABORATIVE NETWORKING (Abstract ID: 28033 | Poster ID: 707)

seaHarmony is a web-based collaboration network that directly links ocean science researchers with educators, managers, traditional practitioners, artists, and communicators to help them form successful collaborations. The connections are made using compatibility algorithms based on member collaboration interests and preferences that help define the partnership framework. Ocean science professionals can also post announcements, share resources, and ask questions about specific ocean science topics, as well as explore posted ideas or opportunities for collaboration, such as grant proposals, internships, workshops, or public events. A primary goal of seaHarmony is to help ocean scientists interested in broadening the impacts of their research find potential collaborators in education, management, media, or community engagement. Created by COSEE Island Earth, seaHarmony was launched in Hawaii in 2013, expanded nationally in 2014, and is now available to users globally in over 240 countries. This poster will describe key features of seaHarmony, present current data on its usage, and explore further functionalities to better serve the coral reef research community.

CORAL REEF DRAG COEFFICIENTS – WATER DEPTH DEPENDENCE (Abstract ID: 27960 | Poster ID: 399)

A key physical characteristic of shallow coral reefs is that they are rough, resulting in large drag that limits the strength of the flow across the reef. The flow is a key factor determining the exchange of water and constituents between reefs and the surrounding ocean, the residence time of water on the reef, and exchange between seawater and the coral bed. These physical factors, in turn, influence a variety of physical and biogeochemical processes that impact coral reef ecosystems such as the supply and uptake of nutrients and the thermal environment. Consequently, drag coefficients, relating the flow to the drag, are a critical input for accurately modeling coral reef systems that is poorly constrained with estimates spanning two orders of magnitude. We test the hypothesis that the wide range of drag coefficients is due, in part, to variations in water depth using observations from three different coral reefs (Red Sea, Palau, Dongsha Atoll) and a previous laboratory study. The estimated drag coefficients for depth-average flow from the field observations and laboratory study range from 0.01 to 1 and depend primarily on water depth. Drag coefficients increase as water depth decreases consistent with simple theory from open-channel flow. Hydrodynamic roughnesses over the coral reefs examined generally fall in a relatively narrow range from 2 – 10 cm. Clearly, knowing the dependence of drag coefficients on water depth is critical to understanding the impacts of sea level rise on reefs.

REVISITING THE IMPACTS OF BLEACHING ON THE REPRODUCTION OF THE STONY CORAL *MONTIPORA CAPITATA* (Abstract ID: 29026 | Poster ID: 172)

Coral reefs in Hawai'i suffered two consecutive major bleaching events in 2014 and 2015 as a result of sea surface temperatures (SST) that, in places like Kāne'ohe Bay, O'ahu, exceeded 27°C for 8 weeks and 15 weeks, respectively. In 2014, up to 73% of the corals on reefs in Kāne'ohe Bay bleached or paled and all dominant coral species displayed high levels of intraspecific variation in their bleaching responses. This allowed neighboring bleached and non-bleached individuals of *Montipora capitata* to be identified and tagged in 2014, so that in 2015 the size and number of eggs per bundle released in the field by these corals could be assessed. All tagged corals released egg-sperm bundles during the June, July, and August 2015 spawning season. There was no difference in the size and number of eggs per bundle released by bleached and non-bleached colonies; however, 40% more eggs were released in egg-sperm bundles in June as compared to July and August, and these eggs were 14% smaller. In July and August 2015, mean SST exceeded seasonal norms by 2°C and the 2015 bleaching event began. A comparison of the 2015 spawning data with 2005, 2007, and 2008 reveals that 2015 eggs were significantly larger and significantly fewer eggs were packaged in each bundle. These bleaching events provide an unprecedented opportunity to examine the long term implications of repeated bleaching on the reproductive success of corals, and in this long-term study, tagged *M. capitata* will continue to be monitored through the 2016 reproductive season and beyond.

HIGH RESOLUTION GEOCHEMICAL ANALYSIS OF MASSIVE PORITES SP. CORALS FROM THE GREAT BARRIER REEF; RARE EARTH ELEMENTS AS INDICATORS OF VARIABLE TERRIGENOUS INPUT (Abstract ID: 28546)

Rapid land clearing for agriculture and coastal development since European settlement on the Queensland coast of Australia has brought into focus the magnitude of increased sediment load and turbidity delivered to inshore coral reefs on the Great Barrier Reef (GBR). However, quantifying changes in sediment flux to reefs is problematic as instrumental records are spatially and temporally limited. Long lived, annually banded massive corals provide a unique opportunity to reconstruct environmental conditions prior to instrumental monitoring because coral skeletons sequentially incorporate geochemical signals that reflect ambient seawater conditions during growth. A currently under-utilised suite of elements in coral geochemistry includes the rare earth elements (REE), of which ~90% are derived from suspended and dissolved riverine input in coastal oceanic waters. Here we present monthly resolution REE data from four modern Porites coral cores across a known water quality gradient from the Wet Tropics region of the GBR. We compared our results to local river discharge data to evaluate the potential of REEs as a proxy for terrigenous input. We show that monthly resolved time-series of total REE (ΣREE) concentrations in corals reliably record sediment flux associated with river discharge events at inshore locations. Our data also indicates that ΣREE concentrations are up to

three times higher at inshore locations compared to the mid-shelf and that ΣREE concentrations associated with river discharge events have increased two-fold since ~1950.

CARBONATE DYNAMICS OF AN ALGAL RIDGE (Abstract ID: 29798)

This study aims to clarify the processes producing cementation on and within tropical algalridge environments. Specifically we aim to determine: 1) whether net calcification is occurring atop the algal-ridge on a diurnal timeframe; 2) the redox nature of the algal-ridge framework interior; 3) if sulphate reduction is driving ridge cementation; and 4) the stoichiometry and rate of carbonate calcification and dissolution reactions on/within the algal ridge. We will use state-of-the-art high precision isotope dilution inductively coupled plasma mass spectrometry techniques to analyse small anomalies in [Ca2+] and [Mg2+] (<0.4 µML-1 and <3 µML-1 respectively). We will test the hypothesis that despite ocean acidification (OA) algal ridges are still undergoing cementation. Within the ridge framework we expect the remineralisation of high Mg-calcite (HMC) into more stable carbonate minerals (calcite or dolomite) to be driven by the reduction of sulphate. This would imply that reefs with HMC algal ridges are less susceptible to OA than previously thought.

IMPACT OF NUTRIENT, SEAWAGE AND CONTAMINANT PRESSURES ON THE WATER QUALITY OF A FRENCH POLYNESIAN REEF LAGOON (FAAROA, RAIATEA ISLAND) (Abstract ID: 28975 | Poster ID: 463)

Coral reefs are among the most diverse and productive ecosystems, sustaining important services (e.g., fishery, pearl farming, tourism). With ever growing population on the coasts, the anthropogenic impacts on these reefs have increased dramatically in the last 30 years. In French Polynesia, the reef lagoon of Faaroa (Raiatea island) is exposed to contamination caused by inefficient and/or inappropriate sewage treatment, erosion from agricultural activities, eutrophication and pesticide use. The aim of this study is twofold: (i) to characterize the main domestic and agricultural pressures exerted on the reef lagoon of Faaroa through personal interview surveys and GIS analyses ; (ii) to assess the water quality of the lagoon through biological and chemical analyses of the water column and sediment, and the study of phytoplankton which plays a critical role in Polynesian lagoon ecosystems (e.g., base of food webs, important role in biogeochemical cycles). The results provide new knowledge on the impacts of human pressures on tropical reef lagoons, and will contribute to improve the conservation and management of these vulnerable ecosystems.

CORAL HEALTH IN THE PAST: A PRE-HUMAN BASELINE FROM PARTIAL MORTALITY RECORDS IN THE PLEISTOCENE OF BARBADOS AND CURACAO (Abstract ID: 28180 | Poster ID: 12)

Coral skeletons archive corallite growth history and therefore partial mortality over tens to hundreds of years. As a result, ancient coral skeletons can provide a proxy for reef health by examining the frequency of partial mortality that resulted from stressors such as disease and bleaching. This study examines 3700 large (.5m-3m) Pleistocene corals in living position from Curacao and Barbados spanning six reef-building intervals (80-450 kya) in order to establish a pre-human baseline for partial mortality and coral health in Caribbean reef corals. For all species and all time intervals partial mortality is low (<5%). *Orbicella annularis* complex, and *Acropora palmata*had slightly higher average incidences overall (both 4%), than other massive species (*Pseudodiploria strigosa, Sideratrea siderea, Colpophyllia natans, Montastrea cavernosa*). Fast growing corals with complex morphology (eg.,*Acropora cervicornis*) were not included. Observed examples of partial mortality and regrowth were small and local and we observed no examples of significant re-sheeting of live coral over dead skeletons, as reported today for *A. palmata* killed by White Band Disease. Very low partial mortality of Caribbean corals throughout the Pleistocene provides a pre-human baseline that is in strong contrast to recent Caribbean reefs where disease and bleaching have led to widespread partial mortality of many or most larger corals alive today.

METHODOLOGICAL UNDERESTIMATION OF NITROGEN FIXATION IN STYLOPHORA PISTILLATA (Abstract ID: 27768)

In tropical coral reef ecosystems nitrogen is a well-described limiting nutrient and its tight cycling implicated as a central component of Darwin's "paradox of the reef" where ambient concentrations of dissolved inorganic nitrogen are very low. On tropical coral reefs the primary source of "new" nitrogen can only be obtained by nitrogen fixation conducted by both photoautotrophic and heterotrophic prokaryotes. Nitrogen fixing prokaryotes are widespread in coral microbiomes and both historical and recent data have demonstrated that corals can fix nitrogen. Methodologically, both acetylene reduction and isotopic tracers have been used to quantify nitrogen fixation. Although it has been suggested that isotopic tracers are a superior approach because labeled products can be followed through various compartments, many recent isotopic experiments quantifying nitrogen fixation have observed significant underestimations for rates of nitrogen fixation in the open ocean. This discrepancy stems from the use of the "bubble technique" versus "constant enrichment", where the latter provides a more accurate approximation of nitrogen fixation rates. Here we present data using the "constant enrichment" technique demonstrating that the Great Barrier reef coral, Stylophora pistillata, does in fact fix nitrogen, although previous studies using the "bubble technique" suggested otherwise. We also present evidence that the isotopically labeled end products are primarily found within the endosymbiotic compartment (i.e., Symbiodinium sp.) of the holobiont as described previously. We hypothesize that the coral microbiome, and not mucous, is the source of this fixed "new" nitrogen.

SYMBIODINIUM EXPOSED: COMPARATIVE TRANSCRIPTOMICS REVEALS GENETIC BASIS OF THERMAL TOLERANCE (Abstract ID: 30064)

Different putative species as well as conspecific populations of Symbiodinium exhibit a range of thermal tolerances that can determine the bleaching susceptibility of their coral hosts. However, the underlying gene regulation governing thermal tolerance in Symbiodinium is entirely unknown. Through physiological assays and transcriptomics, we compared the heat stress responses of a thermo-tolerant versus a thermo-sensitive population of type C1 Symbiodinium in culture. After 9 days at elevated temperature, neither population experienced physiological stress, but both displayed up-regulation of meiosis genes and down-regulation of metabolism genes. After 13 days at elevated temperature, the thermo-sensitive population suffered a loss of photosynthetic efficiency and an increase in reactive oxygen species (ROS) leakage from its cells whereas the thermo-tolerant population still showed no signs of physiological stress. Accordingly, only the thermo-tolerant population achieved transcriptional acclimation to elevated temperature by up-regulating an array of ROS scavenging, molecular chaperone, and metabolism genes. More transcripts of eukaryotic viral origin had also become up-regulated at elevated temperature in the thermo-sensitive population than in the thermo-tolerant population. The correlated physiological and transcriptional heat stress responses observed in our study tightly align with the known bleaching responses of corals harboring these same populations. Thus, we provide substantial, novel insights into the complex molecular mechanisms that underpin coral bleaching.

DEFINING 'COMMUNITY' FOR COMMUNITY INVOLVEMENT IN MARINE RESOURCE MANAGEMENT IN HAWAI'I (Abstract ID: 27882 | Poster ID: 610)

Community involvement in marine and coral reef resource management is viewed by many as critical to achieving long term conservation success, and is a stated priority for local management agencies in the state of Hawai'i. Numerous programs now exist to promote active community stewardship, including formal co-management arrangements through the Community-based Subsistence Fishing Area legislation, partnerships with the State's marine enforcement unit through community Makai Watch programs, and numerous other formal and informal community based management programs. But working with communities to facilitate marine management is complex, and definitions of exactly who "communities" are and who should be included vary. This study explores definitions of community and community involvement in marine resource management in the state of Hawai'i. First, we present the results of a Hawai'i – wide survey which asked state residents how they defined "community" in relation to coral reef management. Second, we explore how these definitions relate to the wide range of actual

community-based marine management program taking place in the state of Hawai'i, with a focus on case examples on Hawai'i Island. Finally, we discuss the implications of these varying definitions and practices for community-based management practice in Hawai'i and beyond.

LOOKING BACK TO LOOK FORWARD: AN EVOLUTION OF ACROPORA RESTORATION TECHNIQUES (Abstract ID: 29847 | Poster ID: 478)

During the last three decades reef-building corals have declined drastically. Restoration efforts have focused on innovative techniques for the propagation and growth of individual corals, as well as their outplanting to bolster remaining coral populations. The efficacy of these techniques varies greatly as well as their appropriateness for large-scale restoration efforts. The Coral Restoration Foundation has been engaged in developing practical techniques for regional reef restoration within the Florida Keys and the Caribbean. The focus of our efforts is to develop methods that result in outplants with a high level of success, are cost effective (in terms of surviving biomass outplanted), scalable for large production efforts, and able to be implemented by locally engaged volunteers for project sustainability. Herein we present an overview of the techniques that have been developed, including their origin, and the lessons learned along the way. Focusing on Acropora spp., details of various outplanting methodologies are presented, contrasting their appropriateness for large-scale restoration projects. Also reviewed are the corresponding nursery techniques that either support, or constrain, outplanting application.

A NEW PERSPECTIVE: ASSESSING THE SPATIAL DISTRIBUTION OF CORAL BLEACHING WITH LOW-ALTITUDE REMOTE SENSING TECHNOLOGIES (Abstract ID: 28874)

Coral bleaching is contributing to the decline of reefs globally. Efficient reef monitoring, which provides information for effective management and conservation strategies, is vital to better understand the extent and severity of bleaching on coral reefs. Current in situ and remote sensing reef assessment techniques are time, money, and personnel-intensive. Consistent surveys of large reef areas using traditional techniques are unfeasible, unavailable, or uninformative at the colony level. We present a new technique using unmanned aerial vehicles (UAVs) that targets an intermediate spatial scale while providing sufficient information at the colony level to understand bleaching distributions of coral communities on patch reefs in Kaneohe Bay, Oahu during the 2015 bleaching event. Images were collected at four reefs during the bleaching period and were processed using StructureFromMotion techniques to produce georeferenced, spatially accurate orthomosaics of reef areas. Mosaics were analyzed using manual or automated classification schemes to identify benthic substrate and bleaching distribution. We found bleached colonies had random or clumped distributions on Kaneohe Bay patch reefs. Our work demonstrates that UAVs provide a low cost, efficient platform that can rapidly and repeatedly collect high-resolution imagery (1 cm) and map large areas of shallow reef ecosystems (5 hectares). We envision that similar low altitude aerial surveys would be incorporated as standard components of shallow-water reef studies, especially on reefs too dangerous or remote for in situ surveys.

'MASTER-SLAVE' OSCILLATOR RELATIONSHIP IN SYMBIOTIC AIPTASIA (Abstract ID: 28565)

Since life first evolved in the sea, an ecosystem that is governed by a multitude of environmental cycles, species inhabiting coastal environments are challenged with complex temporal patterns, dominated by tidal and lunar cycles. Aiptasia provide a strong model for dissecting the roles of solar, tidal and lunar oscillations. A relevant question is how the presence or absence of the symbiotic algae affects Aiptasia endogenous clock. Recently we used symbiotic and aposymbiotic Aiptasia morphs to measure behavioral activity and transcriptomic for temporal gene expression. Very interestingly, our Fourier Transform analysis showed that symbiotic Aiptasia had a period cycle of 23.9 h while the aposymbiotic morphs had a locomotor activity of 12.2 h. Reinfection the aposymbiotic Aiptasia with algae and re-measure the behavior "rescued" the rhythm to a period cycle of 23.9 h under LD cycle. Additionally, transcriptomic analysis of material from our 4 hourly samplings, revealed a pattern similar to that given by the behavioral measurements, where the symbiotic anemones had a higher number of temporal expression genes with a 24 h cycle, while the aposymbiotic forms showed significantly more genes oscillating in a 12 h cycle. All the potential core circadian clock genes displayed a 24 h cycle in both symbiotic and aposymbiotic morphs. Here for the first time we can now distinguish both circadian and circatidal patterns in the Aiptasia, detected at both the behavioral and molecular levels.

ECOLOGICAL SPECIALIZATION AND SPECIES DIVERSIFICATION OF SHALLOW WATER CORAL ENDOSYMBIONTS IN THE WESTERN ATLANTIC (Abstract ID: 29427)

In the Caribbean region, *Symbiodinium* belonging to Clade B are ecologically dominant in coral communities from shallow reef habitats. Several species in Clade B were recently described, yet genetic evidence indicates that many more remain uncharacterized. In this study, we investigate the diversity among members of a putative Pleistocene adaptive radiation exhibiting distinct ecological distributions. While many of these share identical rDNA sequences, rapidly evolving DNA suggest that multiple species exist. In testing this possibility, we sampled numerous taxa of reef-building coral across large geographical ranges and used microsatellite variation to test for recent sexual recombination. Strong genetic partitioning between sympatric populations indicates reproductive isolation. These species overlap in geographic range and correspond to the symbiont's host phylogeny. From these data, we describe the host-generalist *S. faviinorum* associating with Caribbean corals of the subfamily Faviinae as well as *S. meandriniums*associating with coral family Meandrinidae. We also describe *S. dendrogyrum*, a symbiont harbored exclusively by the coral *Dendrogyra cylindricus*, one of many host-specialized species. These investigations show how fine-scale phylogenetic and population genetic evidence reveals cryptic diversity, emphasizes the importance of niche diversification in the speciation of *Symbiodinium*, and serves as an example where the co-evolution with a single host species or monophyletic lineage leads to host-symbiont specificity.

SEASONAL GROWTH AND CALCIFICATION RATES OF CORALLINE ALGAE ON THE GREAT BARRIER REEF AND THE DEVELOPMENT OF AN EFFECTIVE *IN SITU* STAINING METHOD (Abstract ID: 29039)

Coralline algae not only play crucial roles in reef ecology but have also been identified as one of the most sensitive calcifying organisms to ocean acidification, and a potential indicator for the effects of climate change. However, despite their importance little information is available on coralline growth and calcification rates on the Great Barrier Reef (GBR). The current lack of information on growth and calcification is partly due to the difficulty in obtaining field measurements. Therefore the aims of this study were to establish an effective method of gaining growth measurements in the field, and to determine seasonal growth and calcification rates of an abundant reef building crustose coralline algae species on the GBR. To achieve these aims we tested three calcium markers at different concentrations and exposure times on two abundant species of encrusting and branching corallines found on the GBR (*Porolithon onkodes* and *Lithophyllum pygmaeum*). We also deployed and collected *P. onkodes* samples for each climatic season taking vertical growth, marginal growth and buoyant weight measurements. Results from these experiments found calcein to be the most effective calcium marker in the field, and the optimal season for growth and calcification differed across the three metrics measured. Determining these baseline seasonal rates can assist in improving conservation and management practices, refining carbonate budgets, and to better understand the response of corallines to manipulative experiments concerning ocean acidification and warming.

MARINE HOTSPOTS THROUGH TIME: WHAT CORAL FOSSILS CAN REVEAL ABOUT THE LOCATION AND ORIGINS OF THE CORAL TRIANGLE (Abstract ID: 29917)

Indo-Pacific diversity increases from the periphery to the Coral Triangle (CT), the global center of marine biodiversity. There are three main hypotheses to explain this pattern: Center of Origin, Accumulation, and Overlap. The relative importance of these hypotheses can be inferred with direct and indirect methods. Indirect approaches, such as phylogenetics, cladistic biogeography, and phylogeography increase our understanding of processes generating CT diversity, but fossil occurrences are the only direct record of the origin, duration, and demise of a taxon. Although the fossil record shows the hotspot moved from the Tethys Sea to its current location in the Early Miocene, little is known about the origin and spread of coral taxa themselves. To address this, we use fossil occurrence data for scleractinian corals to characterize the changing location of coral hotspots through the Cenozoic, the location of the first occurrence of coral taxa found in

each hotspot through time, and the extinction/origination rates of coral lineages. These analyses directly test hypotheses about the spatial origins of Indo-Pacific taxa as well as those about species longevity and turnover rates in the CT. Despite the substantial fossil data already available, there are inherent problems associated with an unavoidably patchy record, such as accurate species determination in a taxonomically unstable group. We use genera as a taxonomic unit to mitigate current coral taxonomy issues. We discuss causal factors in the formation of the CT and hope it will be of use in global conservation planning.

GREATER DIVERSITY IN SYMBIONT TYPES WITHIN FLORIDA DENDROGYRA CYLINDRUS: PERSISTENT SHIFT IN DOMINANT SYMBIONT SUB-TYPES AND EVIDENCE OF CRYPTIC NOVEL CLADE (Abstract ID: 29745)

Most scleractinian corals form stable symbioses with dinoflagellates,*Symbiodinium* spp, typically with a single dominant symbiont type. The Caribbean Pillar coral, *Dendrogyra cylindrus*, harbors ITS2-B1/cp23S-B184 symbiont as its dominant type. Following a mass hyper-thermal event in August and September 2014 along the Florida Reef Tract, the *D. cylindrus*population was severely bleached. Using high-throughput Illumina sequencing of the 23S cpDNA gene region, symbiont populations within *D. cylindrus* were characterized monthly during four months of recovery. Two operational taxonomic units (OTU0.03) representing B1 phylotypes accounted for > 80% of the relative abundance in symbiont populations prior to thermal bleaching. Shift in dominance of one OTU B1 subtype from <10% pre-bleaching to >50% post bleaching occurred at a site, which recovered more rapidly than sites that did not shift *Symbiodinium*composition. Evidence of cryptic Clade A symbionts (*Symbiodinium necroappetens*) in low abundance prior to bleaching (<0.1%) were found to temporarily increase in relative abundance to 3.5% during early recovery, suggesting an opportunistic growth with an unknown functional role during recovery. These findings indicate greater symbiont diversity within *D. cylindrus* than previously known and the ability to shift to potentially more favorable symbiont types. Previously undetected diversity within symbiont communities of a single coral host may impart ecological benefits, providing a measure of resilience to environmental stressors linked with climate change for this coral species.

GENETIC SLEUTHING: TRAIL OF SHIFTING MICROBIAL COMMUNITIES DURING WHITE PLAGUE OUTBREAK IN DENDROGYRA CYLINDRUS ON THE FLORIDA REEF TRACT (Abstract ID: 30032)

White plague disease has significantly affected Caribbean corals over the last two decades. This disease syndrome is characterized by rapid tissue loss leaving behind dead, white coral skeleton. While three types of white plague have been recognized based on how quickly the disease progresses, the pathogens that trigger this disease have not been identified with certainty. Following the Summer 2014 hyperthermal event along the Florida Reef Tract (FRT), we monitored an outbreak of white plage II (WPII) from the early onset of the disease affecting the Pillar coral *Dendrogyra cylindrus*. In order to identify potential disease-causing agents, changes of the microbial communities were tracked during five-month progression of the outbreak in in this coral species on a reef site in the FRT using 454 high-throughput sequencing of the 16S rRNA gene. Multivariate analyses comparing the microbial communities of the same coral colonies before and after showing signs of disease, compared with coral colonies that remained healthy throughout the entire outbreak, showed both an influence of sampling time and a clear effect of disease condition. Strong correlations were found between the appearance of white plague disease and highly abundant bacterial species from the genus *Sphingobium*, *Sphingomonas* and*Pseudoalteromonas*. Follow up studies using isolates cultured from active white plague colonies in trial infections will allow confirming the actual pathogen or group of pathogens causing the disease from among these identified bacterial candidates.

THE VIRGIN ISLANDS REEF RESILIENCE PLAN: A MULTI-FACETED APPROACH TO CORAL REEF CONSERVATION IN THE US VIRGIN ISLANDS. (Abstract ID: 29673)

Over the past decade, The Nature Conservancy has lead two efforts to directly improve the quality of coral reefs throughout the Caribbean. Coral reef resilience and restoration programs have been focused on the removal/reduction of stressors, improved management of coral reef resources, and the propagation and direct restoration of coral reefs. In the US Virgin Islands, the concepts of these two programs were combined, resulting in the Virgin Islands Reef Resilience Plan (VIRRP). Developed through the TNC/NOAA cooperative agreement, the VIRRP was designed with programs and initiatives to better understand and manage for bleaching and other coral reef disturbances, reduce fishing pressure on important reef fish species, and enhance reef sites through coral restoration activities. Moreover, the BleachWatch Virgin Islands Program, the Reef Responsible Sustainable Seafood Initiative, and the USVI Coral Restoration Program all have significant community components. This active engagement through outreach and volunteer opportunities has helped to better connect Virgin Islanders to coral reefs and has created support for our coral reef conservation efforts. By working to understand and manage coral reef impacts while actively restoring key coral reef sites, we anticipate that the VIRRP will help to build the resilience of coral reefs in the US Virgin Islands.

COMPARATIVE EXPERIMENTS ON 8 NEARSHORE HAWAIIAN CORAL REEFS: SPATIAL VARIATION IN THE ENVIRONMENTAL DRIVERS OF REEF DEVELOPMENT (Abstract ID: 30044)

Several biological and physical factors influence the development of benthic coral reef communities; however, the importance of different factors remains an important question for understanding the dynamics of a given system. We used standard PVC tiles (CAUs) to explore spatial variation in community development (36-mo.) on 8 shallow (2-3 m) coral reefs spanning 60 km of coastline in Maui, HI. Half of the 20 tiles/site were caged to examine the influence of consumers and each of the 8 sites were characterized according to 3 known drivers of nearshore reef dynamics: sediment exposure, herbivore abundance, and nutrient availability. Spatial variation in algal biomass accumulation, coral recruitment, and net accretion of calcium carbonate were compared (a) among sites, (b) among caged vs. open tiles, and (c) in relation to environmental conditions. Macroalgal biomass varied greatly among sites and a site x treatment interaction indicated variable consumer affects among sites. Recruitment varied among sites and appeared to be inversely related to sediment exposure. Open tiles always accreted greater calcium carbonate than caged tiles, indicative of a positive relationship with consumer exposure. Benthic dynamics on these coral reefs appear to be driven by different ecological processes, suggesting that managers may need to examine the specific drivers of local-regional dynamics in order to maximize the effectiveness of specific conservation efforts.

UNCOVERING THE UNSEEN: IMAGING AND COLLECTION TECHNIQUES REVEAL DENSE COMMUNITIES OF CRYPTIC INVERTEBRATES ON HAWAIIAN CORAL REEFS (Abstract ID: 30067)

Inconspicuous motile invertebrates (cryptofauna) are ubiquitous, important components of benthic marine ecosystems worldwide; however, relatively little is known about their ecology on coral reefs. We used two methods, time-lapse imaging and artificial structures, to quantify patterns in density and community composition of cryptofauna (2-25 mm) on shallow fringing reefs in Maui, HI. Caged and uncaged artificial units (CAUs) were deployed at eight sites across 60 km of Maui's leeward coast to examine spatial variability in cryptofauna community structure and the influence of consumers, and a novel time-lapse imaging technique was used to compare communities on four dominant habitat types on natural reef substrata. CAUs demonstrated strong effects of site and caging on cryptofauna, and the effect of consumers was highly site-specific and correlated with variation in macroalgal biomass. Time-lapse imaging revealed significant variation in cryptofauna communities among coral-, algae-, and sediment-dominated habitats. Maximum densities (approximately 2000/m2) and community structure were generally similar between the two methods; however, the methods differed greatly in their strengths and utility, with time-lapse photography proving to be a promising technique for rapid assessments of cryptofauna communities. Given their high density and diversity, it is critical that we continue to develop effective methods for assessing community structure and function of cryptofauna in coral reef ecosystems.

DETERMINING THE MOST DETRIMENTAL SEDIMENT ON CORAL REEFS: TRACING THE SEDIMENT ON THE REEF BACK TO A CATCHMENT SOURCE (Abstract ID: 29308)

We present a conceptual framework that determines the fate and impacts of sediment on marine ecosystems using the Burdekin River, Australia as a case study. We identify the most detrimental sediment to marine ecosystems and trace it back into the catchment to highlight the dominant sub-catchments, erosion processes and management practices that are delivering the excess sediment. We show evidence that Burdekin River discharge, and a portion of the associated particulate constituents, influences photic depth and turbidity on the Great Barrier Reef. Supressed photic depth over a period of time caused negative effects on coral reefs and seagrass meadows in the region. The sediment delivered from the Burdekin River that influences turbidity regimes is fine-grained (<16 µm) and is transported as organic-rich floc aggregates in flood plumes. The Bowen and Upper Burdekin sub-catchments contribute the highest loads of the <16 µm sediment fraction to the end-of-catchment and tracing data suggest that erosion rates in these catchments have increased by 7.5 and 3.6 fold, respectively since European settlement. The major erosion sources in these catchments are sub-surface erosion of scalds, rills, gullies and streambanks. Maintaining long term ground and riparian cover above 70% (in particular on soils identified as erodible) is considered important for maintaining the hydrological function of these landscapes and reducing sediment erosion and delivery from all erosion sources. Controlling livestock access to rilled and gullied areas and streambanks is a priority action to achieve this

CAN CORALS REVEAL LAND-USE CHANGE?: TRACE ELEMENT AND ISOTOPIC RECORDS SUGGEST PATTERNS OF LAND-USE CHANGE IN THE REPUBLIC OF PALAU. (Abstract ID: 30078)

This project uses trace element and isotopic analysis of coral cores to investigate land-use activities in two watershed systems in Palau: Ngeremeduu Bay and Airai Bay. Previous studies have shown increased sedimentation in these bays, which may be correlated to earth-moving projects. Characterization of land-use change impacts on Palau's important watersheds and reef systems is needed to inform management decisions. Coral cores (20-41cm in length) were sampled along a high-to-low sedimentation gradient: near major rivers (high-impact) and ocean (low-impact). The samples were measured for isotopic indicators of environmental conditions: salinity and temperature (δ18O) and light (δ13C). The δ18O and δ13C values (‰ VPDB) ranged from -5.0 to -6.0 (δ18O) & -2.5 to -6.0 (δ13C) in high-impact sites and -5.5 to -6.5 & -2.5 to -3.5 in low-impact sites. The results indicate an isotopic transition along the high-to-low sedimentation gradient suggesting increased freshwater in Ngeremeduu Bay. The periods of lowest carbon fixation (correlated with low δ13C values) occur in high-impact sites, suggesting light-depleted conditions. Airai Bay shows a recent shift to more positive values (-4.5 to -5.5 & -1.75 to -2.25) after a period of sharp change in the isotopic signals. These spatial and temporal variations may correlate with land-use change patterns. Trace element data, including Barium to Calcium ratio, also will be presented to elucidate sedimentation dynamics and impacts of large-scale earth moving events on reef systems.

MONITORING AND SPATIAL-TEMPORAL ANALYSIS OF CORAL REEF BASED ON MULTI-DATA (Abstract ID: 29372)

Xisha Islands, the largest archipelago in the islands of South China Sea, has abundant natural resources. The coral reefs on the Islands are typical oceanic and are the oldest and rarest ones in China. They have immeasurable social and economic values. The future of the coral reef ecosystems on the islands is worrying under the pressures from humankind activities and global warming, although they have a wide scale of self-adaptation abilities. So it should be now on the calendar to carry out the monitoring of Coral Reef,especially coral reef bleaching . In this paper, by using methods of object-oriented classification and Normalized Spectral Mixing Analysis Model, based on multi-source Remote sensing data, such as Landsat, SPOT, Quikbird, IKNOS, we obtain spatial distribution map of coral reef and coral reef bleaching. To be more scientific and convincible for research, we carry out accuracy validation by using field investigation data, analysis spatial dynamic changes and explore reasons lead to those patterns. The results are not only enable to understand real-time monitoring with multi-source images, but also are significant in monitoring of coral reef and coral reef bleaching by using remote sensing technology, in development and protection of the coral reef resources of Xisha Islands.

POTENTIAL MECHANISMS OF INTENSIVE AQUACULTURE EFFLUENTS ON A CORAL REEF IN THE SOUTH CHINA SEA: IN SITU STUDIES (Abstract ID: 27827)

Little is known of the potential impacts and mechanisms of intensive fish farming on coral reefs. This study investigated the relations of live corals with Ulva blooms and environmental parameters along a natural gradient from aquaculture ponds in Sanya Bay. Daily dissolved oxygen fluctuated dramatically from 1.96 mg l-1 in the morning to 15.26 mg l-1 in the afternoon. Redundancy analysis showed that Ulva coverage, DO, temperature and turbidity can significantly and negatively explain the coral's distribution in 2013 and 2014. Higher partial coral mortality were recorded close to the outlet. Significantly lower rETRmax were detected on Favia sp. which was covered by Ulva spp. These resluts suggested that Ulva overgrowth, light shedding and physical abrasion may have caused the coral's physiological stress. High level of dissolved organic carbon was likely linked to severe hypoxia in the morning, which was probably one of chief mechanisms for the coral tissue mortality.

THE EPIGENETIC REGULATION OF THE CNIDARIAN-DINOFLAGELLATE SYMBIOSIS (Abstract ID: 28776)

The symbiotic relationship between cnidarians and dinoflagellates is a keystone of the coral reef ecosystem. Despite the ecological importance of this relationship, comparatively little is known about the genes and pathways involved in the initiation and maintenance of this symbiosis. The sea anemone Aiptasia is an emerging model to study the molecular basis of the cnidarian-dinoflagellate symbiosis, because it also harbors intracellular Symbiodinium like corals, but can be reared with and without symbionts. In this study, we determined changes in DNA methylation using whole genome bisulfite sequencing of symbiotic and aposymbiotic Aiptasia in order to gain insight into epigenetic mechanisms that regulate the cnidarian-dinoflagellate symbiosis. We identified more than 1,300 differentially methylated genes between different symbiotic states. Functional analysis of these genes highlighted several significantly enriched biological processes including immunity, apoptosis, phagocytosis recognition, and phagosome formation. Interestingly, these processes involve previously identified candidate genes from expression and protein screens as well as new genes with potentially important functions in symbiont recognition, apoptotic cell clearance, and nutrient and metabolite exchange. Our data indicate that aspects of cnidarian-dinoflagellate symbioses are under epigenetic control. Further experiments elucidating the correlation of DNA methylation data with mRNA expression data are expected to provide additional insight into the biological role of DNA methylation in cnidarians.

TISSUE LIGHT GRADIENTS SHAPE PHOTOSYNTHETIC ACCLIMATION IN CORAL SYMBIONTS (Abstract ID: 28307)

Coral reefs form some of the most diverse and productive ecosystems on Earth. They are limited to habitats with appropriate light conditions, but inhabit a wide span of light-exposed habitats from shallow reef flats to shaded caves because they are able to optimize the internal light environment for their endosymbionts. The regulation of internal light-field serves to either filter out excess light harmful to the algae, or to increase the photon flux reaching the algae in sun-exposed or shaded environments. There are several ways by which the coral host optimizes the light environment for its endosymbionts, e.g. by screening out harmful UV-radiation by chromoproteins or other fluorescent host pigments, host pigment conversion of short-wave radiation to longer wavelengths, which are more efficient for photosynthetic conversion, or increasing the internal photon flux

density in the tissue by scattering and skeleton reflection. We studied the photophysiology of the oral and aboral layers of symbiotic algae of the coral Montastrea curta to investigate if different acclimation to light exist in hospite on polyp scale. We show that the light perceived in the two layers differed >2-fold, and that this change in light facilitates different quantum yield and photosynthetic electron transport in the oral vs. aboral symbiont layer. This has important implications for the understanding of coral symbiont resilience towards high light stress, and demonstrates that the coral holobiont may exhibit canopy-like properties in respect to spatial microgradients of light and chemical parameters.

## INITIAL FINDINGS OF THE 2014-2015 NATIONWIDE ASSESSMENT OF PHILIPPINE CORAL REEFS: NEW BENCHMARKS (Abstract ID: 28458 | Poster ID: 429)

A nationwide coral reef assessment was initiated in the Philippines in 2014 for a period of three years to update the status of reef benthos in the country. Randomly selected fringing reefs were sampled, stratified by the total area of reefs in each of six biogeographic zones. A phototransect method involving five randomly deployed 50-m transects was used to assess the cover of benthic categories in each station. Initial data up to 2015 covered a total of 80 stations (65 in Luzon, 5 in Visayas, and 10 in Mindanao), sampled across 14 provinces. The calculated average hard coral cover (HCC) was 24.7% (95% CI: 21.8, 27.7). This is comparable with HCC found by others in the Indo-Pacific region. Also, results revealed high coral diversity (average number of taxonomic amalgamation units = 31) despite low HCC in several stations. Using empirically-based benchmarks for categorizing reef condition using HCC (0-22% for poor, >22-33% for fair, >33-44% for good, and >44% for excellent), most (46%) surveyed stations were generally found to be in poor condition. These initial findings provide a firm basis for the revision of policies concerning the conservation and management of Philippine coral reefs.

## A BENCHMARK FOR COVER AND GENERIC DIVERSITY IN PHILIPPINE REEFS (Abstract ID: 28328 | Poster ID: 425)

Benchmarks for metrics such as hard coral cover and diversity are needed for better inferences on reef status, and how these reefs are responding to environmental changes, disturbances, and management interventions. We provide benchmarks based on coral cover and generic diversity in the Tubbataha Reefs, the largest no-take marine protected area and best managed reef in the Philippines. The reef slopes of Tubbataha are monitored annually in a hierarchical manner with random transects embedded in fixed stations, stations embedded in sites, and sites within this one location. Coral cover (mean= 34%, sd=1.7) and number of coral genera in the reef slopes of the Tubbataha reefs have changed little at the location and site level from 2012 to 2015. However, these parameters greatly vary spatially. Most (71%) of the variation in coral cover is at the among site level, 9% at the among station level, and 20% at the among transect level. In contrast, total variability in number of coral genera is mostly due to among transect variation, some among station variation, and hardly any among site variation. These averages and patterns in variability over various spatial scales provide us good bases to guide interpretation of results of assessments and monitoring done elsewhere in the Philippines and the Coral Triangle.

## TEMPERATURE AND FOOD AVAILABILITY AFFECT ASSESSMENT OF PREDATION RISK BY JUVENILE CORAL REEF FISH (Abstract ID: 28566)

Risk assessment in ectotherms is strongly affected by an organism's energy expenditure and acquisition because these will alter the motivation to feed, which is balanced against antipredator behaviours. Temperature and food availability are known to affect the physiological condition of ectotherms, but how interactions between these variables may influence predator–prey dynamics is still poorly understood. This study examined the interactive effects of food availability and temperature on the trade-offs between predator avoidance behaviour and foraging in juveniles of a marine damselfish, Pomacentrus chrysurus. Predator avoidance behaviour was tested by exposing fish to chemical alarm cues obtained from skin extract of conspecifics. When detected, these cues elicit an antipredator response in fish, typically characterized by decreased foraging. Fish maintained under high food ration displayed distinct antipredator responses to chemical alarm cues, regardless of temperature. However, fish maintained in conditions of low food ration and 3 °C above ambient temperature did not display an antipredator response when exposed to chemical alarm cues, whereas those in ambient temperature did. These results suggest that individuals in low physiological condition because of limited food availability are more susceptible to increased temperature and may therefore take greater risks under predation threats to satisfy their energetic requirements. Projected business-as-usual climate change scenario adds urgency for more research on this topics.

## EPIGENETIC CHANGES IN THE CORAL *STYLOPHORA PISTILLATA* IN RESPONSE TO LONG-TERM OCEAN ACIDIFICATION (Abstract ID: 28563)

Coral reefs are in rapid decline, chiefly from anthropogenic factors. As corals have a long generation time, epigenetic adaptations e.g. DNA methylation and histone modifications likely play a large part in coping with long-term stresses, in tandem with natural selection. There is indirect indication that methylation regulate transcriptional noise in the coral *Acropora millepora*based on the assumption that methylated genes had lower amounts of CpG dinucleotides. However, large-scale, direct evidence describing the methylation states of coral genes from whole genome bisulphite sequencing (WGBS) has, so far, been lacking. In our work, we chose the Red Sea coral*Stylophora pistillata* to study changes in the methylation landscape in response to ocean acidification. We obtained WGBS data on coral nubbins grown *in aquaria* for two years in controlled conditions with only the $pCO_2$altered to simulate projected acidities of the world's oceans. We have identified a

number of genes that undergo differential methylation in more acidic conditions, and some of the genes are thought to regulate calcification and bone mineralisation. This is in agreement with the phenotypic changes observed in the corals grown under more acidic conditions, as growth rates of the corals remain constant while the skeleton structure was more porous and less dense. Correlations drawn between gene expression and their corresponding methylation patterns provide further support for observed phenotypic adaptations in response to prolonged ocean acidification.

TOWARDS NETWORKING OF NATIONAL PROTECTED AREAS FOR THE CONSERVATION OF CRITICAL HABITATS OF GREEN SEA TURTLE POPULATIONS IN THE PHILIPPINES (Abstract ID: 29264 | Poster ID: 646)

The establishment of local MPAs and networks for the conservation of coastal ecosystems and fishery management is widely practiced in the Philippines. Some networks are established on the basis of ecological connectivity among MPAs, while others are networks for learning and complementation of coastal resources management activities. Under the cooperation of Indonesia, Malaysia and the Philippines in the SSME, over 10 protected areas across the 3 countries, known to support different life stages of green sea turtles from the same population, are envisioned to form a transboundary network. The Biodiversity Management Bureau and its partners are in the process of establishing the Philippine part of the transboundary MPA network. The process involves developing institutional systems for the operationalization of the network, including improving management effectiveness in each site and strengthening enforcement through better communication and coordination. It also engages other sectors and institutions for advancing sea turtle research and building capacities to address the conservation needs for effective management of sea turtle habitats and to promote sustainable fisheries management in the selected sites. This is a new initiative for the country since this is the 1st networking of national protected areas based on linked habitats critical of a particular population of the endangered green turtle, *Chelonia mydas*. The initiative contributes to the Philippine international commitments that include the CMS,CBD and CTI-CFF.

ECOPHYSIOLOGY OF A CORAL SPECIES IN THE NORTHERNMOST ATLANTIC REEF SYSTEM: EFFECTS OF LOW TEMPERATURES ON SIDERASTREA RADIANS IN BERMUDA (Abstract ID: 28731 | Poster ID: 320)

Thermal stress induced by low seawater temperatures is a primary factor restricting coral growth and distribution. High latitude reefs may support coral populations that are resilient to thermal stress since they are exposed to wide annual temperature ranges. In Bermuda, the northernmost Atlantic reef system, corals are subjected to average temperatures below 18°C in the winter. The physiological responses of the zooxanthellate coral species*Siderastrea radians* to low temperatures were assessed by two experiments. Firstly, replicate colonies were subjected to reductions in temperature of 2°C every two days from ambient (25°C) to an extreme low of 15°C and back to ambient. Gross productivity was significantly depressed only at 17 and 15°C with rates recovering to initial values once temperatures returned to ambient. The photochemical efficiency of the colonies fluctuated over time and reached the lowest levels at 21°C and 15°C. Secondly, replicate colony nubbins were maintained in consistent temperature treatments of 25°C, 21°C and 17°C for two weeks. The exposure to 17°C caused significant decreases in photochemical efficiency and in the chlorophyll a concentration with no signs of recovery over the experiment; however, net calcification rates did not vary among treatments. Overall, even though low temperatures disrupted photosynthetic activities of the algal symbiont within *S. radians*there was recovery over the short term exposure to the extreme low temperatures. This research gives insight into thermal resilience of tropical corals at high latitudes.

SPAWNING PATTERNS DIFFER BETWEEN ACROPORA AND MERULINID CORALS (Abstract ID: 28302)

Spawning patterns of scleractinian corals were examined in situ at Lyudao, southeastern Taiwan in 2010–2015. Spawnings of a total of 47 species were recorded. In the genus Acropora (including 13 species), annual spawning occurred on a single night, 3–11 days after the full moon mostly in May. In contrast, in the massive coral family Merulinidae (including 16 species from six genera, Dipsastraea, Favites, Hydnophora, Leptoria, Goniastrea and Platygyra), annual spawning occurred continuously over 2–3 nights and always around the last quarter moon in April and May. Moreover, spawning of Acropora corals usually occurred on an earlier lunar day at southern coast than at northern coast, but merulinid corals spawned in the same timing of lunar days (around the last quarter moon) between the coasts. The different spawning timing of Acropora corals between the coasts may be caused by different local environmental conditions between the coasts (e.g., seawater temperatures and weather). The results of this study demonstrated the different spawning patterns of Acropora and merulinid corals and suggested different regulatory mechanisms determining their spawning timing.

DO DIFFERENT SEAGRASS SPECIES SUPPORT UNIQUE BENTHIC MACROFAUNAL COMMUNITIES? (Abstract ID: 28536)

Structural complexity is often considered to be responsible for the high biodiversity associated with seagrass beds. This study aimed to examine the effects of different seagrass species on the abundance and community structure of benthic macrofauna. Sediment cores were taken from monoculture beds of five seagrass species in Dongsha Island, a remote atoll in the South China Sea, including Cymodocea serrulata (CS), Cymodocea rotundata (CR), Halodule uninervis (HU), Syringodium isoetifolium (SI), and Thalassia hemprichii (TH) across four seasons. HU and SI demonstrated higher shoot density, but TH, CR, and CS were present at higher seagrass biomasses per unit area. Sediment grain size was significantly larger in the CS beds. The sediments of the TH beds displayed the higher sorting coefficient, as well as the highest silt/clay and organic content. Furthermore, the TH beds were characterized by the highest macrofauna abundance (12,304 individual m-2) and richness (17 taxa). The macrofaunal communities were significantly different between the beds of the five different seagrass species. The TH beds were dominant solely by malacostracans, but polychaetes and malacostracans were co-dominant in the beds of other species. While polychaete abundance was higher in the CR beds, ophiuroids, malacostracans, and ostracods were more abundant in the TH beds. Positive correlations were detected between amphipod abundance and sediment organic content and between gastropod abundance and seagrass biomass, indicating that the macrofaunal communities were primarily influenced by food resources, but not physical structure.

A PHYLOGENOMIC APPROACH REVEALS THE MONOPHYLY OF SCLERACTINIANS (Abstract ID: 28970)

Calcification is one of the most distinct traits of scleractinian corals. Their hard skeletons constitute the substratum of the iconic reef ecosystems and confers corals their remarkable diversity of shapes. The evolutionary relationship between scleractinians and the closely related non-calcifying coralimorpharians is key to understand how calcification emerged and evolved in corals. The crucial question is whether scleractinians form a monophyletic group or, alternatively, if coralimorpharians are nested within corals and have lost their ability to calcify (the so-called "naked-coral" hypothesis). However, despite major efforts based on comparison of morphological traits and molecular markers, the relationship between scleractinians and corallimorpharians has remained unresolved and controversial. Extensive phylogenetic analyses based on a large number of full mitochondrial genomes were not able to unambiguously resolve their evolutionary relationship. This difficulty is partly attributable to the considerable heterogeneity in composition and evolutionary rates of the mitochondrial sequences in the different scleractinian and corallimorpharian clades. Here a new analysis is presented based on 291 single copy nuclear protein-coding genes from 15 anthozoan taxa. Unlike the mitochondrial sequences that suggested the "naked coral" hypothesis, these nuclear markers do not display any distinct compositional bias in their nucleotide or amino-acid sequences. Several phylogenomic approaches congruently reveal a topology consistent with scleractinian monophyly and corallimorpharians as the sister clade of scleractinians.

ANALYSES OF CORALLIMORPHARIAN TRANSCRIPTOMES PROVIDES NEW PERSPECTIVES ON THE EVOLUTION OF CALCIFICATION IN THE SCLERACTINIA (CORALS) (Abstract ID: 28129)

Corallimorpharians have a close phylogenetic relationship with corals and can potentially provide novel perspectives on the evolution of biomineralization within the Hexacorallia. Surveying transcriptomes of corallimorphs led to the identification of orthologs of some skeletal organic matrix proteins that were previously considered to be restricted to corals; this is significant given that surprisingly few of the proteins identified in the skeletal proteome are coral-specific. Whilst carbonic anhydrases are ubiquitous proteins involved in CO2 trafficking, both calcification and photo-symbiosis are assumed to place increased demands on the CA repertoire. These have presumably driven the elaboration of complex CA repertoires that are typical of corals. Comparison of corallimorph CAs with those of corals indicates that corals have specifically expanded the secreted and membrane-associated type CAs, whereas similar complexity is observed in the two groups with respect to other CA types. Similar numbers and type distribution of CAs between the symbiotic and non-symbiotic corallimorphs suggests that, whereas an expansion of the CA repertoire has been necessary to enable calcification, it may not be a requirement to enable symbiosis. Consistent with this idea, preliminary analysis suggests that the CA complexity of symbiotic and non-symbiotic sea anemones is similar. This study is consistent with the idea that coral calcification evolution required relatively few new genes, that are largely involved in the deposition process, but also the expansion of a specific type of CA.

SYMBIODINIUM KAWAGUTII GENOME ILLUMINATES DINOFLAGELLATE GENE EXPRESSION AND CORAL SYMBIOSIS (Abstract ID: 29385)

The lack of a good understanding on establishment and regulation of coral-Symbiodinium symbiosis at the genomic level has hampered efforts to understand and manage coral bleaching and degradation. By high-throughput sequencing we (an international team) analyzed the 1180-Mb genome and RNA of Symbiodinium kawagutii. The genome has been subjected to active (retro)transposition and gene family expansion, especially in processes important for successful symbiosis with corals. We found an altered glycan pathway that specifies (GlcNAc)5(Man)5(Asn)1 glycan rich in free mannose branches and terminal mannose-mannose units available for lectin binding in host recognition. Numerous genes related to legume-root nodule symbiosis and parasite virulence identified may be related to the initiation of the symbiosis. A high number of transporters were catalogued potentially facilitating material exchanges between the Symbiodinium and a symbiotic coral like Acroporal digitifera. We also documented genes potentially governing sexual reproduction and cyst formation, indicating that the symbiotic lineage maintains a typical dinoflagellate life cycle. Most strikingly, we identified an extensive microRNA system that appears to regulate genes expression not only in Symbiodinium but also in a host coral. Further comparative genomics analyses suggest that the type of photosynthate supplied by the symbiotic alga and nutrients by the coral host can vary among symbiosis systems, implying that biochemical complementarity may be key to host-symbiont selection and robustness of the symbiosis system in face of environmental stress.

MULTIPLE STRESSORS ON TEMPERATE CORALS: INSIGHTS FROM EXPERIMENTAL, OBSERVATIONAL AND MODELLING STUDIES (Abstract ID: 29773)

Local and global disturbances are increasingly affecting marine biota and are of major concern for the management of marine ecosystems worldwide. Understanding how these stressors interact and the resulting cumulative impacts is critical to improve our predictions of the evolution of marine ecosystems in changing oceans. While multiple stressors' interactions in corals have been mostly assessed in laboratory, the combination of different approaches such as laboratory, observational and modelling studies is essential to better understand and predict the response of these organisms. Our research focuses on the effects of global and local stressors and their interaction on different temperate corals: the coral Cladocora caespitosa and the octocorals Paramuricea clavata and Corallium rubrum. We will show different results from: (1) laboratory experiments studying the interaction between global stressors such as warming and invasive species, (2) field studies of warming and acidification effects and their potential interaction from observations at CO2 vents and other non-acidified sites, and (3) modelling the effects of multiple stressors and the interaction between warming and local stressors such as fishing or recreational diving. The results point out the importance of bearing in mind the synergistic effects of stressors acting at multiple scales when designing and implementing conservation actions at local scale. Finally, we demonstrate how combining all these approaches can help to better foresee the potential effects of global change in reef organisms.

PALAU'S NORTHERN REEFS: SCIENCE AND MONITORING USED TO GUIDE THE MANAGEMENT AND ASSESS THE RECOVERY OF CORAL REEF FISH STOCKS (Abstract ID: 29390)

As fishing pressure has lead to declines in coral reef fish stocks, it has become evident that new management approaches are needed to ensure the sustainability of these fisheries. We present a case study from the northern reefs of Palau, where two states have decided to co-manage their fishery resources to safeguard their livelihoods, food security and fishing culture. Previous analysis of the main fishery targeted species showed that spawning potential ratios (SPRs) were below the threshold that allows stocks to recover. Here we describe the science and recommendations used to put the stocks back on a path of recovery, and present the monitoring protocols used to assess the effectiveness of these strategies. For baseline monitoring we used fishery-dependent and -independent data collection techniques, including dive and fish landing surveys, where we applied stereo-video technology to accurately and efficiently survey exploited fish stocks. We report on size frequencies and biomass from dive surveys covering 65 km of transects across different depths, habitats and protected area status. Our baseline data reveal that stocks in frequently fished areas exhibit truncated size frequency distributions and reduced biomass compared to stocks in effectively enforced MPAs. We also compare the diving survey data to the local estimates of size at maturity, size frequencies and species composition extracted from catch data collected by local fishers. This case study documents an achievable approach to coral reef fisheries assessment and monitoring that can be applied to other regions.

FOLLOWING PROTEOMIC CHANGES IN SYMBIOTIC *AIPTASIA* CYTOSOL AND SYMBIOSOME MEMBRANES DURING THERMAL STRESS (Abstract ID: 29550)

We are investigating the pathways involved in thermal-induced bleaching in cnidarian-dinoflagellate symbiosis by analyzing in parallel changes in mRNA and protein abundance. Symbiotic *Aiptasia* anemones hosting the clonal *Symbiodinium* strain SSB01 were subjected to thermal stress at 34C and sampled at 0, 24, and 48 h to reflect pre-stress, onset of bleaching, and approx. 50% bleaching, respectively. Anemone homogenates were separated into host and algal fractions. Host fractions were further separated into cytosolic (CF) and membrane-enriched fractions (MF). CF and MF were labeled with isobaric tags and subjected to LC-MS/MS mass spectrometry. Data analysis is in progress. In addition, to allow a more detailed analysis of a particularly interesting protein set, we are preparing a symbiosome-membrane sample using antibodies to guide fractionation. We confirmed that the PC3 monoclonal antibody (Wakefield and Kempf, 2001; a generous gift from S. Kempf) stained material surrounding algae in symbiotic tissues and in host homogenates but not in axenic algal cultures. We also generated a peptide-directed antibody against the glucose transporter Glut8, validated its specificity by Western blots and peptide competition, and showed staining of the symbiosome membrane by immunofluorescence. By sucrose-density-gradient centrifugation, we isolated a fraction that stained strongly with both PC3 and anti-Glut8 antibodies. Further characterization of this fraction (to identify possible contaminating membrane elements) is underway as a prelude to its analysis by LC-MS/MS.

ADVANCING ECOSYSTEM-BASED MANAGEMENT: ECOSYSTEM-BASED FISHERIES MANAGEMENT POLICY AND ROADMAP, WITH PARTICULAR EMPHASIS FOR CORAL REEFS (Abstract ID: 28073)

NOAA has adopted ecosystem-based management (EBM) as the approach for meeting the agency's mandates to sustainably manage the nation's marine resources. Ecosystem-based management is an integrated approach that incorporates the entire ecosystem, including humans, into resource management decisions across all ocean-use sectors. EBM accounts for a changing marine climate and is guided by an adaptive management

approach. EBM is informed by science to ensure resilience in marine ecosystems and in the goods and services they provide. NOAA Fisheries is advancing EBM for the fisheries sector through development of an Ecosystem-Based Fisheries Management (EBFM) Policy Statement and associated Roadmap. This presentation will provide an overview and update of the draft EBFM Policy Statement and Roadmap, how they relate to other efforts, and discuss how we'll know when we're doing EBFM. This work will particularly emphasize the unique and important facets about coral reefs that make them especially amenable and requiring of EBFM.

DIEL PATTERNS OF CELLULAR OXYGEN CONCENTRATIONS AND AEROBIC AND ANAEROBIC ENERGY PRODUCTION IN CORALS (Abstract ID: 28899 | Poster ID: 21)

Corals experience hyperoxia during the day due to Symbiodinium photosynthesis and hypoxia at night due to respiration by the coral holobiont. Previous studies have revealed corals undergo daily oscillations in the expression of putative metabolic genes. However, the anaerobic energy production pathways in corals are unknown. To study the link between nighttime hypoxia in coral tissues and cellular energy production, the branching scleractinian species Acropora yongei was studied in a laboratory setting. Oxygen concentrations were measured in the diffusive boundary layer using microelectrodes, demonstrating daily hyperoxia and nightly hypoxia. Branches were sampled every 4 hours over a diurnal cycle to measure metabolic enzyme activity, metabolites, and protein expression by 2D gels. For the first time, it was shown that corals produce strombine, an end metabolite of anaerobic glycolysis. High amounts of strombine were present in coral tissues during the day as well as at night. Enzyme activity assays revealed that aerobic energy producing pathways were significantly less active during the night versus the day. Thus, the relative contribution of anaerobic glycolysis was greater at nighttime, corroborating the concept of nightly functional anaerobiosis in corals. However, protein expression of detectable glycolytic and TCA cycle enzymes did not exhibit diel patterns. Therefore, the transition from aerobic metabolism during the day to anaerobic metabolism at night appears to be controlled on the substrate level and by posttranslational modifications to metabolic enzymes.

PHAGE-BACTERIA INTERACTIONS IN CORAL REEF BENTHIC COMPETITION (Abstract ID: 28919)

Bacterial communities mediate coral reef ecosystem transitions from coral- to algal-dominated communities through shifts in metabolisms at the interaction zones. Anthropogenic disturbances such as overfishing and nutrient loading stimulate algal growth, aiding turf and macroalgae to outcompete stony, reef building corals. Here we present data using bacterial and viral metagenomes from benthic competitive interaction zones in the Southern Line Islands, a pristine reef system that offers a unique model to assess baselines. We sequenced 200 samples from 15 different types of interactions including corals of the genera Porites, Acropora, and Montipora, and algal functional groups such as Halimeda, filamentous red algae, turf algae, and crustose coralline algae. Our approach allows for a robust understanding of how viral and bacterial communities may mediate physiologic events that lead to phase shifts. This is the most comprehensive and detailed metagenomic dataset on coral reef benthic interactions available to date. We found that coral-associated bacteriophage communities exhibit a higher prevalence of mucus binding properties, indicating that corals utilize phage-mediated immunity against invasive bacterial pathogens. In addition, the algal-associated communities exhibited higher levels of lysogeny, a feature that may facilitate algal microbes to invade coral holobionts by containing more temperate phage communities and thus expressing phage-encoded genes that offer competitive advantages such as virulence factors.

NOAA CORAL REEF WATCH'S PROBABILISTIC SEASONAL-SCALE CORAL BLEACHING THERMAL STRESS OUTLOOK SYSTEM FOR INFORMING MANAGEMENT DECISIONS (Abstract ID: 28196 | Poster ID: 534)

The National Oceanic and Atmospheric Administration's (NOAA) Coral Reef Watch (CRW) and National Centers for Environment Prediction (NCEP) recently released version 3.0 of the global Coral Bleaching Thermal Stress Outlook system, based on sea surface temperature (SST) predictions from NCEP's operational Climate Forecast System Version 2 (CFSv2). Every week, the Outlook system predicts the probability of thermal stress capable of causing mass coral bleaching for several months in advance (current online products are ordinarily released out to four months), using 28 ensemble members derived from the CFSv2 SST forecast runs over the previous week. CRW uses a recently developed skill analysis tool to investigate regionally- and lead-time-dependent skill levels of the Outlook. The v3 Outlook system and associated skill analysis will be presented. An even newer version of CRW's Outlook is currently under development to incorporate additional, short-range SST forecasts from the CFSv2 to increase Outlook skill during the first three months of lead-time. CRW's Coral Bleaching Outlook system is critical to its global decision support system for coral bleaching management and helps managers and other stakeholders prepare for and respond to environmental stresses to coral reefs.

EFFECTS OF OCEAN WARMING AND ACIDIFICATION ON THE SEAGRASS *THALASSIA HEMPRICHII* FROM CORAL REEFS OF KENTING, TAIWAN (Abstract ID: 28666)

Seagrass beds provide important carbon sinks in coastal ecosystems, and it is thought that increasing the quantity of natural carbon sinks could help to slow the rate of global climate change (GCC). Therefore, understanding the natural carbon sinks on seagrass beds, as well as how these high-productivity marine ecosystems are influenced by climate change factors, are critical issues. A mesocosm-based approach was taken herein in which the seagrass *Thalassia hemprichii* and reef corals of Kenting, Taiwan, as well as additional ecological functional groups, were cultured under either control or elevated temperature and/or ocean acidification (OA)-simulating conditions. After 12 weeks, OA (800 ppm) was found to increase seagrass productivity, below-ground biomass, rhizome carbon content, and carbon sequestration. Rising temperature (25 to 31°C) increased the maximum quantum yield (Fv/Fm), productivity, relative dry weight, carbon sequestration, growth rate, and decomposition rate, but reduced shoot density and the carbon content of the roots and leaves. *T. hemprichii*demonstrated highest productivity, relative rate of dry weight increase, Fv/Fm, growth rate, below-ground biomass, shoot carbon content, and carbon sequestration at the high temperature + OA treatment. The estimated carbon budgets models showed that *T. hemprichii*-dominated seagrass bed under OA and 31°C warming displayed the highest leaf production, below-ground production, and above- and below-ground carbon storage, suggesting that *T. hemprichii* could benefit from GCC by absorbing and storing more carbon in the shoots and surrounding sediments.

FOSTERING SOLUTIONARIES AND OCEANPRENEURS IN OCEAN YOUTH'S CORAL WORKSHOP (Abstract ID: 29899)

Ocean Youth is a capacity building program for tomorrow's leaders and change-makers to conserve our oceans. The program is for 13-25 year olds and consists of remote interaction via a digital platform and face-to-face interaction with workshops and special events hosted by SEA LIFE aquariums around Australia. There are 3 phases in the online program starting with an introduction to "Ocean Care" issues (and potential solutions) including climate change, pollution and overfishing. The second phase, "Changemakers

in Action" is about getting inspired by amazing people making a positive difference for oceans by influencing change in their community and beyond. The third phase, "Solutionaries and Oceanpreneurs Unleashed", is about building the skills and confidence to create and implement solutions to protect and conserve oceans. Ocean Youth's Coral Workshop gives participants the chance to experience the fascinating world of reef-building corals. There are hands-on opportunities to learn about coral identification, discover coral fluorescence and go on a virtual dive. They are inspired through interviews with scientists talking about what can be done to reverse anthropogenic impacts on coral reefs. Future opportunities will exist for these participants to get involved in reef restoration and citizen science projects. Ocean Youth Ambassadors are currently being fostered through face-to-face interactions in Sydney, Melbourne & Mooloolaba while the online platform allows for global participation and the world is their oyster.

A TEN YEAR TEMPERATURE RECORD FROM A SHALLOW WATER REEF IN THE MESOAMERICAN BARRIER REEF LAGOON (Abstract ID: 29875 | Poster ID: 362)

The Mesoamerican barrier reef system in the western Caribbean creates a large region of lagoon coral reef habitat. As the largest lagoon habitat within the Caribbean, this region experiences differing oceanographic and temperature conditions as compared to offshore areas. The occurrence of several endemic species within the area also supports this area as a unique biogeographic region. This study presents an underwater temperature record over a ten year period (2004-2014) collected from Wee Wee Caye within the South Water Caye Marine Reserve of Belize. These data will be put into context by comparison to other Caribbean data sets.

JOHNSTON ATOLL: REEF FISH HYBRID ZONE BETWEEN HAWAII AND THE EQUATORIAL PACIFIC. (Abstract ID: 29790 | Poster ID: 32)

Johnston Atoll is isolated in the Central Pacific Ocean (16°45—N 169°31—W). The nearest landfall is French Frigate Shoals , 804 km (500 miles) north in the northwest Hawaiian Islands . It is about 1,287 km (800 miles) southwest of Honolulu, Hawaii. The Line Islands of Kiribati are about 1,440 km (900 miles) south and the Marshall Islands are about 2,560 km (1,600 miles) to the southwest. The labrid species, Thalassoma lutescens has wide range distribution from the Indo-Pacific throughout the Line Islands. The related species, Thalassoma dupperryi, is endemic to the Hawaiian Islands. The larvae of both species make it to Johnston Atoll where we have found a mix of phenotypes representing a range of hybridization events. The hybrids are easily distinguished by coloration. The large number of hybrid individuals and the diversity of their coloration suggest that the hybrid population is also locally sustaining. We also observed the arrival of two damselfish species to the atoll and their subsequent hybridization: Abudefduf adominalis and vaigiensis. This paper is based upon scientific diver observations of fish species at Johnston Atoll during the period of 1983 to 2003. The pattern and abundance of the hybrid wrasse will be described. We will also add notes on species that have been seen only on rare occasions and thus suggest infrequent long-range dispersal.

A PASSIVE ACOUSTIC SURVEY OF FISH SOUND PRODUCTION AT RILEY'S HUMP WITHIN TORTUGAS SOUTH ECOLOGICAL RESERVE: IMPLICATIONS REGARDING SPAWNING AND HABITAT USE (Abstract ID: 27959)

Passive acoustic recorders were used to monitor sound production indicative of the use of spawning habitat by groupers (Serranidae) at Riley's Hump, which is located in the Tortugas South Ecological Reserve (TSER), part of the Florida Keys National Marine Sanctuary. Sound production by black grouper (Mycteroperca bonaci), red grouper (Epinephelus morio), and red hind (E. guttatus) was recorded year-round and at all times of day but occurred more often in the evening during the winter-spring spawning period than during other times of day and year. This pattern for these species is consistent with results of previous studies that documented the association of sound production with reproductive behavior at spawning sites. Distinct diel and seasonal patterns of sound production by the longspine squirrelfish (Holocentrus rufus) and bicolor damselfish (Stegastes partitus) also were recorded. Riley's Hump is a documented spawning site for mutton snapper (Lutjanus analis), and recordings of black grouper, red grouper, and red hind indicate that it is used for reproductive purposes by these species as well. These results demonstrate the importance of the TSER and the need for continued research to understand its effect on the recovery and sustainability of managed fish populations.

STRENGTHENING CITIZEN SCIENCE NETWORKS TO BENEFIT THE GREAT BARRIER REEF (Abstract ID: 29231 | Poster ID: 725)

Citizen science is gaining recognition as a means for public collection of valuable information which can improve reef management outcomes. Benefits include increased data to supplement scientific research programs; community engagement and capacity building; and cost-effective and innovative program structures. Yet, citizen science programs often face significant challenges to deliver sustainable and best-practice programs. Some of the common difficulties include insufficient funding, limited staff capacity, insufficient awareness of the program by data users, and/or perceptions of the low credibility of citizen science data. In 2012, a scoping study consulted a range of stakeholders to identify critical needs and opportunities for a more coordinated approach to citizen science across the Great Barrier Reef (GBR). The Great Barrier Reef Citizen Science Alliance (Alliance) network evolved as a response to this study. The Alliance mission is to foster collaboration, capacity building, advancement and action for citizen science that benefits the Great Barrier Reef. The program is hosted by the Great Barrier Reef Foundation, with support from corporate partner Boeing. Ten member groups from coastal and marine citizen science programs are actively engaged in this initiative. This presentation will share the past successes, strategies and future plans of the Alliance. It will showcase the benefits of a strategic and collaborative approach to strengthen opportunities for citizen science providers, researchers, Reef managers and the Australian community to tackle key Reef issues.

MAKING WAVES: REEF CITIZEN SCIENCE FOR IMPACT (Abstract ID: 29396)

Engaging volunteers in marine citizen science projects has intrinsic value in regards to community capacity building and education. Yet the process of developing strategic citizen science projects and translating data into valued results with natural resource management applications can be challenging. Since 2001, Reef Check Australia has facilitated hands-on marine citizen science research and education projects. Four case studies showcase lessons learned from programs designed to create valuable social and environmental outcomes through engagement of volunteers. 1)Identifying and responding to data gaps through volunteer reef monitoring of subtropical reefs in South East Queensland. 2)Demonstrating citizen science data quality through a precision study on volunteer data and analysis of 14 years of globally standardised Reef Check reef health data in Queensland. 3)Adapting citizen science protocols to expand project opportunities that enhance capacity building, partnerships and strategic natural resource management applications through reef habitat mapping. 4)Tailoring new pathways for sharing citizen science findings and engaging volunteers with the community via a Reef Check Ambassadors community outreach program. Through these case studies, we share our approach, lessons learned and successes. This offers insights into potential approaches

for developing targeted and flexible citizen science projects and showcasing the work of volunteers and project stakeholders, and collaborating with partners for beneficial research, management and education applications.

MANELL-GEUS: A MODEL FOR FOSTERING MULTI-AGENCY COLLABORATION (Abstract ID: 28432)

Guam's Manell-Geus watershed contains extensive coral reefs and sea grass beds. These habitats support a strong fishing tradition and important cultural connections, but they are impaired by poor water quality associated with sedimentation and stormwater management issues. NOAA's Coral Reef Conservation Program and Guam's local coral managers identified Manell-Geus as one of two priority sites in 2010, while NOAA Fisheries named the site a Habitat Blueprint Focus Area in 2013. These two designations have catalyzed new partnerships for increased conservation work in the watershed, including in-kind as well as funding support from a range of local, state, federal and non-government organizations. With coordination and technical assistance from NOAA's Coral Program, partners are currently working on a range of forest restoration, habitat mapping, water quality, and other efforts to address threats to the watershed and its adjacent coral reefs. Private and community partners also participate by volunteering, providing access to private lands, and learning new skills to actively conserve these areas. NOAA's commitment to fostering partnerships for this site is increasing conservation efforts both in Manell-Geus and around the island.

PROFESSIONAL SCUBA DIVERS ABOVE THE WATERLINE: USING EXPERT ASSESSMENT TO INFORM CORAL REEF MANAGEMENT (Abstract ID: 29585)

Scientists and natural resource managers have increasingly recruited SCUBA divers to collect data that will improve our understanding about the status of marine resources and environments. Increased reliance on this group has enabled researchers to expand data collection efforts, while minimizing research costs. In most cases, diver-collected data has been limited to observations recorded by divers while underwater. The present research, however, explores the possibility of employing above-water PGIS methods to collect spatial data that can be used to assess the ecological status of coral reefs. Using PGIS data provided by occupational SCUBA divers in the USVI, the authors propose that local ecological knowledge can be used to provide an expert assessment of the relative quality and threat levels of area coral reefs, as well as understand which reefs are most used. With this information, resource managers can more effectively control management investments and actions to benefit the end-users as well as the coral reef resources. By looking at the co-occurrence of reef quality characteristics and stress levels in coral reef areas used by people, resource managers can better decide whether to monitor reef quality, work to mitigate or reduce threats, initiate restoration activities, or simply divert management effort to other areas. In ideal cases, expert assessment can serve as a supplement to biophysical data collected through regular coral reef monitoring. Where rich biophysical data does not exist, expert assessment may be a substitute.

THE HOLDFAST IS KEY: SARGASSUM REGROWTH FROM HOLDFASTS RAPID UNLESS REMOVED BY HERBIVORES (Abstract ID: 28942)

Macroalgae, especially large, canopy-forming species, are generally seen as a sign of reef degradation. Macroalgal-dominated states are difficult to reverse, as macroalgae pre-empt space on the benthos and shade and abrade coral colonies. However, it has recently been hypothesised that storms/cyclones may provide a window of opportunity for the recovery of coral populations by removing the algal biomass. We conducted an experiment demonstrating the resilience of Sargassum to cyclone impacts by creating 1.5x1.5m 'plots' in which we either cut the Sargassum at the stipe, leaving the holdfast (simulated cyclone effect), removed the holdfasts completely or removed nothing (control). The regrowth of the Sargassum with intact holdfasts was indistinguishable from control plots, demonstrating that Sargassum is capable of rapid regrowth from holdfasts after storm/cyclone damage. Further, we examined if herbivores are capable of damaging these holdfasts, preventing regrowth. Pieces of coral rubble with attached Sargassum were moved to areas of high herbivory, the number and size of holdfasts quantified, and exposed to one of three treatments for a period of 16 weeks: i) caged to exclude herbivores, ii) exposed to herbivores, iii) exposed to herbivores then caged after 8 weeks. Parrotfishes were responsible for the removal of holdfasts and limited the potential for regrowth. The window of opportunity hypothesis for the recovery of coral populations would therefore only be possible when co-occurring with increased herbivory.

GLOBAL PROJECTIONS OF CORAL BLEACHING UNDER WARMING AND OCEAN ACIDIFICATION USING A MECHANISTIC MODELLING APPROACH (Abstract ID: 29909)

Global climate models project increased rates of mass coral bleaching such that many of the world's reefs will disappear by mid-century. Typically, models use a Degree Heating Week (DHW) – based bleaching threshold in combination with sea surface temperature (SST) output from global climate models. While these approaches are empirically justifiable, they are nonspecific in applying a generic bleaching threshold to all coral species and typically do not incorporate the potential for corals to adaptively respond to an increasingly warmer, more acidic ocean. We scaled up a mechanistic model of coral and symbiont ecological dynamics and symbiont evolutionary dynamics to the global scale, and estimate severe bleaching events based on declines in coral cover. The model was run for changes in SST and water chemistry predicted by the NOAA/GFDL Earth System Model 2 through 2100. We normalized the model to achieve a reasonable global severe bleaching frequency (~10%) between 1985-2010 based on ReefBase bleaching observations. Coral bleaching responses to rising SSTs are tested using susceptible versus tolerant coral types, with and without variation in symbiont thermal tolerance, and in combination with ocean acidification. Projected bleaching frequencies are also compared and contrasted regionally to results from previous DHW–based threshold models. A global mechanistic model provides a valuable tool for assessing the potential effects of genetic or community-level variation in symbiont thermal tolerance on projected rates of mass coral bleaching.

INITIAL OUTPLANT PERFORMANCE OF *ACROPORA CERVICORNIS* ACROSS THREE REEF ZONES IN THE CAYMAN ISLANDS (Abstract ID: 28354 | Poster ID: 489)

To date, tens of thousands of nursery-reared staghorn coral *Acropora cervicornis* colonies have been outplanted to restore degraded reefs, largely as a result of increased capacity for coral aquaculture. The fate of outplanted colonies, however, is highly variable and seldom documented. In Little Cayman, Cayman Islands, remnant populations of staghorn coral remain in each of the reef zones where it was historically abundant. These include deep (15-20 m) and intermediate (10-15 m) spur-and-groove reefs, and especially shallow reef flats (0-3 m), where corals are known to have important wave attenuation function. To test the potential for outplanting existing nursery-reared *A. cervicornis* to each reef zone, a total of sixty ~20-cm colonies were outplanted to two plots each within the three zones of interest. Survivorship after 85 days differed significantly between zones, with mortality at deep plots exceeding that of shallow and intermediate plots. Net total linear extension of surviving colonies was significantly higher at deep and intermediate sites compared to shallow sites, which experienced a high rate of natural breakage due to wave action. Following the conclusion of the study, colonies at shallow plots experienced 90% mortality during an anomalous thermal event. Ultimately this study indicates that intermediate spur-and-groove sites in Little Cayman are most advantageous for outplanting activities using existing restoration methods. New strategies must be developed to improve *A. cervicornis* outplanting success in shallow and deep habitats.

VARIATION IN GROWTH, BRANCHING, AND BLEACHING AMONG NURSERY-REARED STAGHORN CORAL *ACROPORA CERVICORNIS* GENOTYPES (Abstract ID: 28398)

Over the last decade, genetic factors associated with Caribbean *Acropora* restoration have received increased attention. However, quantified differences among genotypes are seldom used to inform propagation or restoration. We conducted a one-year *A. cervicornis* propagation experiment in an offshore nursery in the Florida Keys. Our objective was to quantify and document phenotypic variability among ten genotypes while they were being grown for population enhancement. Twelve non-branching, 5-cm apical fragments were taken from nursery-reared colonies of each genotype. These fragments were randomly distributed across four identical PVC tree structures for grow-out. At the start of the experiment and on ~45-day intervals, total linear extension (TLE) and branches

were quantified for each colony. Buoyant weight was measured for each colony on days 0, 122, and 336 to determine calcification rate. Bleaching was recorded on day 207 following two 10-day periods of mean daily temperature above 31°C. All affected colonies had visually recovered by day 291. Significant differences in bleaching incidence, TLE, calcification rate, and branching were detected among genotypes. Unexpected variation in *post-hoc* ranking between TLE and calcification was observed, suggesting genotype-based differences in growth strategy. This information could guide propagation and restoration using the ten study genotypes. In addition, this study may represent a model system for evaluating *A. cervicornis* genetic diversity as corals are grown for population enhancement.

ASSESSMENT OF CORAL REEF FISH BIODIVERSITY: HOW TO CHOOSE THE RIGHT INDICES (Abstract ID: 28096)

Quantifying the biodiversity based on diversity indices is essential both for the development of effective management policies - to mitigate the loss of coral fish diversity - and to study ecological processes. We present the first representative and quantified overview of the indices used worldwide for assessing the biodiversity of coral reef fishes (from 1990 up to the present). Our aim is to assess to what extent and on the basis of which criteria the complexity of biodiversity is taken into account in coral fish studies. We found that the multicomponent aspect of biodiversity, which is considered as a key feature of biodiversity for numerous terrestrial and marine ecosystems, has been poorly taken into account in coral reef fish studies. Species richness is still strongly dominant while other diversity components, such as functional diversity, are underestimated even when functional information is available. We also demonstrate that the reason for choosing particular indices is often unclear, mainly based on empirical rationales and/or the reproduction of widespread habits, but generally with no clear relevance with regard to the aims of the studies. Finally, we propose general guidelines to serve as a basis for the selection of indices that provide complementary and relevant information for monitoring the response of coral reef fish biodiversity in the face of structuring factors (natural or anthropic). The aim of these guidelines was to achieve a better match between the properties of the selected indices and the context of each study.

ORGANIC MATTER BIOAVAILABILITY IN THE GREAT BARRIER REEF LAGOON (Abstract ID: 28290 | Poster ID: 91)

Organic matter (OM) in coral reef ecosystems has been suggested to be a major source of energy and nutrients. However, while the importance of OM cycling for the overall biogeochemical activity has been proposed there are no studies investigating in detail the degradation of OM in reef systems. Therefore, in this study the degradation of particulate (POM) and dissolved organic matter (DOM) was followed over a 50 days period at three locations in the Great Barrier Reef lagoon, during the dry and wet seasons, in dark, temperature controlled, laboratory incubations. Our results demonstrate that the POM fraction was more bioavailable and degraded at a faster rate than the DOM compounds. The data also shows the organic matter, on average, contained more than 90% of the total bioavailable nutrients, suggesting the organic matter fraction is an important and unaccounted source, in sustaining the productivity of this coral reef system.

A SUSPECTED NEW TROPICAL MARINE SPECIES OF AMPHIDINIUM (DINOPHYCEAE)FROM SANYA, CHINA (Abstract ID: 30170 | Poster ID: 369)

A dinoflagellate isolated from Sanya bay in China, with a minute and left-deflected epicone, was identified as a suspected new species of Amphidinium sensu stricto based on morphological and ultrastructural characters combination with LSU rDNA phylogeny. The main diacritic features distinguishing Amphidinium sp. from related taxa were: shape, size, position of distal and proximal cingulum ends, site of longitudinal flagellar insertion, sulcal course, chloroplast characteristics, and mode of cell division. In the present study, genetic phylogenetic analyses based on partial LSU rDNA using Neighbor-Joining and Maximum Likelihood revealed that Amphidinium sp. was in the monophyletic clade of Amphidinium sensu stricto, meanwhile the morphology of 16 species of Amphidinium sensu stricto were compared with the suspected new species, especially morphologically similar siblings (A. massartii, A. klebsii, A. trulla, A. gibbosum, A. carterae).

A COMPREHENSIVE INVESTIGATION OF MESOPHOTIC CORAL ECOSYSTEMS IN THE HAWAIIAN ARCHIPELAGO (Abstract ID: 29928)

During an interdisciplinary effort spanning more than two decades, we characterized the most expansive MCEs ever recorded, with vast macroalgal communities and areas of 100% coral-cover between depths of 50-90 m extending for tens of km^2 in the Hawaiian Archipelago. We used a variety of sensors and data gathering techniques to establish geophysical, biodiversity patterns, population dynamics, and trophic dynamics of algae, corals, fishes and invertebrates in reef-associated habitats down to 150 m. MCEs are associated with clear water and suitable substrate. In comparison to shallow reefs in the Hawaiian Archipelago, inhabitants of MCEs have lower total diversity, harbor new and unique species, and have higher rates of endemism in fishes. Fish species present in shallow and MCE depths have similar population and trophic (except benthic invertivores) structures and high genetic connectivity with lower fecundity at MCE depths. MCEs in Hawai'i are widespread but associated with particular geophysical characteristics. High genetic, ecological and trophic connectivity establish the potential for MCEs to serve as refugia for some species, but our results question the premise that MCEs are more resilient than shallow reefs. We found that endemism within MCEs increases with depth, and our results do not support suggestions of a global faunal break at 60 m. Our findings enhance the scientific foundations for conservation and management of MCEs, and provide a template for future interdisciplinary research on MCEs worldwide.

LATITUDINAL PATTERNS OF REEF FISH FEEDING ON THE BENTHOS IN CHANGING ECOSYSTEMS (Abstract ID: 28712)

Reef fish feeding on the benthos strongly affect ecosystem functioning on coral reefs worldwide. Fish species and feeding intensity can vary with several factors including temperature, depth, human-related impacts and biogeographic history. Large-scale latitudinal comparisons across natural gradients can enhance our understanding of these interactions in changing ecosystems. We addressed latitudinal variation of reef fish feeding on the benthos in terms of intensity, functional and taxonomic composition in 16 locations comprising different biogeographic provinces between latitudes 34°N and 27°S in the Western Atlantic. Feeding pressure on the benthos per unit of time and area was determined using video recordings where we could determine both biomass and bite rates of individual fishes. Feeding intensity was higher in the tropical region and decreased towards extratropical regions in both hemispheres. There was a consistent shift in the predominance of feeding pressure by herbivorous functional groups in the tropics to omnivorous groups in extratropical regions. Composition of feeding pressure by functional group was more similar within regions of similar temperature than biogeography, whereas in terms of species there was a clear biogeographic footprint. Species identity and their relative contribution within functional groups differed between biogeographic provinces. These results can be used to create predictive models of the impact of global changes in reef fish feeding, accounting for potential species range expansions and their impact on the ecosystem.

ENVIRONMENTALLY RELEVANT CONCENTRATIONS OF MICROPLASTIC PARTICLES INFLUENCE REEF FISH ECOLOGY (Abstract ID: 28053)

The widespread occurrence and accumulation of plastic waste in the environment has become a growing global concern over the past decade. While some marine organisms have been shown to ingest plastic few studies have investigated the ecological effects of plastic waste on animals. Here we show that exposure to environmentally relevant concentrations of microplastic polystyrene particles (200-300 µm) inhibits hatching, decreases growth rates and alters feeding preferences and innate behaviors of the spiny Chromis (Acanthochromis polyacanthus) larvae. Furthermore, individuals exposed to

microplastics do not respond to olfactory threat cues which greatly increases predator-induced mortality rates. Our results demonstrate that microplastic particles operate both chemically and physically on larval reef fish performance and development, which is known to have severe effects on recruitment dynamics in coral reef ecosystems.

DISTRIBUTION OF THREATENED CORAL SPECIES IN THE PARQUE NACIONAL SISTEMA ARRECIFAL VERACRUZANO, VERACRUZ, MEXICO (Abstract ID: 29677 | Poster ID: 698)

Sixty sites on 24 reefs were surveyed at the Parque Nacional Sistema Arrecifal Veracruzano (PNSAV) in the southwestern Gulf of Mexico, creating the most robust data set, known to date, on stony coral abundance, distribution, and health for the PNSAV. These data were collected to support effective management of the Park. A total of 6,231 colonies were assessed representing 30 species including six species listed as threatened under the US Endangered Species Act and the IUCN Red list. Threatened species represented 25% of all colonies recorded and at least one of these species occurred on 21 of the 24 reefs surveyed. Orbicella faveolata was the second most abundant species (17% of all species recorded). These species were widely distributed throughout the Park: O. faveolata observed at 88% of the reefs, followed by Acropora palmata (83%), O. annularis (83%), O. franksi (79%), A. cervicornis (62%) and Mycetophyllia (which were not identified to species) (29%). The colonies surveyed were large and relatively healthy: Orbicella spp. and A. palmata colonies had mean diameters over 100 cm and <40% mean mortality, A. cervicornis colonies were 50 cm and 22% mortality, and Mycetophyllia spp. were 16 cm and <6% mortality. These findings provide evidence that these coral reefs are unique having survived continuous anthropogenic impacts for hundreds of years due to their location off the coast of a large urban settlement and commercial shipping area, reinforcing the need for continued and increased protection for the entire PNSAV.

UNCOVERING WITHIN-COLONY GENETIC DIVERSITY USING HIGH-THROUGHPUT SEQUENCING DATA OF CORALS (Abstract ID: 28276)

Genetic mutations provide variability upon which selection acts, and are thus an essential quality for adaptation. High-throughput sequencing generates genomic datasets from which we can identify single nucleotide polymorphisms (SNPs) among samples. These analyses have been done frequently across coral colonies, but not from multiple samples within a single colony. Because coral polyps within a colony are typically asexual clones, intra-colony genetic differences most likely arise from somatic mutations during growth. We analyzed genotype calls of samples from 23*Acropora hyacinthus* colonies and 36 *Acropora nana* colonies. The *A. hyacinthus* analysis involved 4 to 22 samples per colony, while the *A. nana*analysis included 4 samples per colony. Using the Genome Analysis Toolkit (GATK), we compared the genotypes of all samples taken from one colony. We filtered through the SNPs called across a colony's samples to identify what we refer to as "top candidates" for true markers of intra-colony variation. This method allows us to compare relative intra-colonial diversity across colonies. The largest, oldest *A. hyacinthus* colony displayed the highest rate of top candidates for somatic mutants per number of SNPs called when compared to smaller *A. hyacinthus* colonies. The diversity generated by somatic mutations may represent an additional source of adaptive potential for coral colonies as their environments are altered by climate change.

INTRACOLONY VARIABILITY OF THE PHOTOSYNTHETIC PERFORMANCE AND ENERGY BALANCE IN THE SCLERACTINIAN CORAL ORBICELLA FAVEOLATA (Abstract ID: 28452)

The incidence of solar radiation on coral surface is highly variable across massive colonies, where changes of inclination play an important role. To analyze the effect of surface inclination on the holobiont physiology, we exposed fragments of the scleractinian coral Orbicella faveolata to 5 inclinations from 0° to 90°, reproducing a light gradient of an order of magnitude variation. A linear correlation was found between the inclination angle and the light intensity, more likely due to a high diffuse-light component on less irradiated surfaces. Photosynthetic descriptors showed important changes in the photoacclimatory response of the holobiont. This plasticity allowed vertical oriented surfaces to achieve a positive carbon balance during part of the daytime, albeit photosynthesis was never saturated and barely exceeded the compensation irradiance. By contrast, horizontal high-irradiated surfaces that were under photosynthesis saturation during most daytime showed the highest saturation values (Ek) and the lowest absorptance. This enabled holobionts to reduce the absorption of excess light energy, and hence the metabolic costs of photoprotection and repair of Symbiodinium. We concluded that coral surface inclination determines significant intracolony changes in the holobiont physiological condition to enhance the energetic balance of massive species. This plasticity may be a key to explain the intracolony variation in dominant symbionts, as well as the different physiological responses to thermal-stress or other environmental factors in coral colonies.

A CASE STUDY OF ECOSYSTEM-BASED FISHERIES MANAGEMENT IN PUERTO RICO: THE IDEAL AND THE REAL. (Abstract ID: 29203)

Ecosystem-based fisheries management (EBFM) is gaining popularity as an alternative to traditional fisheries management approaches. In western Puerto Rico, the Abrir La Sierra, Bajo de Sico, and Tourmaline (ABT) Spawning Aggregation Areas share management between Puerto Rico and the Caribbean Fishery Management Council. Included within the boundaries of ABT are areas of ecological, social, and economic importance, including mesophotic reefs, multi-species spawning grounds, and traditional fishing areas, making the ABT an optimal candidate for EBFM. To advance EBFM in ABT, new management approaches were recently proposed for these areas, which have been traditionally managed by focusing on single species or particular habitats. However, due to competing interests from multiple user groups, fear of loss of resource access, the perception that there is not enough background information to justify changes in management, and a lack of interest for compromising or addressing trade-offs within the ecosystem, the proposal was unsuccessful. This outcome demonstrates the difficulties and challenges of advancing EBFM in the U.S. Caribbean. We discuss why, even when National Marine Fisheries Service EBFM policy is established, it may be difficult to implement because of the current management framework and the constraints inherent in that management. We also discuss communication difficulties within a cross-cultural environment, and the steps that fisheries managers and constituents are taking to resolve these difficulties and advance the application of EBFM in U.S. Caribbean waters.

COAST-REEF SCALE PHYSIOLOGICAL RESPONSES OF ACROPORA MURICATA HARBORING SIMILAR SYMBIODINIUM GENOTYPES (Abstract ID: 29413)

Coral bleaching events are increasing worldwide as a result of climate change. Coral show differential bleaching susceptibilities depending on host and/or symbiont responses to changing environmental factors. Coral responses have been shown to vary over broad geographical scales with thermally-disparate environments. Of these responses, physiological characteristics such as Symbiodinium density and size, chlorophyll a content and estimated productivity along a coast-reef scale (<1 km) remain to be thoroughly studied. In this study, we examined these characteristics seasonally in Acropora muricata colonies that harbor similar symbiont genotypes along a coast-reef scale in Belle Mare lagoon, Mauritius. The studied reef and near-coast habitats displayed contrasting environmental conditions and bleaching histories with bleaching occurring only at the reef in 2009. We observed similar symbiont densities and cell sizes, albeit with seasonal variation, within corals from both stations. Chlorophyll a content was 30-31% lower in reef than near-coast colonies, irrespective of sampling season. Chlorophyll a content was significantly influenced by station. Estimated productivity was influenced by prevailing environmental conditions, with summer samples of near-coast colonies displaying 52% higher values than reef colony samples. This significant difference was maintained but less pronounced (18%) in winter samples. Our data suggest that similar Symbiodinium genotypes may show physiological acclimatization along a coast-reef scale as a consequence of variable environmental conditions.

HIGHEST SPECIES DIVERSITY OF OCTOCORALS FOUND IN CARIBBEAN AND A NEW VARIABLE NUCLEAR MARKER FOR THE OCTOCORALLIA? (Abstract ID: 28728)

We have observed the highest recorded octocoral diversity in the Caribbean around the Honduran island of Utila, the eastern-most extent of the Meso-American Barrier Reef System. Additionally, the nuclear gene, ALG11, has been tested for its barcoding accuracy for the first time in Cnidaria. Originally tested in sponges, ALG11 was considered

a potential barcoding marker for slow-evolving mitochondrial organisms (Belinky et al., 2012). Extensive unresolved relationships between species exist within octocorals or 'soft corals'. We studied a group of common Caribbean gorgonians, chiefly of the species-rich genus Eunicea and compared its phylogenetic potential with current mitochondrial marker genes mtMutS and COI. ALG11 proved to be significantly more variable than mtMutS and COI combined, and is a potential candidate for population genetic studies. Morphological and ecological differences are related to genetic characters such as well-established adaptations to depth (Prada et al., 2008). Intensive morphometric analysis is included in a detailed inter and intra-species phylogeny to investigate character states that could identify molecular differences. References BELINKY, F., A. DIVE TOURISM AND ITS IMPACT ON INTEGRATED COASTAL MANAGEMENT AND LIVELIHOODS FOR ARTISANAL FISHERS (Abstract ID: 27903)

The Coral Triangle, home to the most biodiverse coral reefs in the world with more than 600 coral species and 3000 fish species, encompasses Indonesia, Malaysia, Papua New Guinea, the Philippines, Solomon Islands and Timor Leste. These countries have formed the Coral Triangle Initiative on Coral Reefs, Fisheries and Food Security to conserve coral reefs. Over 240 million people rely on Coral Triangle coral reefs for income and food security, yet they are threatened by destructive fishing and other impacts. Dive tourism is cited for its capacity to conserve coral reefs and diversify the livelihoods of artisanal fishers, reducing their reliance on fishing for income and food security. Because it is not known whether dive tourism contributes significantly to conservation, livelihoods, or reduction of destructive fishing; or the extent to which traditional marine tenure is supported, we survey dive operators in the Coral Triangle, using an integrated coastal management framework. Our preliminary findings are that some dive operators do little for conservation, livelihoods or reduction of destructive fishing; and fail to recognise traditional marine tenure. In contrast, a few dive operators make major contributions to integrated coastal management by recognising traditional marine tenure and working with fishers as stakeholders. Our study analyses factors that lead to success in dive tourism's contribution to integrated coastal management and the extent to which success can be replicated. We also outline three case studies of best practice in the Coral Triangle and the Pacific.

COLONY SIZE-FREQUENCY DISTRIBUTION OF POCILLOPORID JUVENILE CORALS ALONG A NATURAL ENVIRONMENTAL GRADIENT IN THE RED SEA (Abstract ID: 28435 | Poster ID: 289)

Coral colony size-frequency distributions can be used to assess population responses to local environmental conditions and disturbances. In this study, we surveyed juvenile pocilloporids, herbivorous fish densities, and algal cover in the central and southern Saudi Arabian Red Sea. We sampled nine reefs with different disturbance histories along a north–south natural gradient of physicochemical conditions (higher salinity and wider temperature fluctuations in the north, and higher turbidity and productivity in the south). Since coral populations with negatively skewed size-frequency distributions have been associated with unfavorable environmental conditions, we expected to find more negative distributions in the southern Red Sea, where corals are potentially experiencing suboptimal conditions. Although juvenile coral and parrotfish densities differed significantly between the two regions, mean colony size and size-frequency distributions did not. Results suggest that pocilloporid colony size-frequency distribution may not be an accurate indicator of differences in biological or oceanographic conditions in the Red Sea.

DOES CORAL REEF STRUCTURAL COMPLEXITY AFFECT DENSITY OR TROPHIC LEVEL OF A HABITAT-SPECIALIST SPINY LOBSTER? (Abstract ID: 28810 | Poster ID: 296)

The spotted spiny lobster, Panulirus guttatus, is a sedentary, obligate Caribbean coral reef-dweller with a limited home range. To explore whether loss of reef structural complexity could potentially affect populations of this habitat specialist, we selected two separate coral reef patches (11,200 and 14,000 m2 in surface area) in Puerto Morelos (Mexico) and assessed their structural complexity using the rugosity index and the habitat assessment score (HAS). In each reef, we estimated density of P. guttatus with belt transects and sampled 30 lobsters to compare their stomach contents, three condition indices (weight/carapace length ratio, hepatosomatic index, blood refractive index), and stable isotope values (delta15N and delta13C). Rugosity index and HAS differed significantly between reef patches, but the less complex patch, though more flattened, still exhibited many crevices (potential shelters); hence, lobster density did not vary with reef patch. Lobsters consumed many food types, particularly mollusks and crustaceans, but consumed proportionally more coralline algae and fewer crustaceans in the more complex patch relative to the less complex patch. Lobsters in both reefs had a similar condition (all three indices) and trophic level, as suggested by similar mean delta15N values, but differed in mean delta13C values, indicating differences in organic carbon sources between reefs. Our results suggest that loss of structural complexity, at least to the degree of our less complex patch, has no apparent effects on density, condition, or trophic level of P. guttatus.

INVESTIGATING THE EFFECTS OF SUBMARINE GROUNDWATER DISCHARGE (SGD) ON CORAL GROWTH AND BIOEROSION ON TWO SHALLOW REEF FLATS IN MAUNALUA BAY, OAHU. (Abstract ID: 29687)

Coastal marine ecosystems exist in highly variable physicochemical environments due to biological processes, restricted water motion, terrestrial influences, and feedbacks between benthic productivity and reef calcification. This variability can be augmented by land-based nutrient inputs, which increase productivity and alter carbonate chemistry. Because there is a strong relationship between carbonate parameters, such as pH, and coral calcification and bioerosion, nutrients can impact the accretion-erosion balance on coral reefs. Submarine groundwater discharge (SGD) is a common source of nutrient-rich water into shallow reef systems, yet we know little about how SGD influences coral growth and bioerosion. We used natural SGD gradients at two sites in Maunalua Bay, Oahu to assess the effect of SGD on coral growth and reef bioerosion. Coral nubbins (Porites lobata) and bioerosion blocks were deployed across the gradient for six months and one year, respectively. Coral growth was determined using buoyant weights and photos; bioerosion was quantified by comparing before and after µCT scans. To describe the chemical environment created by SGD, we collected water samples (pH, total alkalinity, salinity, inorganic nutrients, and chlorophyll a) at each experimental location during high and low tide over 24 hour periods in the dry and rainy seasons. These data are crucial in helping understand the accretion-erosion dynamics of SGD-impacted reefs, especially in high islands like Hawaii, where SGD makes up a large portion of freshwater input to coastal reefs.

TRAIT MATCHING IN REEF FISH-CORAL SPECIES ASSOCIATIONS (Abstract ID: 29827)

Reef-building corals are foundational species on coral reefs, creating a complex three-dimensional structure that offers space and food resources for a wide array of organisms, including fishes. In this study we evaluated the relative importance of species morphological, behavioural and ecological traits in determining relationships among coral species and coral-dependent fishes using trait matching (i.e. co-occurring traits of corals and fishes in interacting species pairs). Identifying the traits associated with interacting species pairs, and whether these interactions are general or obligatory, will shed light on how the loss of coral species influences the fish community. We compiled literature records of associations between fishes and corals and combined these with coral and fish trait databases. Using generalised mixed-effects models, we show that trait matching between species pairs predict species associations better than analysing traits of corals and fishes separately. More specifically, matching levels of coral growth form and fish body size were the best predictors of species interactions. We suggest that matching traits of interacting species potentially can reveal the mechanisms behind close

relationships between fishes and corals. The identification of interdependences between functional traits of interacting species is important for predicting the outcome of species loss due to environmental change.

UNMANNED AIRCRAFT SYSTEMS (UAS) FOR COASTAL AND REEF ECOSYSTEM MONITORING AND FISHPOND ARCHAEOLOGICAL SURVEYS OFF LANA'I, HAWAII (Abstract ID: 29974)

The east coast of Lana'i is flanked by extensive shallow reefs and five traditional fishponds. However, the reef ecosystems of Lana'i remain among the least studied in Hawaii. Historical land use on Lana'i included significant destruction of the native flora by cattle, sheep and goats, followed by pineapple monoculture. In many areas the island was left with bare soil. This not only increased sediment runoff onto reefs, but also reduced the ability of the land to absorb water thereby reducing submarine backreef spring nutrient inputs to coastal waters. The past 20 years of land development on Lana'i further exacerbated soil runoff during heavy rains. We describe use of VTOL (Vertical Take Off and Landing) unmanned aircraft systems (UAS) with video cameras as a rapidly deployed tool for monitoring both sediment runoff and reef ecosystem health on Lana'i. This included assessing UAS multispectral imaging to quantify the temporal variability of groundwater inputs to the reef. We also discuss coordination with the Lana'i Cultural Heritage Center and Lana'i City High School using unmanned aircraft to map the island's five traditional fishponds. The ability of UAS to be rapidly deployed and cover extensive coastal areas in a single day was demonstrated as a valuable tool for monitoring runoff and reef ecosystems of Lana'i.

TO BE, OR NOT TO BE NOTICED: THE IMPORTANCE OF SPICULAR ANALYSIS FOR RECONSTRUCTIONS OF SPONGE COMMUNITIES IN MODERN CORAL REEFS (Abstract ID: 27814)

Sponges are a key and inseparable component of modern coral reefs. The knowledge of their taxonomic diversity is thus crucial for ecological considerations of these ecosystems. However, some sponge species might be easily overlooked due to their cryptic and/or excavating nature. This problem might often be solved using the method of spicular analysis. It enables to recognize spicule morphotypes by means of detailed examination of surficial sediments. Here, the spicular analysis has been applied to study the sponge-spicule assemblage in the lagoon reef of Bocas del Toro, Panama. The method allowed to identify some highly diagnostic spicule morphotypes. They belong to four sponge species, i.e. *Samus anonymus,Triptolemma endolithicum*, *Cliona mucronata*, and *Alectona wallichii*, that have not been noticed in this area so far. The last two of them were previously known only from Indian Ocean, and Japanese and South African waters, respectively. The presence of these species enriches our knowledge of the ecological interactions within the coral reef ecosystem of the studied area. Despite some limitations, the method of spicular analysis proves to be useful as a supplementary tool for the reconstruction of modern shallow-water sponge communities.

CORALLIVOROUS FISH PREY ON PORITES LOBATA AT SOUTH JAVA SEA, INDONESIA (Abstract ID: 29454 | Poster ID: 127)

South Java sea (8o23'48.73" S; 112o31'3.59" E) is directly adjacent with the Indian Ocean that has big waves and strong currents. This condition became main factor that only massive coral can growing well and dominate than other coral life form. Poritiids and Faviids coral were found abundant in this area. One of bio-eroder of coral reef is corallivorous fishes. There are about 128 species of corallivorous fishes from 11 different families. Impact of fish bites in coral were became threat of degradation of living coral cover due to the spread of disease and wound in colonies of coral. We observed the fish bite for 14 months (April 2014 - May 2015) on 4 colonies of Porites lobata. Each colony was divided into three plots, the upper part (A), middle part (T) and bottom part (B), on each plot was divided into 4 sub-plots. Then We recorded all various bites mark in each sub-plot using underwater camera and classified as new bytes, old bites and recovery. The total amount of fish bites was 4,315 for 14 months or 25.7 bites/ month. The highest coral bite was in November 2014, with 409 new bites. The most bites were found on upper part (A) area (1,913 bites), second one on middle part (T) area (1,441 bites) and the fewest on the bottom part (B) area (961). There were three species of fish that prey on Porites lobata i.e. Parrot fish (Scaridae), Trigger fish (Balistidae) and butterfly fish (Chaetodontidae). Parrotfish prefer to eat the algae which was located in the middle part, probably that were many algae attached in this part and naturally parrot fish prey always on schooling

CORAL NITROGEN HETEROTROPHY VS. AUTOTROPHY ON A CENTRAL EQUATORIAL PACIFIC REEF: A NATURAL ABUNDANCE STABLE ISOTOPE APPROACH (Abstract ID: 29818 | Poster ID: 87)

Laboratory coral culture experiments have suggested that the coral symbiotic system is capable of both assimilating dissolved inorganic nitrogen (DIN) from ambient seawater via zooxanthellae (N autotrophy) and acquiring N from heterotrophic feeding (N heterotrophy). However, it remains poorly understood which serves as the primary N source for reefs in different ocean environments. In the central equatorial Pacific, corals experience a natural dynamic range of ambient DIN concentrations modulated by ENSO. It provides a site to study the relative sensitivities of N heterotrophy and autotrophy to corals' N sources, because (1) both DIN and food are available; (2) DIN changes greatly from El Niño to La Niña years; and (3) due to the incomplete surface DIN consumption in the equatorial Pacific, natural abundance 15N/14N ratios (d15N) can be used to distinguish between the autotrophic and heterotrophic N sources. Previous measurements from Jarvis Island (160 W, 0.5 S) have shown nitrate concentrations to be as high as 16 uM (La Niña, 2008) and as low as 3 uM (moderate El Niño, 2010). In our most recent sampling campaign in Nov. 2015, when El Niño strength was at its highest since 1998, we found especially low DIN concentrations in the reef water, <1 uM. We will report d15N measurements of nitrate and nitrite, particulate organic matter and size-fractionated plankton, as well as the d15N of coral tissue and zooxanthellae. These data will be discussed in terms of their implications for the relative importance of N autotrophy and heterotrophy by the corals.

A POLYP FROM NOTHING: THE EXTREME REGENERATION CAPACITY OF THE INVASIVE SUN CORALS *TUBASTRAEA COCCINEA* AND *T. TAGUSENSIS* (Abstract ID: 29393 | Poster ID: 225)

*Tubastraea coccinea* and *T. tagusensis* are within the marine invasive species that most dramatically changed the diversity in shallow-waters along São Paulo coastline. In additional to rapid settlement and growth that facilitate their spread and substrate dominance, some *Tubastraea* spp. polyps at Búzios Island were observed recovering from fragmentation. Moreover, on the sandy substrate below these colonies, small solitary polyps were found. To better understand this regeneration capacity, colonies of both species were fragmented into pieces, and its regeneration ability was tested in terms of food supply (unfed and fed), temperature (24°C, 27°C and 30°C), and fragment size (small - 6.9±1.96 mm² and large - 22.15±9.2 mm²). Within the 240 fragments, 83% fully regenerated into one or more new viable polyps. The minimum fragment size that enabled regeneration was 3.51 mm² and, overall, live tissue retreated around 45% and 51% respectively in *T. tagusensis* and *T. coccinea*, before tissue re-organization into a new polyp. The regeneration was more successful on lower temperature, in unfed larger fragments. However, it was slower if compared to higher temperatures (about 8 days faster in 27-30°C) and the effect of food supply was species specific (faster to *T. coccinea* and *T. tagusensis* can be formed from the regeneration of small skeleton fragments containing tissue, enhancing the chances of survival after injury and adding another mechanism contributing to their invasive success.

INTEGRATING CORAL LARVAE INTO POLICY COMPLIANCE USING BULK PLANKTONIC SAMPLES FOUND PEAK LARVAL DENSITY OF 600 PER CUBIC METER, 9 DAYS AFTER THE FULL MOON (Abstract ID: 29892 | Poster ID: 701)

Environmental policy implementation is confronted with difficult and uncomfortable challenges when dealing with coral larvae. Particularly for species protected by the US Endangered Species Act (ESA). This study presents coral larvae density data collected from plankton tows to predict the potential impacts of entraining a large volume of cool-

ing water at a proposed offshore facility near the Jobos Bay National Estuarine Research Reserve, Puerto Rico. Sampling of coral larvae in pelagic waters has not been widely performed. Our approach used 200 µm mesh plankton tows, targeted the surface and 8 m depth, roughly 40 m3, occurred day and night, and counted larvae while live. Surveys in August, September, and October 2015 captured statistically genuine peaks in larval density for August and September, each lasting about 5 days centered about 9 days after the full moon. Coral larvae density ranged from 446 to 6,532 individuals per 100 m3 during peaks and 0 to 83 ind/100m3 off-peak. Densities in October did not exceed 290 ind/100m3 and planktonic coral larvae were noted in November but not enumerated. There was no statistical difference between day and night samples, and densities at the surface were about 50% less than at depth. Modeling based on the reproductive biomass at nearby reefs suggests that about 9% of these larvae could be ESA Threatened species. This study culminates with leading-edge policy implementation guidance representing close coordination with NMFS and EPA that maximizes opportunities to avoid and minimize impacts to ESA-listed corals at their larval stage.

EXPANDING THE REEF RESTORATION TOOL BOX: DEVELOPMENT OF A NEW INVSIVE ALGAE CONTROL METHOD IN HAWAII (Abstract ID: 29105)

The Nature Conservancy (TNC), along with partners at the Hawaii Division of Aquatic Resources, is actively trying to control the spread of *Eucheuma deniticulum*, an invasive non-native alga currently restricted to Kaneohe Bay. Using a combination of mechanical (i.e., an underwater "vacuum" called the Super Sucker) and hand removal, followed by outplanting of cultured, native sea urchins to control regrowth (the Super Sucker method), *Eucheuma* cover on treated reefs can be reduced to <5% cover. Unfortunately, sea urchin propagation has not keep pace with clearing activities, necessitating the development of a method that does not require sea urchin outplanting to be successful. In response, TNC developed and tested a new *Eucheuma* control method (the 100% Clear) on Koamano, a 0.45 ha patch reef in Kaneohe Bay. For this method, control crews used fine tools to remove all *Eucheuma*fragments from the reef (over 450 kg of algae), theoretically eliminating the need for sea urchin outplanting. After 12 months, *Eucheuma* regrowth on Koamano was negligible compared to control plots where algae regrew to pre-clearance levels in 4-6 months. Permanent photo-quadrats on Koamano documented coral tissue regrowth in "dead areas" following removal of overgrowing *Eucheuma*, conclusively demonstrating positive benefits of algae removal. While time needed to clear the reef was greater for the 100% Clear than the Super Sucker method, time and cost savings were realized during post-clearing maintenance, making the 100% Clear method a viable alternative for invasive algae control.

CONTINENTAL SCALE ESTUARINE WATER QUALITY TRENDS FROM REMOTE SENSING TIME SERIES (Abstract ID: 29034 | Poster ID: 543)

The relationship between reefs and water quality is well studied, and has led to an intensive effort in many places worldwide to mitigate and eliminate both point- and diffuse-source pollution. Monitoring the efficacy of palliative action on water quality can be difficult, and is a significant issue in Australia, since the whole gamut of reef types exist along its extensive and often isolated coastline. Gauging station data has high accuracy and temporal resolution, but the spatial coverage is poor and is often limited to upstream water quality. Water quality data has been successfully derived from satellite data for deeper coastal waters, but has yet to provide consistent information at the coastal interface. There have been many local scale empirical studies looking at individual estuary or reef systems, but as yet there has not been a consistent analysis over large spatial scales (i.e. continental). We demonstrate analysis of water quality trends for all estuaries in Australia defined by OzCoasts (~600) from 1987 to 2015. We obtained time-series stacks of Landsat reflectance for each estuary via Geoscience Australia's *Data Cube* infrastructure, which included data from the TM, ETM+ and OLI sensors. We used simple analytical water quality metrics to explore various trends and hypotheses with smoothing techniques and linear models. Models ranged from simple linear models with a single linear term, to generalised additive models, with both fixed and random effects, including terms to account for seasonality, catchment properties, as well as estuary type, size, and status.

THE EFFECTIVENESS OF MARINE PROTECTED AREAS ON CONSERVING THE FISH POPULATION IN THE GULF OF AQABA, EGYPT. (Abstract ID: 28339)

Fisheries on the Egyptian coast of the Gulf of Aqaba are conducted mainly by the local community (Bedouin). It is a traditional activity where fish are mainly used for subsistence and the surplus consider a source of income. As part of the effort of the Egyptian government to protect the coral reef ecosystem and maintain this traditional activities, a network of three Marine Protected Areas in the Gulf of Aqaba were established. In this study, we investigated the change in diversity, density and size of fish populations (9 families) over 10 years (2002-2012) of conservation efforts in the Gulf of Aqaba. Four regions were studied, with different level of protection and fishing pressure. We found that Nabq decreased significantly in total species by 2012, while Dahab significantly increased in both total species and diversity. Nabq and Ras Mohamed National Park decreased significantly in fish abundance by 51% and 39% respectively while Dahab the least region in fish abundance increased by 75% over time. Size of the target herbivore and carnivore species were significantly decreased over time with Nabq and Dahab having the smallest fish size by the end of our study. Fishing pressure has been increasing in Nabq and affecting the fish population dramatically, due to Dahab fishers and non-compliance by fishing the No Take Zones, even in the Ras Mohamed National Park, fishing occurred causing decline in abundance of target species. Ensuring long term effective law enforcement is critical for the Marine Protected Areas to maintain the fish populations in the Gulf of Aqaba.

ECOLOGICAL DETERMINANTS OF DEPTH RANGES IN CORAL-FEEDING BUTTERFLYFISH: ARE DEEP REEFS A REFUGE? (Abstract ID: 28143)

Declining coral abundance on many reefs globally is altering the composition of coral reef fish communities. Many reef fish species depend on live coral for a range of ecological processes, but coral specialists such as obligate coral feeders are among the most threatened. The most severe declines in coral abundance often occur in shallow water and deeper reefs may therefore provide a refuge for reef fish if they can maintain suitable stable habitat in the face of shallow water reef degradation. However, the ecological factors influencing depth distributions in coral reef fishes are currently poorly understood, and our ability to assess the depth refuge potential has therefore been limited. Here, we analyse how resource use, territorial area, territorial behavior, movement, and body condition of an obligate coral feeding butterflyfish species varies along a depth gradient from 0-40m. We relate patterns in these behaviours to changes in the availability and nutritional quality of food sources along the depth gradient and across time to demonstrate that suitable deep-water habitat can provide a refuge for an obligate coral feeding reef fish in a clear-water, low-latitude reef system.

A NEW WAY OF MEASURING CORAL HEALTH AT LAOLAO BAY, SAIPAN. (Abstract ID: 29860)

Coral reef health in Laolao Bay, Saipan, Commonwealth of the Northern Mariana Islands has deteriorated over the past several decades due to resource over-harvesting, land-based sources of pollution, and climate change. The Bay is most susceptible to effects of land-based sources of pollution, such as sedimentation and polluted runoff. Corals respond physiologically to environmental stress by increasing or decreasing levels of various regulatory proteins or biomarkers. Heat-shock proteins and detoxification enzymes are examples of proteins used by corals to cope with heat or toxicant stress. These molecular biomarkers can be quantified and used by managers to evaluate coral health. Local government agencies have begun to restore the Laolao Bay watershed in hopes of improving coastal water quality and associated coral reef health in Laolao Bay. My research will investigate the change of coral health in response to the Laolao Bay watershed restoration project. Stress-associated biomarkers in the reef coral*Porites lobata* will be quantified from samples collected before and after the restoration project. The results of this study will 1) provide resource managers with key information on the specific stressors affecting the corals studied and 2) provide baseline information for future comparison and for tracking the effectiveness of land-based mitigation measures. Knowing the causal effects of coral stress is important for the "real time" conservation and management of Laolao Bay coral reef ecosystem.

COOPERATIVE PARTNERSHIP FOR CORAL REEF CONSERVATION (Abstract ID: 29807)

The Nature Conservancy and the NOAA Coral Reef Conservation Program recently completed a $10 million six-year partnership to support effective management and protection of coral reefs. The work focused on providing planning, science, and on-the-ground implementation activities in Hawaii, Commonwealth of the Northern Mariana (CNMI), American Samoa, U.S. Virgin Islands, Puerto Rico, and Florida. Successful strategies were further leveraged through global capacity building activities for coral reef managers. This presentation will outline TNC, NOAA and local resource management agency contributions to support this body of work, and will highlight processes for effective collaboration, progress made and lessons learned in the implementation of long-term cooperative agreements to build coral reef management capacity.

FUNCTION-BASED MANAGEMENT OF MULTISPECIES REEF FISHERIES (Abstract ID: 28319)

Coral reef fisheries often include multispecies catches that are rarely well monitored, making traditional fisheries management impractical in many places. Even with some form of fisheries restriction present, it is difficult to set management objectives and evaluate their effectiveness without clear ecosystem targets. I will outline our regional and global approach to solving these problems through multiple large-scale analyses of reef fish biomass. I start by highlighting ecosystem tipping points across gradients of fishable biomass and link these to a function-based approach to fisheries management. I go on to show that while more than 80% of fished reefs have lost more than half their expected reef fish biomass, few coral reef fisheries have collapsed completely, with the majority of fished reefs maintaining important ecosystem functions above biomass levels associated with a predictable series of rapid declines. Encouragingly, the majority of reef fisheries can maintain functionality by adopting one of several management alternatives that support both livelihoods and ecosystems. This large-scale analyses provides an empirical basis for relatively simple fisheries guidelines at the local scale, conditional on factors relating to environmental setting, catch composition, and social context. Where people want to sustain their fisheries and are willing to restrict them in some way, effective multispecies reef fishery management is possible in most jurisdictions.

TOWARDS AN EMPIRICAL DEMONSTRATION THAT HEALTHY REEFS NEED SHARKS: EMERGING POLICY AND MANAGEMENT TOOLS TO SUPPORT THE CASE FOR PROTECTION (Abstract ID: 29100)

A prevailing opinion that coral reefs can be conserved by simply protecting the grazers at lower trophic levels misses the implications of rates of energy flow on reef systems and the resultant mitigating role that reef predators such as sharks play. The relationship between top predators and coral reef health is not obvious. Until recently, scientists did not believe a coral reef could even support a large biomass of top predators because the ecological models came from grasslands with much slower rates of energy turnover. The rates at which the primary producers, sharks, and microbes are growing are the essential paths that link top predators to coral reef health. Unfortunately, compared to standing stocks of sharks and corals, rates are much harder to measure and visualize. From a conservation policy perspective, the lack of a simplified, instructive model that communicates the reality of rates and the invisibility of energy flow creates a major conceptual challenge when trying to convey the importance of sharks to mostly non-scientist policy makers. Meeting this challenge head-on, this presentation describes a pioneering collaboration currently underway between scientists and conservation professionals to bridge the conceptual hurdle of rates and energy flow on reefs through the development of an interactive online visualization tool that demonstrates the role of apex predators as energy sinks and mediators of reef health. We also propose an assessment of jurisdictions most receptive to stronger legislative protection of sharks as a result of this new understanding.

PERSISTING *TERPIOS HOSHINOTA* OUTBREAKS IN INDONESIAN REEFS – PROLIFERATION, INVASION OR TRANSITION? (Abstract ID: 28472 | Poster ID: 72)

Proliferative growth of *Terpios hoshinota* in a coral reef was first reported by Bryan (1973) in Guam, Northern Marianas. Since then, outbreaks of the encrusting and coral-killing sponge have been observed at numerous Western Pacific sub-tropical and tropical locations. Previous studies on *T. hoshinota* have suggested that the sponge is currently widening its geographical range, but that *Terpios* outbreaks may be sporadic and reversible in nature. In Indonesian waters, the so-called black disease sponge has been reported only recently. From 2013 to 2015 we surveyed coral reefs across the Indonesian archipelago for Terpios hoshinota. These surveys revealed that the sponge so far has been severely underreported in Indonesia. Alarmed by these frequent occurrences and their wide geographical range. With our present survey we have shown that under certain circumstances outbreaks may persist over several years. Consistent with previous studies, the sites where we found high abundances of Terpios where characterized by high nutrient levels, high turbidity, and extensive physical destruction to the reef. The numerous discoveries of Terpios in our survey may be interpreted as corroboration of this hypothesis, but may also be explained by the proliferation of a native species or simply by the fact that the sponge has recently been more frequently recognized because it is has received a wider attention. Coral reefs may undergo a phase-shift towards sponge-dominated reefs and a proliferation of Terpios on reefs may be one indication of such a global transition.

THE PULLEY RIDGE INTERACTIVE DECISION SUPPORT RESOURCE (DSR) (Abstract ID: 29536 | Poster ID: 190)

*Connectivity of the Pulley Ridge - South Florida Coral Reef Ecosystem: Process to Decision-Support Tools*, is studying the Pulley Ridge mesophotic coral community in order to better understand its connection to the ecosystems of the Florida Keys National Marine Sanctuary, other ecosystems in Florida, the Gulf of Mexico, Bahamas, and Caribbean region. The results of this study will improve understanding of the physical and ecological processes that affect Pulley Ridge. This improved understanding can then inform decision making regarding management, conservation or protection of Pulley Ridge based on its connections to other communities in the region. As part of this project, the Pulley Ridge Decision Support Resource (DSR) is being developed to provide comprehensive access to scientific data and analyses generated by the project. This publicly available web-based application is written in Java, Javascript, and HTML, and makes use of Apache Solr to provide a rich user interface and rapid search capabilities. Users may search across datasets, view previews and summaries of dataset contents, as well as access and download published data, model output and analyses using text, concept and map-based searches.

A TRAIT-BASED APPROACH TO ADVANCE CORAL REEF SCIENCE (Abstract ID: 28507)

Modern coral reefs are biologically diverse and ecologically complex ecosystems constructed by stony corals. Despite decades of research, basic questions relating to coral population biology and community ecology remain unanswered. Trait-based research can lead to improved understanding and management of ecological systems, which is vital in the current era of rapid environmental change. Here, we first present a database of species- and individual-level information from published field and experimental studies alongside contextual data that provide important milieu for analysis. The Coral Trait Database (https://coraltraits.org) is an open-source clearinghouse that welcomes contributions and improvements from the community. We contend that progress in addressing basic questions in population biology and community ecology has been hampered by a paucity of trait data for many, often rare, species and reliance on non-quantitative approaches. Therefore, we present an approach that focuses on filling data gaps by prioritizing traits that are easy to measure, estimating key traits and vital rates for species with missing data, and identifying "super-traits" that capture a large amount of variation for a broad range of biological, ecological and evolutionary processes. We believe that such approaches will accelerate our understanding of coral biology and ecology, and therefore our ability to protect this critically threatened global ecosystem.

THE ENIGMATIC DIVERSITY OF SCLERACTINIAN-ASSOCIATED HYDROZOANS (Abstract ID: 28337)

Scleractinian reef corals are able to establish intimate associations with several organisms. Recently, hydrozoans have been included into the plethora of coral symbionts. These poorly known hydrozoans belong to the genus *Zanclea* and are strictly associated with their hosts, growing partially embedded by coral tissues. In this work, we evaluated the ecology and the diversity of this symbiosis through the integration of ecological, morphological and molecular approaches. Coral-associated hydrozoans were found in several geographical localities including Indo-Pacific Ocean, Atlantic Ocean and Red Sea and were associated with 29 coral host genera. According to polyps and medusae morphology, three morpho-types were identified. Nevertheless, molecular phylogenetic analyses revealed an unexpectedly high genetic diversity and several divergent molecular clades were identified. The majority of these genetic lineages were host-specific and cryptic since they were not detectable through morphological analyses. We therefore applied DNA taxonomy techniques to our dataset and we identified several independent species. With the exception of one highly generalist species, the other detected cryptic species could be identified integrating morphological characters, host genus and in few cases geographic provenience. Overall, this work suggests that these diminutive hydroids are more widespread and more commonly associated with coral than previously known and that they hide an unexpected cryptic biodiversity.

DOES OCEAN CURRENT CONNECTIVITY PREDICT SIMILARITY OF CORAL COMMUNITY COMPOSITION IN THE INDO-PACIFIC? (Abstract ID: 29354)

The hard coral community composition of reefs in the Indo-Pacific ocean exhibits a pattern of declining richness from the coral triange that appears to be non-random. The actual processes that generate the pattern are not fully understood, but the ability (or lack thereof) of larvae to disperse between reefs via ocean currents may be one of the causes. To bridge this knowledge gap, we test the extent to which coral dispersal driven by ocean currents could contribute to large-scale species distribution and richness patterns at over 10,000 reefs across the Indo-Pacific. Specifically, we test whether community similarity amongst reef clusters is predicted by networks that represent reef connectivity according to (a) geographic distance, (b) environmental similarity, and (c) ocean currents, using a combination of oceanographic modelling, spatial statistics and network analysis. Our results are expected to indicate that similarity in reef community composition is best predicted by ocean currents. This would suggest that ocean currents play an important role in coral biogeography, and that dispersal is a more influential process than environmental filtering for maintaining underlying coral species distributions that have been generated over long time scales.

INTEGRATION OF MULTIPLE CONSERVATION OBJECTIVES IN MARINE PLANNING FOR CORAL REEFS (Abstract ID: 27773)

Decision-makers focus on representing biodiversity, maintaining connectivity, and strengthening resilience to climate warming when designing marine protected area (MPA) networks. However, the development of MPAs intended to achieve these goals might fail if multiple conservation objectives are not adequately formulated from the outset of marine planning. By using Brazilian coral reefs as a case study, we devised conservation objectives for biodiversity, connectivity and resilience to climate warming and we determined the extent to which existing MPAs achieve these objectives. In doing so, we explored interactions between different sets of objectives and evaluated the consequences of pursuing single objectives in marine planning, leaving other objectives to be achieved incidentally. We found that MPAs in Brazil are more effective for biodiversity than for connectivity and resilience to climate warming. Moreover, we identified extensive misalignment between existing MPAs and priority areas that strategically achieve a well-balanced set of objectives. Although better synergies between objectives were found when planning directly for biodiversity, multiple-objective approaches will provide the best opportunities for integrated MPA design. Our analyses reinforce the utility, feasibility, and value of setting multiple conservation objectives, support efforts to expand MPAs for Brazilian coral reefs, and yield insights for planners of coral-reef MPAs elsewhere.

ASSESSMENT OF A BARNACLE BIOERODER AND ITS IMPACT ON A DOMINANT REEF-BUILDING CORAL FROM A HIGH CORAL COVER REEF (Abstract ID: 29765 | Poster ID: 244)

Although multiple studies use density as a proxy for the impact of macrobioeroders on a coral reef, few assess the only genus of thoracican barnacles known to burrow, *Lithotrya*. This study aims to 1) develop a procedure for quantifying *Lithotrya dorsalis* density in colonies of *Orbicella franksi* from photos of coral reef benthos, 2) describe the bioeroder's distribution within populations of this coral, and 3) determine its impact on host colony growth. We used a NOAA dataset spanning 2006-2015 collected from ~40 long-term coral reef photostations at the Flower Garden Banks (Gulf of Mexico). Log-transformed mean barnacle densities in 2014 were similar in the East and West Banks but significantly decreased with increasing colony area and depth, contradicting previous reports that density exhibited no relationship or increased with depth. Based on published modeling efforts, the 2014 size structure of *O. franksi* indicates this coral population experiences minimal disturbance. Ongoing time-series analysis is investigating how bioeroder colonization affects colony growth and population demographics from 2006-2015 photos. In past decades FGBNMS has experienced consistently high coral cover (~50%) and minimal nutrient pollution, in stark contrast to many Caribbean reefs. The methods described in this study can be extended across a spectrum of reef disturbance regimes to better understand how bioeroders impact their hosts.

AN EMPIRICAL STUDY ON IMPACT OF DIVERS AT SIPADAN ISLAND PARK, SEMPORNA, SABAH (Abstract ID: 27970 | Poster ID: 447)

This study are to assess the dive frequency on each dive site based on the presence of iconic fishes, to investigate diver contact on the reef and to evaluate the pre diving briefing by dive operators. A total of 66,243 dives were recorded from 12 established dive sites. Four dive sites location were found to have exceeded their safe limit and the foremost popular dive site is Barracuda Point. Statistical analysis showed a the higher sightings of iconic fishes corresponded with the popular dive sites. However, the rate of sighting record was similar in all months. Diver with Open Water licence recorded the highest percentage of coral contact, followed by Advance Open Water and Rescue and higher skilled licence. No significant difference in coral contact rate by diver for different gender. Divers who dived with a big sized camera recorded highest coral contact rate which were 42.91% (N=49), followed by divers with a small sized camera with a contact of 37.27% (N=224). Diver without having any camera recorded the lowest with only 19.82% (N=590) contact. Divers are also more likely to make contact if the ratio between divemaster and divers are higher. A divemaster who dives with 8 or more divers recorded coral contact of 60.65% (N=513), while the ratio of a divemaster and divers of 5 to 7 people make contact of 49.70% (N=876). For ratio of 4 divers and a divemaster recorded lowest contact with only 45.14% (N=513). Almost all dive operators, especially the larger operators classified as Category I had low scores recorded during the pre-diving briefing evaluation.

DESIGNING FISHERIES MANAGEMENT AREAS FOR PATE ISLAND, LAMU ARCHIPELAGO, KENYA (Abstract ID: 29410)

Fisheries resources in Kenya are facing increasing threats from overfishing and habitat destruction resulting from weak governance system and increasing demand for fisheries resources. The situation is exacerbated by impacts of climate change on marine ecosystems. One key to containing these threats could be fisheries co-management approaches that have been widely adopted internationally in response to the widespread degradation of fisheries resources. Fishing is an important source of livelihood and food security along the Kenyan coast and especially in the northern coast of Lamu. The Kenyan government has provided frameworks within which natural resources including fisheries can be co-managed more sustainably and effectively. In compliance, the fisheries Beach Management Units in Pate Island initiated the process of developing co-management plans for their respective areas. A series of community-led marine managed area planning processes were held since 2014 characterized by robust stakeholders consultations and capacity building sessions. These included input from latest science that helped inform decisions by fishers to ensure proposed rules/zones achieve desired community

benefits. Six different zones were proposed including a multi-use zone, no-take zone, species-specific zone, seasonal closure and gear restriction zone. This paper shares experiences from Pate Island where local communities and partners are taking advantage of the new innovative co-management structures and latest science to design effective fisheries co-management areas.

ONE HUNDRED YEAR OCEAN THERMAL SIGNATURES INFORM CLIMATE RISK AND REFUGE FOR CORAL REEFS (Abstract ID: 29219)

Temperature rise is killing corals and undermining their ability to recover and provide key ecological services. However, there is growing recognition that histories of thermal variability influence ecological responses of corals and other species more than the average climatic change. Here, we deconstruct 100-year historical records of global sea surface temperature time series to derive spatially explicit thermal regimes and evaluate associations with reports of coral bleaching. Our results identified the intensity, frequency, and duration of warm and cool thermal anomalies plus time series entropy as important predictors of coral bleaching. A consensus of 4250 statistical models revealed new locations where corals may find refuge in a warming world – with approximately 100 times more predictive power than Degree Heating Month metric. We conclude that climate impact models and satellite-derived metrics of coral bleaching could be significantly improved with the addition of a long-term climate variability perspective.

HOW ACCESSIBLE ARE CORAL REEFS TO PEOPLE? A GLOBAL ASSESSMENT BASED ON TRAVEL TIME (Abstract ID: 27807 | Poster ID: 532)

The depletion of natural resources has become a major issue in many parts of the world, with the most accessible resources being most at risk. In the terrestrial realm, resource depletion has classically been related to accessibility through road networks. By contrast, in the marine realm, the impact on living resources is often framed into the Malthusian theory of human density around ecosystems. Here, we develop a new framework to estimate the accessibility of global coral reefs using potential travel time from the nearest human settlement or market. We show that 58% of coral reefs are located less than 30min from the nearest human settlement. We use a case study from New Caledonia to demonstrate that travel time from the market is a strong predictor of fish biomass on coral reefs. We also highlight a relative deficit of protection on coral reef areas near people, with disproportional protection on reefs far from people. This suggests that conservation efforts are targeting low-conflict reefs or places that may already be receiving de facto protection due to their isolation. Our global assessment of accessibility in the marine realm is a critical step to better understand the interplay between humans and resources.

THE REEF RESILIENCE NETWORK: CHALLENGES, LESSONS LEARNED, AND CAPACITY BUILDING RECOMMENDATIONS FOR IMPROVED GLOBAL CORAL HEALTH. (Abstract ID: 30084)

Despite contributing to human and economic health in innumerable ways, coral reefs suffer increasing degradation from man-made threats such as pollution, overfishing, and warming oceans. The Reef Resilience Network brings together resource managers, scientists and advisors, and supporting organizations to safeguard naturally resilient reefs and restore reef fisheries worldwide. The Network offers interactive webinars, an online toolkit with case studies and article summaries, a virtual discussion forum, and online and in-person trainings to enhance skills and knowledge of site-based practitioners so they can implement strategies based on the latest science. To help managers and practitioners launch or strengthen conservation education, monitoring, and threat abatement projects, the Network also sometimes provides seed funding and mentorship. This presentation will focus on challenges, lessons learned, and capacity building recommendations for improved global coral health.

COEVOLUTION ADAPTATIONS OF BUTTERFLYFISH TO CORAL ALLELOCHEMICALS (Abstract ID: 28093 | Poster ID: 110)

Butterflyfish have coevolved with corals for millions of years, yet the evolution of this highly specialized coral consuming mode remains poorly understood. Plants and corals are sessile creatures producing allelochemicals to prevent predations. A mechanism to counter adapt and consume allelochemically-rich organism, such as soft coral Sinularia maxima, is through detoxification. Cytochrome P450 monooxygenase (CYP) is the primary enzyme system for detoxification of dietary allelochemicals. CYP2 and 3A have had some associated with butterflyfish that preferentially consumes allelochemically rich soft corals. This research shows butterflyfish CYP3A's involvement in coral allelochemical metabolism. Oral exposure to S. maxima toxin 5-episinuleptolide (5ESL) hard corals specialist Chaetodon multicinctus experienced 100% mortality compared to a generalist, Chaetodon auriga, which had significantly more CYP3A (3-6 fold higher) basal content and catalytic activity. The specialist, Chaetodon unimaculatus, which preferentially feed on S. maxima in Guam, but not in Hawaii, had 100% survival, a significant induction of 8-12 fold CYP3A, and an increased ability (2-fold) to metabolize 5ESL over other species. In vitro incubations with liver microsomes coupled with computer modeling data of CYP3A4 are consistent with the formation of 5ESL epoxide metabolite and correlated with CYP3A content, catalytic activity, induction and NADPH dependent oxidase formation. These results are a starting point for marine ecologists seeking to explain the vast differences in consumer tolerance.

CORAL RESTORATION AND ARTIFICIAL REEFS FOR THE PROTECTION OF VAAN ISLAND, FISHERY PRODUCTION AND CLIMATE ADAPTATION – CASE STUDY FROM GULF OF MANNAR, INDIA (Abstract ID: 29262)

The Vaan Island is one of the 21 islands in Gulf of Mannar and the corals are distributed around the island. This island was the most affected in the last 4 decades because of coral mining. Erosion has been a serious threat to Vaan Island as it is shrinking in size over the years. In 1896 the Island covers an area of 16 hectres and it reduced to 2.5 hectres in 2015. Combination of several factors is responsible for fast erosion. Coral mining around the Island caused instable substratum and the change of current direction during southwest and northeast monsoons also reflects on the Island. The Tamil Nadu State Coastal Zone Management Authority has taken steps in 2015 to protect the island from further erosion. Coral restoration in 3 Km2 degraded area has been successfully conducted following transplantation technique with native coral species. Wave Dynamic and Bathymetry Studies have been conducted to design artificial reef (AR) modules and deployment location. The deployment of AR modules (each 2.5m width, 2m height and 1 m longitudinal length) parallel to Vaan Island in the seaward side of the island has been to reduce the effect of waves and currents commenced. The ARs would not only help to protect the fast eroding Vaan Island, but also enhance fish production for sustained livelihood to artisanal fishers, natural coral recruitment and climate adaptation by increasing fish habitats. The reef areas around the island are shallow predominantly with 0.5-3.0m depth and coral restoration and artificial reef would assist in the conservation of coral and associated biodiversity in particular fish population against climate variation.

GENETICS OF ADAPTATION IN A TEMPERATE SEA ANEMONE: SEARCH FOR SELECTION AMONG ECOLOGICALLY AND MORPHOLOGICALLY DIFFERENTIATED POPULATIONS USING NGS DATA (Abstract ID: 29401)

*Anemonia viridis* is a symbiotic temperate species commonly found from the English Channel to the Mediterranean Sea from shallow water down to 30m deep as well as in lagoons. Five different morphs have been described in this species based on the expression profiles of GFP-like proteins. Two ecologically contrasted populations (shallow vs deep, open sea vs lagoon) were sampled from 5 locations, and individuals from three morphs were sampled in several locations from the English Channel and the Mediterranean Sea. In order to understand the genetic basics of adaptation to differing temperature regimes, we are scanning the genome of over nearly 400 individuals for signature of selection. We looked for Fst outliers from a pool dataset of RAD and 12 EPIC markers. Each EPIC marker targets a different gene whose expression is modified under a temperature stress, as revealed in our lab by a transcriptomic approach (Ganot et al. 2011, Moya et al. 2012). Based on a subset of individuals, preliminary results did not show any clear genetic differentiation among the morphs. Through the analysis of the whole dataset, we will answer the following questions: Is there any genetic differentiation among the morphs of *A. viridis*? Is there any genetic adaptation in this species considering the wide range of habitats it colonizes? And, finally, are stress response genes involved in local adaptation?

FEAR AND FORAGING: REVEALED PREFERENCES OF A CORAL REEF FISH (Abstract ID: 29007)

Top-down and bottom-up processes structuring fish communities are central to coral reef fish ecology and conservation. Many studies have investigated how reef fish populations respond to bottom-up processes over time. However, less is known about top-down controls impacting fish populations. Specifically, predators and the fear of predation may greatly impact the behaviors of prey, their population dynamics, and population sizes. Previous studies interested in top-down effects looked at fish behaviors through tethering experiments. Tethering experiments, widely used to quantify foraging and predation risk, effectively document presence and foraging activity, but cannot quantify foraging costs. With depletable food patches, as shown here, we can quantify costs of foraging experimentally. We quantified risks and rewards of foraging with depletable food patches to quantify spatial and temporal preferences of fishes on patch reefs of Kaneohe Bay, Oahu, Hawaii. Food patches targeted a common benthivorous fish, Thalassoma duperrey. Optimal foraging from experimental food patches was confirmed through prey density experiments, thus validating our methodology. Results revealed on-reef foraging preferences. Early morning foraging was preferred to afternoon, and open, sandy microhabitats were preferred to sites with high rugosity. This study quantifies habitats as safe and risky as revealed through the fishes themselves. Revealed preferences through foraging behaviors can provide managers with internal state of reef inhabitants and quality of the reef from the fishes' point of view.

A FRAMEWORK TOWARDS INTEGRATING REEF FISHERIES MANAGEMENT IN SMALL-SCALE FISHERIES IN THE TROPICS (Abstract ID: 29162)

Coral reef ecosystems provide vital goods and services to millions of people in the world. In the Philippines, where more than 50% of the total population is found along coastal areas, the dependency for these goods and services continues to rise but increasingly exacerbated by high poverty incidence especially among the small scale fishers. Further, the delivery of these goods and services is greatly hampered by the poor current state of many of its coral reefs subjected to various forms of threats such as overfishing, habitat degradation, unregulated coastal development, pollution, and recently vulnerability to climate change impacts. This requires improvement of present management strategies which can be described as weakly implemented, piecemeal and isolated, and data deficient, among others. This paper shows the utility of a conceptual framework previously developed to highlight the integration of biophysical, ecological and social aspects addressing both human (e.g. overfishing) and natural perturbations (e.g. storm surges) towards an informed management decision across varying levels of governance. In this study, the assessment of some fishing communities and their coastal habitats showed varying degrees of suitability, susceptibility, and sensitivity along the ecological-social linkage and, hence, prompts management formulation based on options from corresponding site-specific adaptation strategies.

USING VALUE CHAIN ANALYSIS TO IMPROVE FISHERIES MANAGEMENT IN THE FIJI ISLANDS (Abstract ID: 27836)

Fiji's population is largely coastal and therefore highly reliant on inshore fisheries for their subsistence and livelihoods. However, the commercialization of resources and increased access to markets has resulted in illegal and overharvesting of coastal resources, which is impacting communities' food security, and the biodiversity and resilience of the systems that sustain them. In partnership with the Department of Fisheries, we conducted a value chain analysis (VCA) of the wild caught sea cucumber and mud crab fisheries in Fiji. VCA is a useful tool to understand the relationships between buyers, processors, sellers, and other service providers, to identify opportunities and constraints to industry growth and competitiveness. The study highlighted fisher dependency on fisheries, inequalities in income received by fishers, the role of women, market preferences and demand, as well as the obstacles to value-adding and sustainability. We also documented the socioeconomic costs to communities engaging in dangerous practices like SCUBA to harvest sea cucumbers at increasing depth. By looking at resource value and dependency through the lens of a value and supply chain analysis, we were able to better understand the linkages between fisheries and food systems and identify pathways to conservation, management and policy interventions. We also obtained a wealth of information about two invertebrate fisheries in short period of time, for relatively low costs, making VCA a useful tool in data-poor countries.

ASSESSMENT OF THE RESILIENCE POTENTIAL OF PALK BAY REEF THROUGH KEY INDICATORS (Abstract ID: 28149 | Poster ID: 423)

Palk Bay reef in the southeast coast of India has the ecological foot prints of both climatic and anthropogenic stress leading to their continuous degradation. This study assess the recovery and resilience potential of the Palk Bay reef through key indicators. The diversity, density and overall recruitment rate of juvenile corals was low and it varied spatially along Palk Bay reef. Species diversity of juvenile corals differed from the adult corals indicating reef connectivity. In total, >90% of the juvenile corals survived the bleaching and sedimentation stress. Seasonal bloom of C. racemosa and E. flexuosa reduced the live coral and crustose coralline algal cover by 4% and 8.5% yr-1 respectively. Increased exploitation had kept the standing stock of reef herbivore fishes consistently low and this had further enhanced the colonization of turf algae over corals and other available hard substrates in Palk Bay leading to their degradation. Corals were bleached during summer and returned to their normal state without any post-bleaching mortality despite the increase in the sea surface temperature and photosynthetically active radiation in 2014 compared to 2013. Results suggest that the seasonal macroalgal bloom and reef fishing activities are the major disturbances to the corals in the Palk Bay reef hindering their natural recovery potential. Wide spread prevalence of stress tolerant coral juveniles and their ability to withstand the stress is a positive sign of resilience that will contribute to the coral dominance in the Palk Bay reef despite the prevailing disturbances.

CQUNIVERSITY INDIGENOUS LAND AND SEA EDUCATION PROGRAM (Abstract ID: 28026)

An institution based program has been integrated with an Indigenous approach to foster environmental career development. The Indigenous Land and Sea Education Program (ILSEP) based at the Central Queensland University of Australia focuses on: Recognition of the environment; reduction of pressures and threats; and preparing for success. The program is delivered together with Traditional Owners, on-country, using Indigenous teaching approaches. Students learn to recognise biocultural values and their relevance to their everyday lives through culturally appropriate education, and the program provides support and inspiration to students to pursue their dreams and career aspira-

tions; understand and appreciate their environment; identify mentors and supports; and plan for achieving their goals. Developed by a Dharumbal Traditional Owner from the Rockhampton area in Queensland, Malcolm Mann has accrued experience in management agencies such as the Queensland Parks and Wildlife Service and Great Barrier Reef Marine Park Authority. He has developed and implemented biocultural education programs within the Great Barrier Reef World Heritage Area that aim to promote cultural awareness, a deeper awareness and an appreciation of country through traditional ecological knowledge and western understandings with a collective aim to raise the value of 'looking after country together'. In this talk, Malcom will share his learnings and experiences about bringing together traditional knowledge and education with management agencies to enhance conservation outcomes.

DESIGNING TRANSBOUNDARY MARINE PROTECTED AREA NETWORK BETWEEN THAILAND AND MYANMAR TO BUILD ECOSYSTEM RESILIENCE AND IMPROVE CORAL REEF CONSERVATION (Abstract ID: 29423 | Poster ID: 648)

The Andaman Sea in the Bay of Bengal experienced unprecedented mass coral bleaching with very high mortality rates in 2010. Five year post-bleaching surveys in Thailand revealed that the bleaching impact was differed both at regional and local scales. Some local sites at Mu Ko Surin National Park in Thailand which lied at the border with Myanmar show most remarkable recovery and revealed the importance of protecting the sources of recovery upstream in adjacent Mergui Archipelago. In Thailand, twenty-two indicators were identified through a participatory workshop with local experts to assess coral reef resilience at over 220 survey stations across the region. Long-term quantitative data collected by Phuket Marine Biological Center and semi-quantitative method were also employed to assess and determine resilient reef areas both inside and outside Marine Protected Areas (MPAs). The results helped to identify the priority areas that need to be protected to enhance connectivity and ecosystem resiliency across Andaman Sea in Thailand. This paper suggests the key actions toward applying the same analysis including identifying critical habitats, assessing ecosystem resilience and using simple decision support making tool to develop MPA network in transboundary areas with Myanmar. In addition, this paper also recommends the potential governance platform in which such a transboundary conservation can be implemented through collaborative capacity building program, joint long-term monitoring program and marine spatial planning in Andaman bioregion.

ENVIRONMENTAL AND BIOLOGICAL FACTORS ASSOCIATED WITH CORAL REEF RESILIENCE IN THE FLORIDA KEYS (Abstract ID: 29608)

Coral reef decline in the Florida Keys has been well-publicized, controversial, and polarizing. The Florida Keys have experienced unprecedented warming that has led to seven Keys-wide mass bleaching events since 1987. Not surprisingly, coral cover has plummeted to ≤ 5% on offshore reefs and continues to decline. An exception to this trend are the inshore patch reefs that are located between the islands of the Florida Keys and the offshore reefs. Coral cover on the patch reefs ranges from 15-35%, with some reefs having values > 40%. Coral extension and calcification rates are higher inshore and show marked resilience to both cold and warm-water stress. Although 2014 was the warmest year on record, mortality at Cheeca Rocks, an inshore study site, was low. This inshore-offshore dichotomy in reef health is enigmatic because inshore reefs experience greater thermal variability, increased turbidity, increased sedimentation, elevated nutrients, and are nearer to human populations versus those offshore. Our current research is taking advantage of the 2015 mass bleaching event to determine if this inshore resilience is a result of: 1) Thermal acclimatization/adaptation, 2) Higher turbidity/shading ameliorating bleaching impacts, 3) Increased heterotrophy, owing to turbidity, during bleaching and recovery, 4) Heat-tolerant algal symbionts, and/or, 5) Elevated nearshore pH. This talk will summarize our past and present research in the Florida Keys on climate change, ocean acidification, and the factors associated with the resistance and resilience to these impacts.

WHAT MAKES TEMPERATE CORAL SO ROBUST IN AN ERA OF GLOBAL WARMING? A COMPARATIVE TRANSCRIPTOMIC STUDY BETWEEN SUB-TROPICAL AND TEMPERATE CORALS (Abstract ID: 27825)

Rapid increase in atmospheric CO2 drives global warming and ocean acidification and raises concerns regarding corals that are adapted to a narrow range of pH and temperature. We studied the effect of slow, chronic temperature increase integrated (over a period of 8 months) with low pH values, on a sub-tropical Red Sea coral, Stylophora pistillata, and on a temperate Mediterranean Sea coral Balanophyllia europaea. We utilized Ilumina Hiseq barcoding and further bioinformatic tools to generate and analyze the transcriptomes of S.pistillata and B. europaea. In S. pistillata an elevation of 2 degrees C above control was sufficient enough to change patterns of gene expression. In contrast, it required B. europaea > 9 degrees C to cluster apart from the control. Enrichment analysis showed that processes related to metabolism and energy were enriched in B. europaea at an early stage, yet in S. pistillata, protein degradation and cell death were apparent at the beginning of the experiment. The results imply that there is a synergistic effect between pH and temperature in terms of gene expression and algal photosynthesis yield. Here we demonstrate for the first time a differential gene expression pattern where the temperate coral, that in nature experiences annual temperature fluctuations two fold higher than sub-tropical coral, exhibited a more effective cellular coping mechanism when faced with temperature and pH stress. This strategy might involve diverting cellular resources into massive up-regulation of genes in general and in particular genes that are related to generation of cellular energy.

GLOBAL AND LOCAL IMPACTS ON THE PHYSIOLOGY OF SYMBIONT-BEARING FORAMINIFERS, HYDROCORALS AND CORALS OF BRAZILIAN REEFS: A MESOCOSM APPROACH (Abstract ID: 29329)

Coral reefs are threatened by large-scale stressors (e.g., global warming and ocean acidification) and local impacts (e.g., nutrients and pollutants). We studied symbiont-bearing foraminifers (*Amphistegina gibbosa*), calcareous hydrozoans (*Millepora alcicornis*) and Brazilian endemic corals (*Mussismilia harttii*) exposed to increased temperature (+1 to +4.5°C), acidification (reduction of 0.3 to 0.9 pH units) and copper contamination (1.0 to 6.7 µg $L^{-1}$) of sea water, either isolated or in combination. Experiments lasted for up to 30 days in a mesocosm system. Biomarkers associated with oxidative status (total antioxidant capacity, lipid peroxidation, DNA damage), calcification (calcification rate, carbonic anhydrase and Ca,Mg-ATPase activity), and photosynthesis (Fv/Fm) indicated that acidification and exposure to dissolved copper affected the calcification process. Copper exposure also induced oxidative damage, suggesting an increased susceptibility to bleaching. The effects on calcification and bleaching were potentiated when both stressors were combined. Increasing sea water temperature affected calcification and photosynthesis. Combination of elevated temperature, acidification and copper contamination reduced photosynthesis and increased bleaching and mortality rates. Future scenarios of climate changes combined with local impacts can reduce the resiliency of coral reefs. Calcification and oxidative status biomarkers were adequate tools to assess reef organisms' health and can be effective tools in management strategies.

CORAL SKELETAL LIGHT SCATTERING AND SUSCEPTIBILITY TO THERMAL BLEACHING (Abstract ID: 29452)

Differential coral bleaching has been attributed to a variety of factors and mechanisms; one recent focus has been on light collection capabilities. Multiple scattering of coral skeletons and tissues increase light availability to*Symbiodinium*, forming a very efficient biological collector of solar radiation. As photosynthetic performance of symbionts is often impaired during thermally-induced bleaching, light enhancement may promote a more severe bleaching response. Multiple lines of evidence indicate that light transport in the upper ~200 µm of the skeletal surface ('microscopic' reduced-scattering coefficient, $\mu_s'_m$ = inverse distance a short-path photon travels before randomization) affects light enhancement and bleaching response. Physical models of coral tissues indicate that $\mu_s'_m$ is predictive of the rate of light increase as symbiont densities decrease. The historical record of coral taxon-specific bleaching is correlated with $\mu_s'_m$. The rate and severity of experimentally-induced bleaching of 10 coral species is correlated with $\mu_s'_m$. And mathematical modelling using empirically determined parameters indicate that skeleton-derived light absorbed by symbionts, and its temporal rate of increase during

bleaching, are determined by $\mu_s'_{,m}$. Although the exact mechanism by which $\mu_s'_{,m}$ affects the bleaching response is not fully understood, it is becoming clear that skeletal optical scattering is an important determinant of differential bleaching.

HIDDEN DIVERSITY OF CORAL REPRODUCTIVE AND GENOMIC TRAITS AND THEIR CONSEQUENCES FOR DIVERSIFICATION (Abstract ID: 30103)

To better understand coral evolution and speciation, it is useful to draw on theory and methods from the study of plants. This talk will cover three new findings from Curacao that expand our understanding of coral reproductive strategies and evolutionary mechanisms. First, we'll present evidence for marked differences in genome size between closely-related species in a low-diversity coral family (Meandrinidae). This observation supports the notion that non-ecological genetic mechanisms such as polyploidization or retroelement activity contributed to rapid diversification in this group. Second, we'll present evidence for self-fertilization in a subset of colonies of a broadcast-spawning coral species that is thought to be self-incompatible (*Colpophyllia natans*). This phenomenon could be due to germline mutations in individuals or chimerism in the population, with differing consequences for morphological and genetic diversity. Third, we'll discuss growing evidence for spermcast mating and internal fertilization in coral species that are currently classified as broadcast spawners (e.g., *Dendrogyra cylindrus*). Incorporating this often-overlooked intermediate mating strategy (neither broadcast spawning nor brooding) into models of coral trait evolution could advance our overall understanding of the process of speciation. Together these new observations help to illuminate the variety of mechanisms by which corals create genetic variation and the resulting paths along which coral diversification may proceed.

RECONSTRUCTING CORAL COMMUNITIES THROUGH TIME TO DETERMINE THE EFFECT OF HUMAN INFLUENCE ON THE INSHORE GREAT BARRIER REEF (Abstract ID: 28414)

With human pressure in coastal regions rapidly increasing, chronic anthropogenic stressors are now regarded as an important catalyst in the global demise of coral reef systems. However, understanding the drivers of ecosystem change remains challenging, due to a lack of data preceding shifted ecological baselines. Inshore reefs are inherently vulnerable to the effects of intensifying development in coastal areas, suffering diversity loss, changes in habitat complexity and a reduction in the abundance of reef dwelling biota. Following European settlement (1780-1870) of the Queensland coast, the water quality within the Great Barrier Reef lagoon has declined. Heavily modified river catchments and large areas of land cleared have resulted in high sediment and nutrient-loaded runoff. Using reef matrix cores to extract fossil coral assemblages from the shallow reef slope environment of the Frankland Islands, we reconstruct coral community structure over the past 300 years. We established an ecological baseline of the relative abundance of coral taxa prior to European influence using a highly constrained temporal framework derived from U-series radiometric age dating. Inshore reefs were consistently dominated by hard coral but a substantial ecological change occurred over the past 50 years from a highly diverse to an almost mono-generic hard coral community. The shift in coral community structure occurred under an intensified disturbance regime since 1970 and highlights the importance of a historical perspective in understanding reef response to environmental change

EXPANDING A LOCALLY MANAGED MARINE AREA NETWORK IN EASTERN INDONESIA: DRAWING FROM TRADITIONAL KNOWLEDGE AND MANAGING 'JEALOUSY' (Abstract ID: 29384)

Small-island communities in Eastern Indonesia widely apply traditional marine management methods. Responding to continuing coral degradation, these methods have been integrated with Locally Managed Marine Area (LMMA) approaches and are demonstrating success in developing locally effective regulations, strengthening local institutions, and restoring coral reef resources. The case study explores findings from the Upper and Lower Padaido Islands of Biak, Papua Province. Close collaboration between communities and the Indonesia Locally Managed Marine Area network (I-LMMA) has expanded the coverage of LMMAs from 9,000 hectares around a single island to 190,000 hectares over 21 island-communities. Communities are managing marine environments through village-level regulations that are officially recognized by the government. The growth of local management over a 5-year period is examined, with its expansion from establishment of LMMAs in individual villages to establishment of networks of LMMAs in numerous villages, islands and subdistricts. These networks are pursuing multiple management objectives over large areas including: long-term resilience, biodiversity conservation, ecosystem management, fisheries sustainability and climate change adaptation. Successful expansion hinged on the ability to (i) expand through existing customary networks, (ii) apply the latest marine science guidance in managed areas design (iii) apply effective and adaptive management strategies to address intercommunal 'jealousy', (iv) gain political support, and (v) develop trustworthy collaborations.

CO-MANAGEMENT AND MARKET FORCES DRIVE SIZE OF FISHERIES LANDINGS (Abstract ID: 28659)

Co-management is typically based on agreements between governments and local communities to share the responsibility of resource management. The implementation of community-based co-management for fisheries has been going on in Mozambique since 2003. The first evaluation of the ecological effects of co-management, using the Cabo Delgado province as a case study, is presented here. The existing 78 fishing centers were classified according to their management situation, and the distance to the nearest town. Several diversity metrics were compared for each management level and some effects on community structure and diversity of reported landings detected, specifically in terms of species abundance distribution. The type of management affected the sizes of fish caught, with more active management leading to larger fish. Furthermore, the distance to markets had a strong effect on sizes, with more remote fishing centers having larger individuals, indicating that markets alongside management are a strong driver of the size of fishes caught by artisanal fisheries. Co-management in the north of Mozambique has a positive effect on maintaining larger sizes of fish caught, but markets are a powerful influence and with the predictable development of the region can potentially undermine co-management benefits.

REALISING RESILIENCE: INTEGRATING ECOLOGICAL AND SOCIAL INFORMATION FOR ENLIGHTENED MANAGEMENT OF CORAL REEFS (Abstract ID: 28360)

We need to understand and manage coral reefs as linked social-ecological systems. Yet their complexity and dynamism, combined with our uncertainty about many aspects of their functioning and future, challenges both our governance arrangements and research efforts. Resilience theory has emerged as a framework for accommodating change and uncertainty, and for structuring decisions that incorporate the linkages between biodiversity and people. Operationalising resilience concepts has been an important focus of recent research at the science-policy interface, with valuable progress made in applying ecological resilience ideas. The crucial next goal is to develop frameworks, models and decision-support tools that explicitly connect biodiversity condition with social and economic benefits for coral reef management decisions. We note recent progress, highlight pitfalls and showcase early successes to provide a roadmap for taking social-ecological resilience from theory to operational reality in coral reef management.

THE INTERACTION BETWEEN HERBIVORY AND ALGAL TURF DYNAMICS ON CORAL REEFS: INSIGHTS FROM A SIMULATION MODEL (Abstract ID: 29015)

Herbivory is an important process that helps to maintain the balance between corals and algae on coral reefs. Therefore, it is necessary to better understand the complicated interaction between herbivores and algal dynamics. Here, we investigate whether the field-observed algal turf standing crop biomass can be predicted based on local estimates of fish grazing and observed algal productivity rates. We used a spatially realistic model with daily rates of algal turf growth and fish herbivory in order to explicitly integrate short-term antagonisms in algal turf dynamics. The model was used to predict algal turf biomass in two contrasting reef crest environments (leeward vs windward),

on Heron Island, southern Great Barrier Reef. We tested hypotheses about the rates of grazing intensity and algal productivity in each habitat by comparing observed and modelled algal turf biomass. We further used the model to assess the relative importance of each process driving algal turf biomass on the reef, and the impact of different reef fish families and size classes in maintaining algal turf biomass. Finally, the model was used to simulate the impacts of different fishery-scenarios on algal turf dynamics; highlighting the model as a potential future tool for reef fisheries management. The model provides new insights, and challenges our understanding of the interaction between grazers and algal turf dynamics on coral reefs, enhancing our knowledge of the processes involved in these complicated relationships.

THE WEST HAWAI'I CORAL RECRUITMENT PROJECT (Abstract ID: 28996 | Poster ID: 712)

Maintenance of adequate levels of coral recruitment is vital to sustain coral reefs. Because early life stages are often more susceptible than adults to environmental stressors, data on settlement and recruitment can help predict potential effects of disturbance from, and resilience to, environmental change. The spatial-temporal variability of scleractinian coral recruitment is currently being investigated along the west coast of Hawai'i. Starting in April 2004 to the present, terra cotta coral settlement tiles have been placed at ten sites spanning the leeward side of Hawai'i Island. Eight tiles at each of the nine sites are replaced biannually before and after known seasonal peaks in coral reproduction and recruitment. A new site Acropora Gardens, was added in August 2013, because of the discovery of a species of coral (Acropora gemmifera) never described in the main Hawaiian Islands. Distinctive characteristics in recruitment patterns underline the important role of life history strategies in understanding the spatial-temporal patterns of coral populations. The comparably low coral recruitment rates noted in this study indicate that recovery from natural and/or anthropogenic influences will likely be slow.

A NEW GENUS FOR THE HAWAIIAN CORAL PARASITE PODOCOTYLOIDES STENOMETRA (DIGENEA: OPECOELIDAE) AND A COMPLEX OF NEW SPECIES FROM THE SOUTH PACIFIC (Abstract ID: 27976)

The only trematode known to parasitise corals, *Podocotyloides stenometra*, was first described from off Hawaii in 1966. Since then it has been reported from coral reefs elsewhere in the Indo-Pacific. The larvae of this trematode infect coral polyps, causing the disease *Porites* trematodiasis. The parasite matures in the intestine of corallivorous butterfly-fishes (family Chaetodontidae), which preferentially predate infected polyps. However, the type-species of *Podocotyloides* is known only from *Diagramma pictum*, a haemulid fish that does not feed on corals. We generated comparable sequence data for specimens of *P. stenometra* from Hawaii and a 'true' *Podocotyloides* species from a haemulid of the Great Barrier Reef and found them to be phylogenetically distant. We also generated sequences for specimens collected from chaetodontids of French Polynesian waters and found that *P. stenometra* actually represents a cryptic complex of at least six species. We characterise these new chaetodontid-infecting species and will propose a new genus to accommodate them and *P. stenometra*. The new data allow us to discuss patterns of biodiversity, evolutionary expansion, host-specificity and biogeography for species of the new genus and interpret the evolutionary significance of their unique life-cycles.

GENE EXPRESSION DIFFERENCES IN CARIBBEAN CORALS IN RESPONSE TO NATURALLY ACIDIFIED SUBMARINE SPRINGS: RESULTS FROM A RECIPROCAL TRANSPLANT EXPERIMENT (Abstract ID: 30089 | Poster ID: 22)

Increasing amounts of atmospheric carbon dioxide are acidifying the ocean, causing negative impacts on coral survival and calcification. Previous studies have shown some coral species may be more capable of growing at low aragonite saturation levels than others. To test how corals may acclimate or adapt to low calcium carbonate saturation conditions, we developed a reciprocal transplant experiment at natural, low pH submarine springs in the Yucatán Peninsula (Mexico) next to the Mesoamerican Barrier Reef. Genetically identical nubbins of Siderastrea siderea and Porites astreoides collected in the springs, nearby in the lagoon (control site) and on the fore-reef were reciprocally transplanted into the low pH springs and into the control sites (away from the discharge and not impacted by low pH water). One year after transplantation, 45 corals were sampled and high-throughput RNA sequenced to analyze transcriptome differences. Preliminary analyses reveal significant changes in gene expression due to transplantation (i.e. acclimatization) as well as coral origin (i.e. adaptation). We will present in depth analyses of differential gene expression and gene function among the different locations and species, which may help to better understand the molecular mechanisms of acclimation and adaptation of corals to ocean acidification.

PATTERNS OF CORAL BLEACHING IN THE MAIN HAWAIIAN ISLANDS DURING THE 2015 MASS CORAL BLEACHING EVENT (Abstract ID: 29678 | Poster ID: 357)

In 2015 there were several reports of bleaching across the Hawaiian Archipelago. The Office of National Marine Sanctuaries partnered with the University of Hawai'i Sea Grant College Program and the Hawai'i Department of Aquatic Resources to conduct coral bleaching surveys at the islands of Lāna'i, Maui, and Hawai'i Island aboard a NOAA research vessel. Data was collected using 1 m x 10 m belt transect methodology with an emphasis on coral demographics and bleaching extent and severity. Here we explore trends and patterns of observed coral bleaching across taxa and examine these trends across coral size, morphology, and spatial scales. This survey contains some of the only data at fine scale for coral reefs at Lanai Island and the Kohala area on Hawai'i Island from this 2015 coral bleaching event. Future efforts are needed to monitor the recovery of these integral coral reefs.

IMPACT OF THERMAL STRESS ON GROWTH AND PHOTOSYNTHESIS IN LARVAE AND ADULT STAGES OF PORITES ASTREOIDES (Abstract ID: 27972 | Poster ID: 347)

Coral reefs face a number of environmental changes, chief among them rising temperatures, with consequences that are not entirely understood. A rise in sea surface temperature can affect physiological processes in different ways during each development stage, leading to higher or lower growth rates, or decreased survivorship. Here we determine the impact of thermal stress on photosynthesis and growth in P. astreoides at different developmental stages. Photosynthetic efficiency (Fv/Fm) of adults and larvae were measured using a Diving PAM (Walz). Growth rates of adults were measured using the buoyant weight technique and larval growth rates (planar area) were measured using light microscopy and Image J-Fiji software. The preliminary data for both stages show high values of effective quantum yield (Fv/Fm) when exposed to a temperature of 30°C, which may suggest an ability to acclimate to higher temperatures. With an exposure time of five days however, there was a reduction in effective quantum yield, indicating that in the long term this may be a stressful condition for corals. We see similar responses in growth rates at 30°C for adult and larvae stages. This suggests that P. astreoides is relatively tolerant to high temperatures but that they are dependent on diurnal temperature decreases to avoid a build-up of damage to the photosynthetic machinery.

DIFFERENTIAL REEF FISH RECOVERY IN SELECTED MARINE PROTECTED AREAS IN THE PHILIPPINES AFTER SUPPLEMENTAL MANAGEMENT INTERVENTION (Abstract ID: 28622)

Establishing marine protected areas (MPAs) is a common management intervention utilized to allow for the recovery of fish stocks. To supplement this strategy, RARE Philippines have conducted pride campaigns in selected MPAs in the country. This is a social marketing strategy that aims to elicit community involvement in conservation and enforcement of MPAS. We monitored the performance of selected MPAs prior to and 2-3 years after the introduction of the pride campaigns. Fish visual census was done on transects both inside and outside the MPAs. Despite all having good pride campaigns, the sites showed variable rates of change in fish species richness, abundance, and biomass across a series of monitoring surveys. This may be attributed to differences in the initial standing stock. In some sites the fish communities improved and then became stable, suggesting that the community may have reached a ceiling that is unique to the

site. We also observed changes in the composition of specific trophic groups which warrants further investigation.

SEXUAL REPRODUCTION OF THE ENDANGERED AND ENDEMIC CORAL PORITES SVERDRUPI AND ITS RELATIONSHIP WITH ENVIRONMENTAL FACTORS (Abstract ID: 28530)

Corals around the world are facing threats at both local and global scales. In order to understand how species will face such threats it is necessary to understand the basic biology of these organisms. Sexual reproduction is a determinant process in the life of scleractinians since it ensures the continuity of lineages and increases populations' resilience through genotype diversification. Moreover, the study of coral reproduction is essential to develop successful strategies for coral restoration and conservation. This study is part of Porites sverdrupi's recovery program, an endemic species of the Gulf of California considered a "Vulnerable" species in the IUCN's Red List whose range of distribution has decreased in recent decades probably due to the effects of global change. The purpose of the study was to document P. sverdrupi's gonadal cycle and to relate it with oceanographic variables. This coral is a gonochoric brooding species that produces planuale from June to August, although female gametes can be found throughout the year while male gametes appear from March to October. Planulae were found at temperatures from 29 to 32 °C and at photosynthetically active radiation (PAR) levels above 50 Einstein/m2/day; while mature gametes were found at temperatures above 25 °C and similar PAR levels. The study was partially carried out during a strong ENSO event (2015), which may cause results to not be typical under normal conditions.

BIOGEOCHEMICAL PATTERNS OBSERVED BY AUTONOMOUS SENSORS ON THE REEF TERRACE AT PALMYRA ATOLL (Abstract ID: 29125)

For the past six years we have operated a variety of autonomous sensors at coral reefs in the tropical Pacific Ocean, most frequently at Palmyra Atoll. This presentation will provide an overview of the different technologies used at Palmyra, focusing in particular on a five month dataset of pH, pCO2, oxygen, salinity and temperature on the reef terrace. The hourly observations of reef biogeochemistry reveal the dynamics of the environment experienced by organisms living in this sensitive habitat. In this study we characterize the natural variability in the CO2 system on time scales from hourly to seasonal and discuss the physical vs. biological drivers that give rise to the cycles captured by the sensors. In addition, we examine the relationships between biogeochemical variables including dissolved inorganic carbon, and oxygen, and physical variables including temperature, salinity, density and tidal stage.

CORAL TAKEOVER BY THE ENCRUSTING EXCAVATING CARIBBEAN SPONGE CLIONA TENUIS HAS REACHED A STANDSTILL IN COLOMBIAN CORAL REEFS (Abstract ID: 29785 | Poster ID: 245)

On Caribbean reefs, the excavating sponge *Cliona tenuis* colonized the dead skeletons of the elkhorn coral *Acropora palmata* after its massive die-off in the 1980s. Further coral death occurred through *C. tenuis* lateral growth. To follow up a previous 2001 characterization at Islas del Rosario (Colombia), abundance and size structure of *C. tenuis* were again measured in 2014, along with its substratum preference. The fate of sponge individuals colonizing massive coral colonies marked in 2001-2004 was also followed. Although *C. tenuis* is still disproportionally occupying dead *A. palmata branches*, its abundance and density and the cover of other benthic elements did not significantly changed over the 13-year period, indicating that a standstill had been reached. *Cliona tenuis* was thus initially favored, but substratum monopolization did not occur. Small individuals increased in number and very large ones decreased, indicating that, in addition to new recruitment, larger sponges are fragmented as the *A. palmata* branches where they dwell continually collapse. Marked sponges killed corals over the first few years, but over longer times they retreated or died, and corals were able to resume growth. However, it could not be ascertained whether the sponge retreat was age-related or the result of some environmental effect. The apparent preference for recently dead clean coral by larvae of *C. tenuis* and its current dynamics of recruitment, growth, fragmentation and mortality have stabilized its space occupation at Islas del Rosario.

A BASIC STUDY ON BENDING FRACTURE BEHAVIOR OF *ACROPORA INTERMEDIA* (Abstract ID: 27819 | Poster ID: 236)

It is known that formation of skeleton in branching coral is affected by environmental factors. However, bending strength property of the skeleton in branching coral is not really investigated in the field of biological engineering. In this study, we investigated bending property of *Acropora intermedia* which were kept in Okinawa Churaumi Aquarium from the point of view of mechanical engineering. We conducted 4-point bending test based on "JIS R 1601 standard" which was "Testing method for flexural strength (modulus of rupture) of fine ceramics at room temperature" of Japan Industrial Standard. And we observed internal structure of the skeleton by using the X-ray Computed Tomography technique. The results show the following: (1) The root portion of skeleton show a high bending strength because the density of skeleton is higher than the that of tip portion. (2) The surface side of colony show higher bending strength than the inner side because the porosity density is low.

TEMPORAL EXPRESSION PATTERN OF BIOMINERALIZATION PROTEINS DURING EARLY DEVELOPMENT IN THE STONY CORAL POCILLOPORA DAMICORNIS (Abstract ID: 27829)

Reef-building corals begin as non-calcifying larvae that, upon settling, rapidly begin to accrete skeleton and a protein rich skeletal organic matrix (SOM) that attaches them to the reef. Here, we characterized the temporal expression of a suite of biomineralization genes during three stages of larval development in the reef-building coral Pocillopora damicornis: Stage I - newly released, Stage II - oral-aborally compressed, and Stage III - settled and calcifying spat. The transcriptome analysis revealed 3,882 differentially expressed genes that clustered into distinct patterns across the three developmental stages. Among these, we identified 74 novel acidic proteins (CARPs) that are highly conserved across calcifying cnidarians, but lack detectable homologs in non-calcifying taxa. Immunolocalization supports the direct role of several CARPs in calcification. Our results reveal, for the first time, the developmental sequence that leads to formation of the organic scaffold of corals and the initiation of aragonite precipitation in a stony coral.

INTER- AND INTRA- SPECIFIC VARIATION IN HAWAIIAN CORALS RESPONSE TO ELEVATED SEA SURFACE TEMPERATURES (Abstract ID: 29908 | Poster ID: 359)

Coral bleaching is a natural phenomenon that occurs as a result of increased sea temperatures and solar irradiance. Global climate change has increased the frequency of warm ocean temperatures and bleaching events which often follow such conditions. Unprecedented bleaching events occurred in the Main and Northwestern Hawaiian Islands during the Fall of 2014 and 2015. Hawaiian corals reacted variably with differing levels of recovery and/or mortality spanning across locations and taxa. This project aimed to document the extent of the events in an attempt to understand the variation in bleaching susceptibility for the reefs at Ka'ohao (Lanikai), Oahu. In situ data loggers were used to record seawater temperature from July 2014-December 2015; highest recorded temperatures were 30.8 C and 31.1 C in 2014 and 2015, respectively. Health of 80 individual coral colonies of Porites, Montipora, and Pocillopora was assessed weekly. Mixed effects models were used to compare bleaching and recovery metrics between species, within species, between dates, and the interactions between these factors. Video transects were conducted every other month from September 2014-December 2015 to assess the extent of bleaching by species. Mean percent bleaching (± SE) for all species in September and October, the two warmest months, was 21.0% (± 2.20) and 30.3% (± 2.25) in 2014 and 2015 respectively. Through multiple monitoring methods and this project revealed complex response and recovery patterns of Hawaiian corals to these unprecedented bleaching events.

SUCCESSFUL CORAL RESTORATION VIA FRAGMENT TRANSPLANTATION IN GULF OF MANNAR, INDIA (Abstract ID: 28535 | Poster ID: 488)

The reefs of Gulf of Mannar degraded extensively during the period between 1960 and 2000 due to rampant mining and other destructive activities. To regain the coral cover in the degraded area, coral transplantation (low tech method) was initiated in the Vaan Island during 2004. The fragments of eight native coral species were transplanted on concrete frames (1m X 1m) in approximately 30 m2 area. Transplanted corals were monitored regularly to document survival and growth between 2004 and 2010. 73.26% of the transplanted fragments survived until 2010. Acropora intermedia had the highest average growth with 11.75 cm/year. Coral cover, diversity and recruitment on restored and adjacent natural reef were monitored between 2005 and 2014. Coral cover increased from 30 to 850 m2 in the restored site and significant increase of live coral cover was noted from 5.82±4.38% to 47.37±9.75% between 2005 and 2014. Whereas in the nearby natural reef, an increase in the live coral cover from 7.82±3.85 to 18.23±1.97% was observed. Natural coral recruitment was higher in the restored reef than in the natural reef. Fish abundance increased from 22 to 450 individuals/100 m2 and the reef associates like coralline algae and mollusks were also common in the restored sites. The increase of coral cover in the restored site can be attributed to the successful sexual and asexual reproduction of the transplanted coral colonies. The decadal observation revealed that transplantation with native coral fragments especially with Acropora and Montipora species has been successful in Gulf of Mannar.

TROPICAL FISH ABUNDANCE IS PREDICTED BY HABITAT ACROSS A TROPICAL TO TEMPERATE GRADIENT (Abstract ID: 28964 | Poster ID: 363)

Ocean warming is driving rapid poleward expansion of tropical marine organisms, particularly in areas surrounding poleward flowing ocean currents. Each summer the East Australian Current transports fish larvae from tropical latitudes to temperate coastal and offshore locations. Many coral reef fish larvae rely directly on live corals for settlement and the availability of preferred corals can dictate survival and performance of these fishes. Benthic reef communities differ markedly between tropical, subtropical and temperate latitudes, yet it's unclear how changes in availability of preferred habitats influence distribution, abundance and fitness of tropical fishes. We quantified abundance and composition of reef fishes and benthic assemblages across 17 degrees of latitude on the east coast of Australia, from the northern Great Barrier Reef to Sydney. We present trends on the relationships between habitat type and structural complexity with abundance and diversity of reef fish communities. Species correlated with areas of high coral cover did not extend beyond the Solitary Islands. Conversely, tropical species with more generalist habitat associations did extend to Sydney. These results contribute to understanding range expansion and how tropical reef fishes may utilize refugia at higher latitudes. With global degradation of coral reefs, declines in coral cover and range expansion of tropical fishes, more detailed studies are needed to gain greater insight into implications of range expansion and tropicalisation of temperate reefs.

USING COMPLIMENTARY SAMPLING METHODS TO ADDRESS SIMILAR QUESTIONS: RESOURCE AND HABITAT USE OF SYMPATRIC CORAL TROUT (Abstract ID: 28431)

Understanding the ecological role and associated behaviours of aquatic animals is often difficult because sampling techniques have inherent limitations. The goal of this study was to explore how different sampling approaches (passive acoustic telemetry and dietary proxies) can be used in conjunction to provide a more refined account of fish behaviour. Fifty-eight acoustic receivers were deployed at three reefs to monitor the movements of an economically significant species group – coral trout (*Plectropomus* spp.; n=156 individuals). Additionally, gut content identification (visual and DNA) and stable isotope analysis were completed over a two year period to assess spatial and temporal changes in foraging patterns. By using multiple approaches, we found that broad resource and habitat selection trends differ between sympatric species, but interestingly, the way they differ is unique to each species pairing. For example, at offshore reefs the space use of *P. laevis* overlapped with *P. leopardus*, and they consumed distinct prey; while at inshore reefs, the space use of *P. maculatus* had little overlap with P. leopardus, and they consumed similar prey. This research highlights the need for species-specific management initiatives since *Plectropomus* spp. are often treated as a single stock in the Great Barrier Reef fishery. Further, these findings demonstrate the value of using complimentary sampling approaches to address research questions.

PHYLOGENETIC AND MORPHOLOGICAL ANALYSES REVEAL CRYPTIC SPECIES COMPLEXES IN GLOSSODORIS NUDIBRANCHS (Abstract ID: 28824)

Chromodorid nudibranchs (Opisthobranchia: Nudibranchia) are tropical sea slugs that live in biodiverse and threatened coral reefs and act as early indicators of climate change and reef health. The evolutionary relationships within this family have not been well understood, especially in the genus*Glossodoris*, which has sustained over 100 taxonomic changes in part due to morphological characters being the sole traditional taxonomic identifiers. Advances in molecular systematics have led to a rapid increase in the discovery of cryptic species - species that are classified under the same name, but differ genetically and oftentimes morphologically - in organisms exhibiting diverse and complex coloration with complicated taxonomic histories. *Glossodoris* nudibranchs exhibit a wide range of color patterns from aposematic coloration to camouflage, and are a model group for understanding cryptic diversity. In this study, 80 individuals comprising 38 species were used to build the most robust phylogenetic tree of *Glossodoris*and related genera using mitochondrial genes COI and 16S, and nuclear 28S. Maximum likelihood, Bayesian inference, and Parsimony statistical analyses verified recent taxonomic reclassifications among genera in the Chromodoridae with minor revisions, and identified two cryptic species complexes within *Glossodoris* and three new species of *Doriprismatica*, which were confirmed through specimen dissections and SEM micrographs. Species within the cryptic complexes presented biogeographic and morphological differences. http://gatescorallab.com/shayle-matsuda

PHOTO-PHYSIOLOGY OF IN HOSPITE ZOOXANTHELLAE IN DISEASED AND HEALTHY SCLERACTINIAN CORALS FROM MAURITIUS (Abstract ID: 29620)

The recent increased incidence of coral diseases due to ocean warming is threatening the health of coral reefs. Diseases in reef-building corals are likely to modify the holobiont micro-environment which has a direct impact on the photosynthetic potential of the symbiont. This study investigates the occurrence of coral diseases, namely tissue sloughing (white band disease, WBD) and complete whitening (white plague, WP), among scleractinian corals in the tropical lagoon of Belle Mare Mauritius, and also characterises the photosynthetic responses of *in hospite* zooxanthellae in diseased and healthy corals using an underwater Pulse-Amplitude Modulated Fluorometer. The coral disease occurrence survey (n=20 colonies) and sampling for diseased/ healthy corals were carried out at nine stations along three transects across the lagoon from coast to reef over the summer months of 2013 - 2015. A high percentage (90%) of disease occurrence was observed in the branching *Acropora muricata*, both WBD (45%) and WP (55%), as compared to *Pocillopora damicornis* (10%) with WBD only, *P. eydouxi* (0%), *Galaxea fascicularis* (0%), *A. cytherea* (0%) and *Fungia repanda*(0%). Maximum quantum yield (Fv/Fm) was normal (0.6±0.008) in all healthy corals, but was very low (<0.2) in diseased corals indicating damage to the photosynthetic apparatus. *A. muricata* was the most common host and most susceptible among the corals studied, thus having implications for coral reef management and conservation in the face of a climate-driven ocean warming.

PARTNER SWITCHING AND NUTRITIONAL INTERACTIONS IN A MODEL CORAL-DINOFLAGELLATE SYMBIOSIS: THE APPLICATION OF COMBINED TRANSCRIPTOMIC AND METABOLOMIC ANALYSES (Abstract ID: 28399)

Coral bleaching potentially provides an opportunity for corals to form novel symbioses with algae better suited to the prevailing environment, which could allow for the future

survival of reefs. However their potential success is dependent on functional and sufficient nutritional exchange. Here, we present a novel approach combining gene expression with metabolite profiles to investigate the nutritional potential of various symbiont types when in symbiosis with the model anemone Aiptasia sp. Transcriptomic and metabolomic analyses were carried out, respectively, with next-generation RNA sequencing and gas chromatography mass spectrometry on aposymbiotic Aiptasia, and Aiptasia experimentally infected with either the homologous Symbiodinium type B1 or a thermally tolerant type D1a. Symbiosis establishment was more successful with type B1 (>300%) than type D1a. Correspondingly, our analysis revealed differential expression of metabolic pathways according to symbiotic state (Apo/B1/D1a), allowing us to generate testable hypotheses about the nutritional implications of symbiotic state. We will present a comprehensive gene-to-metabolite perspective of the nutritional significance of partner switching and potential for adaptation to climate change. Integrating transcriptomics and metabolomics as reported here will facilitate more powerful studies of coral physiology and the effects of biotic/abiotic stress on the coral-algal mutualism. A better understanding of these molecular mechanisms will contribute to the development of strategies to promote post-bleaching recovery of corals.

RECONSTRUCTING AND FORECASTING OUTBREAKS OF CROWN-OF-THORNS STARFISH ON THE GREAT BARRIER REEF: SPECIES DISTRIBUTION AND POPULATION MODELLING APPROACHES (Abstract ID: 28267 | Poster ID: 212)

Outbreaks of the coral eating crown-of-thorns starfish (CoTS), Acanthaster planci, have contributed greatly to sustained declines in live coral cover on the Great Barrier Reef (GBR), accounting for 48% of coral loss over the past 30 years. Unlike other disturbances (e.g., cyclones and coral bleaching), CoTS outbreaks may be amenable to direct management, especially if reef-wide outbreaks originate in small, well-defined areas. This study reconstructs reef-wide outbreaks using extensive empirical data on population structure and distribution, to help establish when, where and why outbreaks originate. We define habitat suitability for CoTS using an ensemble Species Distribution Modelling approach coupled with larval connectivity estimates across the GBR, allowing us to identify the probabilistic pathway of the southward propagation of CoTS outbreaks. Higher proportions of suitable habitat and high between-reef connectivity were found in the northern GBR, supporting the hypothesis that this area acts as an "initiation zone" for reef-wide outbreaks. These results will be coupled with a stage-based, spatially explicit meta-population model, allowing us to simulate the initiation and propagation of CoTS outbreaks under a range of management strategies. Our model will provide invaluable predictions for decision makers, identifying the key locations for control measures to help prevent the spread of future outbreaks. These predictions are an integral step towards reducing coral loss caused by CoTS outbreaks, and hence protecting live coral cover on the GBR.

USING GENOMICS TO RECONSTRUCT CORAL POPULATION SIZES OVER THE PAST 100,000 YEARS (Abstract ID: 29553)

One way to understand how corals will react to climate change in the future is to examine how they were affected by similar changes in the past. We have used 2bRAD to generate extensive genome-wide single nucleotide polymorphism (SNP) datasets for Acropora millepora in the Great Barrier Reef and two coral species in Florida Keys, Siderastrea siderea and Montastrea cavernosa, and applied dadi and PopSizeABC methods to reconstruct past population sizes. To scale the results in calendar years we experimentally determined the per-generation mutation rate for Acropora millepora, based on the frequency of novel mutations in larval offspring compared to parents. We detect dramatic changes in coral population associated with the last glacial maximum. Perhaps surprisingly, in the Great Barrier Reef A. millepora appears to have been in decline since the onset of last deglaciation. We hypothesize that these changes are predominantly driven by sea level variation.

MAKAI WATCH: BUILDING A BRIDGE FOR GOVERNMENT ENGAGEMENT WITH COMMUNITY STEWARDS (Abstract ID: 29895 | Poster ID: 563)

In Hawaii, gaps in resources enforcement capacity has prompted the Department of Land and Natural Resources, coastal communities, and NGOs to work together creating a community-based marine resource stewardship program called Makai Watch (MW), with support from NOAA Coral Program. Now more than 10 years evolved, Makai Watch volunteer programs conduct outreach activities and participate in annual awareness raising and observation incident report trainings, providing trained "eyes on the reef" and reports to Div of Enforcement (DOCARE) on illegal marine resources related activities. The state formalized the Makai Watch Strategy (2014), program standards and operating guidelines as an official State program of DLNR- DOCARE. It currently engages officially with 8 communities throughout the state, and less formally with an additional 15. MW communities are estimated to engage with 200,000 beachgoers yearly. With a year into implementation, the program has provided many beneficial lessons learned from the planning and implementation phases to more recent evaluations of the program. Lessons include cross-agency communication and collaboration, increased community engagement opportunities with DOCARE officers, as well as national and international spotlight from communities looking to steward their coastal areas in relationship with resource managers and resources enforcement officers, including in the Caribbean region after a successful cross-basin learning exchange. Next steps include creating Memorandum of Agreements with MW communities and the DLNR-DOCARE.

TOXICOLOGY OF EXPLOSIVE COMPOUNDS TO CORALS (Abstract ID: 29983 | Poster ID: 457)

Military activities in marine environments (i.e., training and demilitarization) have resulted in munitions and unexploded ordnance being located throughout the world's oceans, yet the ecological impacts to marine life from the associated chemical constituents and their breakdown products remains largely unknown. Coral reefs are particularly vulnerable ecosystems found in proximity to many key U.S. military installations in the Caribbean and Pacific Islands. We investigated whether munitions compounds or their breakdown products impact coral and coral health by conducting standard laboratory toxicity testing of nine munitions compounds (TNT, 2,4-DNT, 2,6-DNT, 2,3-DNT, 4-NT, 2-ADNT, RDX, HMX and picric acid) with Pocillopora damicornis coral. NOEC and LOEC values and effect-concentration (LC or EC) values were established using a coral cell toxicity assay. Findings showed all nine munitions compounds had some level of toxicity, differences in coral species' sensitivity to munitions compounds, and photo-enhanced toxicity of certain compounds. The toxicity reference values for corals exposed to munitions compounds will provide metrics for assessing risk of munitions to coral and coral reef health and serve as a basis for establishing screening and action values for management of this vulnerable resource.

PLASTICITY OF HERBIVOROUS FISH FUNCTION IN RESPONSE TO FISHERIES AND WATER QUALITY IN FIJI (Abstract ID: 28601)

Human impacts can interact with ecosystem functions in complex ways, investigation of which necessitates multivariate perspectives. Using underwater visual census and remote cameras, this study identified functionally important herbivorous fishes based on behavioural feeding traits and quantified trait plasticity across different levels of water quality and fishing effort in Fiji. Catch surveys and interviews with fishermen elucidated consistent morphological and aesthetic traits responsible for a fishes' vulnerability to coral reef fisheries throughout the archipelago. Feeding observations illuminated functional plasticity driven by the nature and magnitude of anthropogenic influence where reefs with poor water quality and highest fishing effort exhibited functional niches not occupied by resident herbivore assemblages. Comparing data sets compiled from camera footage and catch surveys provided a novel insight on the impact of fishing and other anthropogenic influences to herbivorous function in the region. Functionally important fishes observed on more pristine reefs were virtually absent from reefs near more heavily fished areas, while some ubiquitous fishes surprisingly occupied narrower functional niches on impacted reefs. High sediment input is likely responsible for niche compression in such areas. The synergy of poor water quality and inshore fisheries' selectivity for key herbivores could lead to undermined reef resilience near densely populated areas.

IN OR OUT: DOES THE EXPANSION OF CORAL POLYPS EXPLAIN HETEROTROPHY VS. AUTOTROPHY IN CARIBBEAN GORGONIANS? (Abstract ID: 28447)

Gorgonian corals (Octocorallia) dominate Caribbean coral reefs, yet knowledge about their metabolic intake is sparse. With suspension feeding they capture a variety of nutri-

ent sources from dissolved organic matter to plankton. They can also obtain products translocated from their endosymbionts, *Symbiodinium* spp. We evaluated heterotrophy vs. autotrophy to the metabolic needs of 6 shallow gorgonian species belonging to the families Plexauridae, Gorgoniidae and Anthothelidae. In the Mexican Yucatan Peninsula, we observed gorgonian polyp activity, polyps contracted or extended, and whether the tentacles were expanded in the extended polyps, over 24 hours. Polyp activity may impact feeding and the light environment thus affecting the *Symbiodinium*. Polyp activity did not correlate with taxonomy. One species expanded its polyps with extended tentacles for all 24 hours, 3 species expanded polyps and tentacles during the day but retracted them at night, and 2 species expanded polyps during the day but not their tentacles, retracting their polyps during the evening. Increased tentacle activity correlated with gorgonians having high lipid and protein content, while species with the least amount of polyp activity had the lowest lipid and protein content. Analyses of $C^{13}$ and $N^{15}$ stable isotopes is ongoing. Understanding gorgonian coral reliance on heterotrophy or autotrophy will aid in deciphering why in the Caribbean gorgonian corals better withstand changing environmental conditions than many scleractinian corals.

MULTI-CRITERIA ESTIMATES OF CORAL REEF FISHERY SUSTAINABILITY (Abstract ID: 28002)

A holistic and scientific basis for achieving ecosystem-based management is needed to counter the continuing degradation of coral reefs. A holistic basis for sustainability is developed that includes information on reported and modeled yields, biomass and ecosystem thresholds, biomass recovery rates, and changes in yield over time. The coral reef fisheries literature reports high variability but this aligns well with high variation reported for biomass recovery and associated logistic model yield predictions. Recovery rate variability can, however, be attributed to a number of factors other than variation in endogenous production, including poor compliance and movement of fish into closures. Nevertheless, high harvest rate variation is more likely due to both temporary and long term harvesting beyond sustainable levels. For a conservative stock of 0.50 pristine biomass (~50 tons/km2), the most controlled recovery studies predicted mean yields of 7 tons/km2/y but high variability ranging from 2 to 13 tons/km2/y. There are few studies of reef fisheries yields over time but Kenyan fisheries studied for >10 years indicate that yields of > 6.9 tons/km2/y were not sustainable. Fish production at low biomass can increase and offset predicted declines in yields but biomass studies in Kenya found a small increase that would be insufficient to avoid declining yields. Ecological change occurs prior to the logistic model's maximum yield predictions, with 3 of 8 abrupt changes occurring before MSY. Knowing fishable biomass is important when predicting sustainable yields and a variety of metrics suggest that it should be maintained above 50 tons/km2 to avoid unsustainable yields.

STRONG SPATIAL SIGNAL OF CORAL LOSS DETECTED FROM 240 YEAR-OLD NAUTICAL CHARTS (Abstract ID: 28008)

Large declines in the cover of live coral have been documented across the Caribbean over the scale of decades. However, analyses based on recent data alone may may miss larger scale changes that took place before modern observations (i.e. the loss of whole reefs). Therefore, creating temporally extended spatially-specific baselines based on historical data is important to quantify the full extent of long-term change. Early nautical charts provide one solution to the issue of lacking spatial data over long time scales; high-resolution nautical charts produced as part of European colonial expansion frequently contain high quality ecological information that can be used to reconstruct spatial change, but remain an underutilized source of information in quantifying long-term ecological change. Here, we use 18th century British nautical charts to quantify spatial changes and overall loss of coral reef habitat in the Florida Keys over 240 years. We find a strong spatial dimension to this decline; coral in Florida Bay and near shore declined substantially, while offshore coral remained largely intact. The near complete elimination of near-shore coral represents an under-appreciated spatial component of the shifting baseline syndrome, with important lessons for other species and ecosystems. In particular, assessments of change focusing only on species' extant range may overlook larger-scale loss over longer time frames and provide overly optimistic views of their current conservation status and underestimate restoration potential.

A MODERN FISH TOOTH REFERENCE COLLECTION TO HELP TRACK HISTORICAL CHANGE IN CARIBBEAN REEF FISH COMMUNITIES FROM TOOTH FOSSILS FOUND IN REEF SEDIMENTS (Abstract ID: 29948 | Poster ID: 4)

Centuries of overfishing along with more recent habitat degradation have altered Caribbean reef fish communities and caused a loss of 50-80% of corals since the 1980s. The lack of an ecological baseline for Caribbean reef ecosystems, including data on reef fish abundance and composition, prevents an understanding of the full extent and causes of the recent Caribbean reef collapse. Fossil records of fish teeth are abundant in reef sediments and can provide a quantitative reconstruction of changes in reef fish communities over periods of both low and high human impact. To track changes in reef fish assemblages and demonstrate the variety of tooth morphotypes found within the ichthyolith record, we have constructed the first fish tooth reference collection for modern Caribbean reef fishes. From 375 specimens amassed from museum collections in the US and fish markets and field collections in Panama, totaling 81 unique families and 256 unique species, we developed a photographic reference collection via dissection and photography of oral and pharyngeal jaws and teeth. The collection, available at http://ichthyolith.ucsd.edu/, highlights the noticeably small tooth sizes of almost all species regardless of body size and diet. This collection has been utilized to classify abundant fossil teeth from reef matrix cores from Caribbean Panama to family level, enabling us to track changes in ecologically important groups such as parrotfish from the prehistorical period to the present.

OPERATIONALISING THE PRECAUTIONARY PRINCIPLE FOR DEALING WITH UNCERTAINTY: THE EFFECTS OF DREDGING ON THE GREAT BARRIER REEF AS A CASE STUDY (Abstract ID: 29920)

Management agencies and policy-makers must make decisions and take action in the face of uncertain and often controversial knowledge, as illustrated by public debate about the effects of dredging on the Great Barrier Reef (GBR). Although the Precautionary Principle is often advocated for such situations, for government agencies it risks being operationally/politically infeasible, amounting to a "disallow everything" until all scientific questions have been definitively answered; this may take decades. Taking an innovative approach to dredging impacts on the GBR, we assembled a panel with a broad range of expertise and perspectives. We then developed an independent, balanced compilation of the full range of expert views. Rather than aiming for a single, definitive "consensus" view on all matters, we took a more pragmatic approach of identifying areas of i. agreed knowledge, ii. agreed knowledge gaps, and ii. areas where the experts don't agree. This allows progress, instead of getting caught in contention and controversy. In this case, many but not all of the experts consider that dredging effects have probably been historically under-estimated. Their main concern was the long-term contributions to fine sediments and turbidity, by ongoing resuspension of dredge material, especially at disposal sites. The direct effects of excavation and burial are severe but have a limited footprint. Our approach provided a timely scientific foundation (of knowledge and uncertainty), contributing to a major shift in policy including banning marine disposal of sediments from capital dredging.

SOUNDS LIKE TROUBLE: ANTHROPOGENIC SOUND IMPACTS REEF FISH DYNAMICS (Abstract ID: 27818)

Anthropogenic noise may have detrimental effects on the ecology, physiology and behaviour of organisms, but the impacts of noise pollution on survivorship are not clear. We use juvenile coral reef fishes to examine the impact of outboard motorboat noise on predator-prey interactions. Our previous studies have shown that boat noise from 2-stroke 30hp engines affect survival of juveniles through physiological stress and a diminished startle response, leading to higher levels of predation. Here we show using a field experiment that real boat noise alone does not have a detrimental effect on fish to alter their survival. Boat noise did alter the way fish use the cues that indicate predation risk. Laboratory exposure to boat noise playback prevented juvenile damselfish from learning the identity of 3 common predators, such that they died 3x faster in the field compared to fish who learnt predator identity under ambient reef sound. Field experiments also showed that the behaviour of juveniles exposed to continuous real boat noise returned to a pre-exposure state after 20min. This may be due to damage of the acoustic sensory apparatus or habituation. While juvenile damselfish may have the ability to habituate to noise the detrimental short-term effects of boat noise through distraction

and physiological stress appear to dramatically influence mortality levels. This suggests boat noise has the potential to markedly alter population replenishment and community dynamics in busy waterways.

ESTIMATING NEARSHORE FISHERIES CATCH FOR THE MAIN HAWAIIAN ISLANDS (Abstract ID: 28770)

Nearshore fisheries in the main Hawaiian Islands (MHI) have great economic, recreational, and cultural value. Currently, information on these fisheries is disparate and incomplete, creating a challenge for effective management. This study combines and synthesizes several commercial and small-scale non-commercial datasets to estimate the total catch of nearshore fisheries in the MHI. Data used came from catch reports submitted by commercial fishers, a statewide recreational fisheries survey, and 12 small-scale, non-commercial creel surveys conducted at sites in Kauai, Oahu, Lanai, Maui, and Hawaii. Results include an estimated range for total nearshore catch between 1,441,407 and 7,739,548 kg/yr., with the non-commercial catch between 9 and 53 times the reported commercial reef fish catch. Additionally this study provides a comprehensive overview of the MHI nearshore fishery, including best-available estimates of fishery data such as catch-per-unit-effort (CPUE), gear-preference and participation rates, with data broken out at island-scale. This is likely more appropriate for management purposes than the statewide level at which nearshore catch data is currently reported in the MHI.

HOW CORALS CONTROL CALCIFICATION IN A HIGH $CO_2$ WORLD (Abstract ID: 28616)

Scleractinian corals have been spectacularly successful in building the calcium carbonate coral-reef edifices that harbour a significant part of the oceans biodiversity. Their success can largely be attributed to their ability to biologically mediate the composition of their calcifying-fluid and thereby increase the carbonate saturation state (Ω) to enhance the kinetics of calcification. Manipulation of calcifying-fluid composition is thought to occur via Ca-ATPase controlled up-regulation of pH and replenishment of DIC by still poorly understood transport mechanisms. We have undertaken a global survey of both zooxanthellate and azooxanthellate corals across tropical and cold-water environments. Boron isotopic and elemental systematics from their carbonate skeletons have been used to determine calcifying-fluid pH, DIC and hence the Ω required to sustain biomineralisation across these diverse environments. We find that zooxanthellate bearing reef-building corals all have elevated pH (+0.3 to +0.5) above ambient seawater with the azooxanthellate tropical coral *Tubastrea*exhibiting even higher pH up-regulation (+0.5 to +0.6 pH units), similar to that found in azooxanthellate cold-water corals. The DIC characteristics are found to be systematically enriched (x1.5 to x2) relative to seawater which together with higher pH gives significantly elevated Ω (14 to 20). Thus combined up-regulation of pH, DIC and hence Ω in the calcifying fluid is a ubiquitous feature of aragonitic corals and crucial to their ability to calcify in a high $CO_2$ World.

BENTHIC FORAMINIFERA AND CORALS AS INDICATORS OF WATER QUALITY IN WAR IN THE PACIFIC NATIONAL HISTORICAL PARK, GUAM, USA (Abstract ID: 28718)

Land-based sources of pollution threaten coral reefs, particularly in areas where streams from poorly managed watersheds drain onto reefs. In Guam, two such reef areas occur within War in the Pacific National Historical Park (WAPA). Since 2008, annual benthic cover surveys have been conducted to monitor the state of coral reefs within WAPA. Surface sediment samples were also collected at the monitoring sites on 2 to 3 occasions, and foraminifera in the samples were identified to calculate relative species abundances and FoRAM index (FI) values. Here, the benthic cover and foraminiferal datasets are combined to provide insight on short and long-term effects of water quality on the reefs at WAPA. Coral cover across the park is low in most areas, and distribution is not clearly related to the water quality gradient due to confounding stressors and historic catastrophic events. Coral cover has remained stable since 2008. However, changes in the foraminiferal community are evident across the water quality gradient. Relative abundance of symbiont-bearing foraminiferal species, most notably Amphistegina spp., and FI values are significantly related to water quality ($p<0.05$). FI values ranged from 5 near stream outputs to 9 at uninfluenced areas, and FI values declined at sites that were resampled across years. The shorter life span of foraminifera causes the communities to respond more rapidly to changes in water quality. Therefore, by paring coral and foraminifera monitoring, valuable information can be gained on short and long-term changes in water quality conditions in Guam.

THE UNSEEN WORLD OF CORAL REEFS: BIODIVERSITY OF, AND HUMAN IMPACTS ON, THE CORAL MICROBIOME (Abstract ID: 29661)

Recent studies have revealed that the composition of diverse and abundant reef-associated microbial communities may influence coral resistance to local and global stressors currently threatening reefs worldwide. Combining benthic surveys, environmental data and 16S rRNA gene sequencing of*Montipora foliosa*, *Porites lobata* and overlaying reef water, this research evaluates the relationship between reef-associated bacterial communities and coral resistance by monitoring these bacterial communities before and during a thermal stress event at the island of Kiritimati, the world's largest atoll. Kiritimati is an ideal study site because it spans a large gradient of human disturbance (i.e. fishing pressure and nutrient runoff), with reefs highly degraded near the villages and becoming near pristine at remote sites. We evaluate 1) how bacterial community structure is related to individual coral colonies and overall coral community structure; and 2) how these relationships are influenced by human disturbance and a thermal stress event. We have data from 143 coral and water samples, focusing on two highly disturbed and two near-pristine sites. By quantifying coral reef microbial community composition and variability across ecosystem components, coral species, a temporal scale and a gradient of human disturbance, my research will provide new insights into microbial community ecology and the role of microbes in reef resistance to disturbance.

DESIGNING AND FINANCING OPTIMAL ENFORCEMENT FOR SMALL-SCALE FISHERIES AND DIVE TOURISM INDUSTRIES (Abstract ID: 29740 | Poster ID: 562)

Effective enforcement can reduce the impacts of illegal, unregulated, and unreported (IUU) fishing, resulting in numerous economic, ecological, and social benefits. However, resource managers in small-scale fisheries often lack the expertise and financial resources required to design and implement an effective enforcement system. Here, a bio-economic model is developed to investigate optimal levels of fishery enforcement and financing mechanisms available to recover costs of enforcement. The model is parameterized to represent a small-scale Caribbean lobster fishery, and optimal fishery enforcement levels for three different stakeholder archetypes are considered: 1) a fishing industry only; 2) a dive tourism industry only; and 3) fishing and dive tourism industries. For the illustrative small-scale fishery presented, the optimal level of fishery enforcement decreases with increasing levels of biomass, and is higher when a dive tourism industry is present. Results also indicate that costs of fisheries enforcement can be recovered through a suite of financing mechanisms. However, the time-scale over which financing becomes sustainable will depend largely on the current status of the fishery resource. This study may serve as a framework that can be used by resource managers to help design and finance economically optimal fisheries enforcement systems.

MONITORING AND REPORTING ON REEF HEALTH AND MANAGEMENT IN THE MESOAMERICAN REEF (Abstract ID: 29806)

The Healthy Reefs for Healthy People Initiative (HRI) is a collaboration of 65 partner organizations working to conserve the Mesoamerican Reef. HRI conducts biennial training courses and leads reef monitoring expeditions. There is an open access database

and annual meeting to discuss conservation priorities and issues within the region. Data are used by partners for local management purposes and by HRI to produce popular user-friendly Report Cards on the health of the reef. These reports are used by a variety of stakeholders from top political officials to fishermen. They include reef management recommendations which are evaluated for their degree of implementation in national level and Eco-Audits.The 2015 Report Card surveyed 248 sites finding most reefs remain in poor (40%) or fair (34%) condition. The number in critical condition (17%) declined while the amount in good or very good remains 9%. Coral cover improved since 2006, increasing from 10%-16% cover; although fleshy macroalgae also increased. Key herbivorous fish continue to increase in numbers, and have been fully protected in most of the region. Commercial fish have increased in biomass, although large groupers are rare outside of the fully protected zones of marine reserves.The 2016 Eco-Audit measured increased implementation of management actions, with improvements in 27 recommended management actions. This adaptive management framework allows for collaborative monitoring and management at a variety of spatial scales and has become a valuable tool for catalyzing public awareness and reef management actions.

IN SITU METABOLISM, SOLAR HEATING, AND CONVECTIVE COOLING OF CORALS IN REEF ENVIRONMENTS (Abstract ID: 30002)

Incident bottom solar radiation is a source of significant heat energy to the benthos that must be either dissipated or stored. The dissipation and storage of this radiative heat has been shown to be a function of coral radiative properties, coral physical properties, and bottom mixing. Since coral surfaces heat and cool when there are changes in water temperature, coral substrate temperatures require time to thermally acclimatize. We used BEAMS (Benthic Ecosystem Acidification and Metabolism System) boundary layer measurements to quantify metabolism and measure both the radiative forcing (> 100 W/m2) and convective heating/cooling of corals at Palmyra Atoll (Line Islands) and Panama/Galapagos (eastern tropical Pacific) in 2014. This allowed us to investigate, for the first time, the diurnal cycle of metabolism and heat exchange and their potential impacts on coral reef systems. Since temperature is a critical control on the metabolism and bleaching response of corals, interactions between these physical parameters can have significant implications for coral health.

INTEGRATING TELEMETRY-DERIVED DATA INTO SPATIAL DECISION-MAKING AND PRIORITIZATION FRAMEWORKS (Abstract ID: 29086)

Spatial planning strategies for conserving mobile marine species primarily focus on the protection of nesting or breeding sites and predictable coastal foraging habitats. Yet, conservation of these areas alone does not protect the migratory life stages, where many threatened mobile species continue to face population declines and mortality at sea. Although some protection of pelagic and key foraging habitats occurs incidentally, most pelagic pathways where species experience incidental mortality from artisanal fishing, commercial bycatch or targeted consumption remain exposed. We address this conservation deficiency by developing novel, quantative methods to incorporate telemetry and tracking data into conservation planning approaches. Our case studies illustrate how conservation planners can translate spatiotemporal variability in individuals movements into quantitative spatial planning objectives for highly mobile marine species. We investigate optimal spatial management strategies for pelagic protected areas (static/seasonal closures and gear modification zones) that minimize the probability of mobile species bycatch occuring across all taxa. Combining individual movement data with at sea threats from artisanal and commercial fishing, we identify areas and conservation actions that reduce the likelihoods of mortality from anthropogenic pressures.

FUNCTIONAL SIGNIFICANCE OF SYMBIONT DIVERSITY WITHIN A CORAL-ALGAL ASSOCIATION (Abstract ID: 29449)

Research on various host-symbiont study systems has now recognized the importance of the diversity and organization of symbiotic species to mutualism function. The octocoral Briareum asbestinum, benefits from associations with endosymbiotic algae of the genus Symbiodinium for nutrient acquisition on oligotrophic reefs. Using stable isotope tracers of H13CO3- and 15NO3- we examined the nutritional quality of single species and mixed species symbiont assemblages. We found that the relative abundance of two species of symbionts in B. asbestinum, Symbiodinium A1 and B1 significantly influenced the acquisition rate of carbon and nitrogen by the symbionts and the translocation of those nutrients to the host. Our results demonstrated physiological differences between symbiont species with some evidence of competitive interactions among symbionts and/or host regulation of nutrient supply within mixed species Symbiodinium assemblages. However, complex ecological interactions among symbionts and between the host and symbionts were difficult to tease apart.

ASSESSING RELATIVE RESILIENCE POTENTIAL OF CORAL REEFS TO INFORM MANAGEMENT (Abstract ID: 27911)

Ecological resilience assessments are an important part of resilience-based management (RBM) and can help prioritize and target management actions. Use of such assessments has been limited due to a lack of clear guidance on the assessment process. We provide that guidance from a resilience assessment undertaken in the Commonwealth of the Northern Mariana Islands (CNMI). We assessed spatial variation in ecological resilience potential at 78 forereef sites near the populated islands of the CNMI: Saipan, Tinian/Aguijan, and Rota. The assessment was based on measuring indicators of resilience processes and was combined with information on anthropogenic stress and larval connectivity. We found great spatial variation in relative resilience potential with many high resilience sites near Saipan (5 of 7) and low resilience sites near Rota (7 of 9). Criteria were developed to identify priority sites for six types of management actions (e.g., conservation, land-based sources of pollution reduction, and fishery management and enforcement) and 51 of the 78 sites met at least one of the sets of criteria. The connectivity simulations developed indicate Tinian/Aguijan are each roughly 10x the larvae source that Rota is and twice as frequent a destination. These results may explain the lower relative resilience potential of Rota reefs and indicates actions in Saipan and Tinian/Aguijan will be important to maintaining supply of larvae. The process we describe for undertaking resilience assessments can be tailored for use in coral reef areas globally and applied to other ecosystems.

ESTABLISHING INDICATORS FOR A REPORT CARD IN A COMPLEX MARINE ECOSYSTEM. (Abstract ID: 27804)

Marine environmental report cards are an increasingly popular tool to communicate scientific results to stakeholders and communities. The challenge in developing a report card for complex marine habitats where changes in abundance, cover, distribution and

species can occur is establishing appropriate indicators to evaluate habitat condition. We developed an innovative approach for reporting on the condition of seagrasses as part of a broader report card on the environmental, social, cultural and economic health of one of Australia's largest multi-commodity ports located in the Great Barrier Reef World Heritage Area. The process used expert opinion to determine the best indicators of seagrass condition (above-ground biomass, meadow area, species composition), trialled four approaches to determine a baseline condition of each indicator, and defined five condition categories (very good - very poor) to grade each seagrass meadow relative to a baseline. Threshold levels for each condition category were determined based on the historical variability of each indicator in a meadow. The report card approach allowed for the presentation of a large amount of spatial information, including the location, condition, and the reason for each meadow's grade to be presented within a single map. This allowed not only for rapid comparison of seagrass condition across the range of meadows within the port, but also at a broader regional scale.

SURVEY OF HAWAIIAN CORAL PHYSIOLOGY ACROSS A NATURAL RANGE OF TEMPERATURE AND PH GRADIENTS (Abstract ID: 29723 | Poster ID: 405)

Coral reefs worldwide are threatened due to ocean acidification and increasing seawater temperatures, yet the potential for coral to adapt or acclimatize to global change is poorly understood. Kaneohe Bay, Oahu, Hawaii, is an unusual reef location in that it currently experiences temperatures and $pCO_2$ concentrations not expected to occur on most Hawaiian reefs for another 30-50 years. We hypothesize that coral located in this reef have adapted to the above average conditions, and possess certain physiological and biogeochemical traits that facilitate this resilience. Four of the most dominant coral species (*Montipora capitata, Porites compressa, Porites lobata* and *Pocillopora meandrina*) from across the Hawaiian archipelago were surveyed from various different locations. These locations span the natural physical gradient in coral species distribution in Hawaii, and exhibit seasonal pH and temperature profiles that span conditions representative of today, through those predicted for 2050. We analyzed chlorophyll a concentration and tissue biomass in each species from each site. Preliminary results show that *M. capitata* varies between sites, whereas *P. compressa* does not. Further research is being conducted to determine if there is a link between variation in other physiological traits (lipid, protein and carbohydrate content) and variation in physical regimes among sites. These findings will further our understanding of which traits underlie coral resilience and/or adaptation capacity to future ocean condition on coral reefs.

LINKING PATTERNS AND PROCESSES WITH SHIFTING BASELINES ON CORAL REEFS (Abstract ID: 27969)

Understanding how and why coral-reefs have changed in the last twenty to thirty years is crucial to sustaining coral-reef resilience. This is especially relevant for small-island nations that depend heavily on their marine resources, such as Kosrae, Federated States of Micronesia. We used a unique historical baseline to examine how Kosrae's coral and fish assemblages have shifted since 1986, and identify potential drivers of change. Key findings were that natural gradients in both fish and coral assemblages with wave exposure and watersheds have become amplified over that past three decades, as species are now more geographically restricted and metapopulation connectivity is reduced. Fishing access best predicted declining fish assemblage condition through time, and in turn, declining fish assemblages were correlated with negative changes to coral assemblages. This was especially pronounced on the leeward side of the island. A pollution proxy was further identified as a predictor of coral assemblage condition, but only in the modern time frame, and only in a few densely populated watersheds. Because large-scale disturbances have been minimal in Kosrae, declining coral condition was likely caused by the accumulation of small-scale disturbances through time, whereby compromised ecosystem resilience would have impeded coral recovery. Improving reef health on small islands like Kosrae will require prioritized management policies focused on local stressors, like over-fishing, that damage ecological resilience.

FORTY YEARS ON: THE SCIENTIFIC LEGACY OF THE 1973 'STODDART EXPEDITION' TO THE NORTHERN GREAT BARRIER REEF. (Abstract ID: 28413)

The work of the 1973 Royal Society and Universities of Queensland Expedition lead by David Stoddart shed new light on the history and morphological development of the northern Great Barrier Reef system. Evidence from shallow coring, surface geomorphology, lithology of exposed limestone rocks, superficial sediment accumulations, vegetation patterns and the historical record of sea level derived from radiometric dating suggested a sequence of reef and island development in Holocene times. An assessment of the results of the expedition over forty years on reveals some of the conclusions made subtle incremental advances to our comparative knowledge of reefs and reef islands as well as providing a robust launch-pad for others. But the tightly constrained Holocene sea level history provided the strongest demonstration to date that there were regional differences in sea level and not just one global eustatic story; that has been the expeditions most lasting legacy.

CHALLENGES AND GUIDANCE INTEGRATING CLIMATE CHANGE INTO CORAL REEF PLANNING AND MANAGEMENT (Abstract ID: 28890)

Coral reef ecosystems, including the communities that depend upon them, are particularly vulnerable to climate change. However, reef managers and conservation planners face a number of challenges integrating potential climate change impacts into their conservation strategies. They may lack access to climate model data, or the data may be too coarse for site-based planning. Uncertainties in climate data and outputs make it challenging to interpret and apply in conservation decisions. Guidance is needed on how to identify the most appropriate tools and outputs for assessing climate impacts, and how to apply climate projection data to decision support frameworks including how to weight these data alongside other social and ecological factors. This session will outline these challenges and explore how they are being addressed through the Reef Resilience Network. The Network provides reef managers and practitioners with access to the latest science and management tools, strategies, and recommendations to incorporate climate change and others stressors into coral reef planning and management. A web-based toolkit includes an overview of climate stressors and projections, guidance for managing such stressors including case studies, and best practices addressing social and ecological resilience.

ONTOGENETIC MIGRATION OF SNAPPER LINKS FOOD WEBS ACROSS A TROPICAL SEASCAPE IN THE RED SEA. (Abstract ID: 29649)

Many socio-ecologically important coral reef fishes undergo impressive ontogenetic migrations across tropical seascapes, linking distant habitats, populations, and food webs. We examined ontogenetic migration patterns of Ehrenberg's Snapper (*Lutjanus ehrenbergii*) populations on coastal and oceanic coral reefs in the Red Sea using a new otolith-based compound-specific stable isotope method. We then applied a new amino acid isotope fingerprinting approach within a Bayesian mixing model framework to identify the sources of primary producers (phytoplankton, coral, macroalgae, seagrass, and mangroves) fueling the local snapper populations during different stages of their ontogenetic migration. We found that seascape configuration played a critical role in determining migratory connectivity of *L. ehrenbergii* among essential habitats. We also found that *L. ehrenbergii* occupied fundamentally different resource niches associated with different phases of their ontogenetic migration. For instance, adult *L. ehrenbergii* on shelf reefs often relied heavily on a seagrass-based food web as juveniles before switching to a macroalgal-based food web once they migrated out to the adult population on shelf reefs. Conversely, adult *L. ehrenbergii* on offshore oceanic reefs typically showed minimal ontogenetic change in either habitat or baseline carbon source, relying heavily on a water column phytoplankton-based food web throughout their lives. Our work provides insights into the roles that ontogenetic migration plays in linking essential habitats and food webs across tropical seascapes.

RECENT DAMAGE TO OFFSHORE CORAL REEFS IN THE SOUTH CHINA SEA: QUANTIFICATION, IMPLICATIONS AND POTENTIAL SOLUTIONS (Abstract ID: 28225)

The offshore reefs of the South China Sea may be important in preventing extirpation of overharvested species throughout the region. Overlapping jurisdictional claims by bordering nations have led to actions, including military base construction, intended to support these claims. This has resulted in unprecedented rates of essentially permanent coral reef decline due to island building and reinforcement. Channel and harbor dredging has permanently altered important reef processes. Additionally, the widespread dredging of materials for the island construction activities has led to damage of decadal or

longer time scales. The total area damaged, in conjunction with the growing levels of over-harvesting, may be enough to substantially impact regional fisheries production and destabilize populations of many species. Consequent hardships may lead to more pressure to strengthen claims, resulting in an intensifying spiral of ecological degradation and political tension. A potential means to halt this spiral is to institute a renewable multilateral treaty consisting of a freeze on claims, a freeze on claim-supportive activities, and a joint plan for resource management. One embodiment of such as plan would be a Greater Spratly Islands Peace Park.

LARVAL DISPERSAL AS A MECHANISM FOR CORAL PERSISTENCE ON REEF COMMUNITIES (Abstract ID: 29852)

Connectivity through larval dispersal is thought to be a major determinant of coral persistence, especially in terms of the recovery potential for populations that suffer catastrophic mass bleaching events. However, our understanding of the interactions between coral recruitment and mortality on reefs is limited, particularly when reproduction occurs in a discrete, seasonal manner as in most stony coral species in the Indo-Pacific. Here, we model coral-algal competition on a reef patch, accounting for larval input from within the patch and an external source. We incorporate coral recruitment in two ways, with larvae arriving either seasonally or continuously through time. Our goals were to (1) determine the conditions under which connectivity can offset the effects of higher mortality due to bleaching and (2) evaluate the impact of recruitment and mortality on the stability of coral- vs. algal-dominated regimes. In general, incorporating coral recruitment, even seasonally, erodes the basin of attraction associated with algal-dominated states. This allows coral to persist in a parameter space that, without larval input, would lead to algal dominance. When coral cover is low, there exists a threshold number of arriving larvae to a patch that will stimulate coral recovery; this threshold depends on the initial algal cover. If algal cover is beyond a critical level, however, no amount of larval input can induce a shift to coral dominance. In this case, there is an increase in the importance of within-patch processes in setting the trajectory towards a particular reef state.

SEARCHING FOR CODIVERGENCE AMONG CORALS AND BACTERIA WITH THE GLOBAL CORAL MICROBIOME PROJECT (Abstract ID: 28101)

It has been previously demonstrated that microbial communities associated with coral animals display patterns of host species-specificity. We hypothesized that important members of the coral microbiome have codiversified with their hosts, that these members can be detected among a large community of associates, and that the degree of their codivergence will vary among coral groups depending on certain life-history traits such as reproductive method. As part of the Global Coral Microbiome Project (GCMP), we have systematically sampled more than 1500 healthy individuals from ~130 species of corals in ~20 Scleractinian families, plus anthozoan and hydrozoan 'outgroups', and abiotic controls. We have separately extracted DNA from the mucus, tissue, and skeleton of each of these samples, and have used high-throughput sequencing of the 16S marker gene to assess bacterial community composition. We have begun to test our hypotheses by applying novel bioinformatic techniques. Preliminary data suggest that at least one bacterial taxon, *Endozoicomonas sp.*, is distributed in a manner consistent with coevolution on large timescales. We have also contrasted the variance in microbial communities explainable by sampling location and host phylogeny, finding distinctive patterns in each. The data generated by this project are freely available to the community, providing a large resource to which future data can be compared.

CARBON-CYCLING ON CARIBBEAN CORAL REEFS: THE INCREASING ROLE OF GIANT BARREL SPONGES (Abstract ID: 28192)

Benthic suspension feeders support a number of ecosystem processes, including benthic-pelagic coupling and the cycling of carbon and nutrients. Sponges now dominate Caribbean reefs, with the giant barrel sponge*Xestospongia muta* playing the largest role. Barrel sponge populations increased by 122% for 2000-2012 on Conch Reef, Florida Keys, with a 40% increase in volume (approx. 2 liters of sponge tissue per square meter). Barrel sponges are estimated to overturn the water column every 2-18 days, and selectively feed on bacteria and other picoplankton, but have a diet that is mostly (~70%) made up of dissolved organic carbon (DOC). Using demographic data from 2000-2012, and measurements of filtration rates of particulates and DOC, we parameterized a stage-based matrix model of carbon flux for *X. muta* to investigate the demographic mechanisms that change benthic-pelagic coupling. Population-mediated carbon flux increased over time with increasing sponge density and volume, with the largest individuals making the greatest contribution. Elasticity analysis revealed that the growth of sponges in all stages, the survival of sponges in the two largest stages, and the production of new recruits by the largest sponges had the greatest influence on changes in carbon flux. Projections indicated that population-mediated carbon flux will continue to increase under present conditions; thus, *X. muta* is expected to play an even larger role in the transfer of carbon from the water column to the benthos on Caribbean coral reefs.

MULTIFACETED IMPACTS OF THE STONEY CORAL PORITES ASTREOIDES ON PICOPLANKTON ABUNDANCE AND COMMUNITY COMPOSITION (Abstract ID: 28084 | Poster ID: 146)

Picoplankton foster the essential recycling of substrates in the oligotrophic waters sustaining coral reef ecosystems. However, how specific interactions between corals and planktonic bacteria and archaea (picoplankton) contribute to reef productivity are not well resolved. Here, we utilized mesocosm experiments to investigate how corals and coral mucus influence picoplankton and nutrient dynamics in reef waters. Over 12 days, we tracked nutrient concentrations, picoplankton abundances and taxonomic composition of picoplankton using direct cell-counts, sequencing of SSU rRNA genes and fluorescent in situ hybridization-based abundances of dominant lineages in the presence or absence of Porites astreoides corals or their mucus. Our results demonstrate that when corals are present, Synechococcus , SAR11 and Rhodobacteraceae cells are preferentially removed and Alteromonadaceae and Oxalobacteraceae cells increase in abundance. When corals were absent, their exudates enhanced the growth of diverse picoplankton, including SAR11 and Rhodobacteraceae. A ten-fold increase in nitrate concentration, apparently caused by nitrogen remineralization within the coral, may have further facilitated the growth of these taxa. In contrast, the addition of mucus resulted in inconsistent responses by the picoplankton community. This study presents evidence of the multifaceted influences of corals on picoplankton, in which the coral holobiont selectively removes and promotes the growth of diverse picoplankton and remineralizes nitrogen, thereby fostering reef productivity.

INDUSTRY AND RESEARCH COLLABORATION TO LEVERAGE CORAL REEF SCIENCE FOR ENVIRONMENTAL RISK ASSESSMENT AND MANAGEMENT (Abstract ID: 28142)

Woodside Energy Ltd and the Australian Institute of Marine Science (AIMS) enter a new working partnership in 2016 based on over twenty years of collaborative scientific studies supported by various funding models. The studies have underpinned impact assessment for upstream oil and gas activities and proposed developments in the offshore waters of Western Australia. This showcase includes: one of the world's key long-term monitoring programs of a remote oceanic reef system including mesotrophic coral communities, seismic survey potential impacts, updated baseline for the World Heritage Areas of Ningaloo Reef and Shark Bay and the repurposing of industry acquired geophysical data for habitat mapping to support environmental risk assessment.

GREAT BARRIER REEF MARINE SOUNDSCAPES: LIZARD ISLAND - A CORAL REEF CASE STUDY (Abstract ID: 29200)

Marine soundscapes are acquiring a growing level of social and academic awareness. Advancements in technology and ecological modelling now provide opportunities to progress research and monitoring programs, but large knowledge gaps remain in the following key areas: soundscape spatio-temporal patterns, methodology and sound-source identification. This presentation provides a synopsis of Lizard Island marine soundscapes. Great Barrier Reef marine soundscapes have received limited coverage, making this a rare and important study. Sets of continuous sound recordings were

collected at field sites across a number of seasons (2014-2016). Several prominent fish choruses were identified at specific locations around the island, exhibiting a range of different temporal patterns. Cyclone Nathan hit Lizard in March 2015 causing widespread damage to the Island's coral reef. A comparison of reef soundscapes prior and one year post-cyclone will be presented. Simultaneously measuring environmental co-variables at a site level is an important step in identifying soundscape contributors and explaining observed patterns. Environmental co-variables, wind speed, temperature and relative light levels were collected at field sites on a 10 minute duty-cycle. Additional information on salinity, pH and tide height was obtained from open-access oceanographic datasets. The influence of ship-radiated broadband noise from a nearby commercial shipping lane had a significant influence on the underlying soundscape. Masking of fish choruses up to several hours was common in the presence of passing ships.

CORAL TRAIT DIVERSITY AND FUNCTIONAL COLLAPSE ON CARIBBEAN CORAL REEFS (Abstract ID: 27900)

To explain patterns of shifting function in coral assemblages, we must consider how species differ in their contribution to ecosystem processes, and how they respond to local and global stress. Here, we use a multi-trait analysis to measure the relative contribution of Caribbean corals to numerous reef-level processes, such as reef accretion, primary productivity, and habitat provision. We identify coral functional types (CFT's) in the Caribbean, allowing us to explicitly measure functional diversity and redundancy in coral communities. By analysing the abundance of corals during multi-decadal shifts in community structure, we show that in Jamaica, coral species of similar functional type exhibit similar responses to disturbance (low response diversity), such as hurricanes and bleaching events. This, along with unprecedented stress from the loss of herbivores, has led to regime shifts, whereby all corals, and coral functions have been lost. Low response diversity is also evident on degraded reefs that are recovering, resulting in alternate coral assemblages, with substantially different biogeochemical, trophic and constructional processes. This study asserts that the stability of function in ecosystems is largely a product of the association between 'response' and 'contribution' traits in critical groups of organisms.

SPECTRAL SIGNATURES OF BRAZILIAN CORAL REEFS (Abstract ID: 29664)

Studies involving spectral signatures are important as they provide a base for the interpretation of data obtained through remote sensing at different levels, allowing better mapping and environmental monitoring. An investigation of the spectral signatures of Brazilian corals and hydrocoral includes as selected species Agaricia agaricites, Favia gravida, Mussismilia braziliensis, Mussismilia harttii, Milepora alcicornis, Porites astreoides and Siderastrea stellata. Spectral signatures were collected using a portable FieldSpec 3 Hi-Res spectroradiometer and subsequently processed using two techniques: mean and derivative analysis, using the first and the fourth derivates. Results classify the coral P. astreoides within the blue group, while the hydrocoral and other corals fall within the brown spectral group. Features in the first derivate are used to distinguish some of the species, while the fourth derivate presents positive and negative peaks that confirm the differences among species observed in the first derivate. Possibly, fluorescent or non-fluorescent pigments present in the tissue of corals were responsible for the differences in spectral signatures. Thus, apparently, it will be possible to distinguish some coral species through their spectral signatures using data about the different fluorescent and/or non-fluorescent pigments present in corals tissue. The final objective is to use these spectral signatures to classify WorldView-2 satellite imagery into coral cover maps.

COMMUNICATING THE SCIENCE OF THE MEXICAN CORAL REEFS TO SUPPORT THEIR PROTECTION AND CONSERVATION (Abstract ID: 28727)

Mexico is a privileged country thanks to its location in the tropics and having coastlines on two oceans, where coral reefs and their associated organisms develop, having a direct and indirect impact on the use of resources that sustain national economy. However, it is remarkable the ignorance that the general public has on organisms and phenomena associated with these ecosystems. The purpose of the project was to improve the awareness in the society about the current situation of the Mexican coral reefs and the studies that students and scientists are producing and publishing. Results included products aiming several groups of people: two types of radio spots; an updated web site to support students and scientists interested on coral reefs, but also complemented with information for the general public; workshops on science journalism focused on scientific meetings, particularly about coral reefs; field trips to two relevant coral reefs in the Pacific and Caribbean to produce coverage that was published in 12 press and TV notes; several talks to students and general public in different cities; and a colorful booklet with information about coral reefs. Most of the products can be found in the Mexican Coral Reef Society web site (www.somac.org.mx) and the radio spots can be downloaded freely (soundcloud.com/arrecifes-coralinos-somac). The information and products include valid information that can be use for some years, increasing the chances to reach more people and improving the knowledge on coral reefs, which can help in their protection and conservation.

LEARNING NETWORKS AS A POWERFUL TOOL FOR INCREASING EFFECTIVENESS OF CORAL REEF CONSERVATION (Abstract ID: 30116)

Collaborative management and adaptive learning are some of the most effective and powerful ways to engage stakeholders to improve local management at the site level. Especially in the marine realm, where coastal areas and reef ecosystems are in the public domain, a particpatory and community-based approach is necessary. Inspired by the Locally Managed Marine Area (LMMA) Network, The Maui Nui Makai Area Learning Network was established in 2013 by 6 communities from Maui, Lanai and Molokai and 2 supporting organizations. This emerging network would like to share their experiences and lessons learned on how to form networks that build capacity for communities that rely on the health of their marine and coastal environments. Success stories and challenges with community outreach, engagement, co-management, governance, developing appropriate bio-cultural indicators and traditional knowledge will be discussed and shared by community leaders from the Maui Nui Makai Network to provide examples of how scientists and reef managers can better engage and support communities in improving coral reef conservation and fisheries management.

THE COMMUNITY WATERSHED SNAPSHOT: LOCAL MEASURES OF AHUPUA'A HEALTH (Abstract ID: 30043 | Poster ID: 571)

Hawaii Conservation Alliance's (HCA) Community Watershed Snapshot is a status report on the health of our watersheds produced from geospatial data gathered by the community. This initiative is the first community-based conservation effort of HCA, under the Effective Conservation Program (ECP). The ECP's goal is to facilitate effective conservation of Hawai'i's native ecosystems in terrestrial, aquatic, and marine realms by measuring and maximizing effectiveness, strategic planning, and success of the collective conservation community through active management, protective designation, and stakeholder support for a stable track record of expanding biodiversity. In 2013, HCA consulted with local leaders and stakeholders from eight communities across the main Hawaiian Islands on how best to measure the health of local watersheds. Community representatives identified a set of mauka (terrestrial), makai/wai (ocean/fresh water), and na'ike (social-economic) factors that they believe are important in understanding the status ("snapshot") of the health of their ahupua'a. Following formal review and consideration by HCA members, a set of Watershed Snapshot Metrics was endorsed by HCA in 2014. During 2015 and 2016, volunteer communities have begun to implement the watershed snapshot measures. Participating communities aim to use the information gathered through the watershed snapshot measures to inform and advance their community-based natural resource management efforts.

HUMANS AND SEASONAL CLIMATE VARIABILITY THREATEN LARGE-BODIED CORAL REEF FISH WITH SMALL RANGES (Abstract ID: 27844 | Poster ID: 422)

Coral reefs are among the most species-rich and threatened ecosystems on Earth, yet the extent to which human stressors determine species occurrences, compared to biogeography or environmental conditions, remains largely unknown over broad spatial scales.

With ever-increasing human-mediated disturbances on these ecosystems, an important question is not only how many species can inhabit local communities, but also which biological traits determine species that can persist (or not) above particular disturbance thresholds. Here we show that human pressure and seasonal climate variability are disproportionately and negatively associated with the occurrence of large-bodied and geographically small-ranging fishes within local coral reef communities. These species are 67 % less likely to occur where human impact and temperature seasonality exceed critical thresholds, such as in the marine biodiversity hotspot: the Coral Triangle. Our results identify the most sensitive species and critical thresholds of human and climatic stressors, providing opportunity for targeted conservation intervention to prevent local extinctions.

IMPORTANCE OF HETEROTROPHIC FEEDING FOR *PORITES CYLINDRICA* AS AN ALTERNATIVE SURVIVAL STRATEGY. (Abstract ID: 29224)

Emissions of anthropogenic carbon dioxide have been increasing both the temperature and acidity of the oceans and consequently challenging the future of many calcifying marine organisms such as corals. High diversity of corals and their varying response to climatic change, make understating future changes important. Previous research suggests *Porites cylindrica* can survive several months longer than other species in a bleached state. This project aims to establish how heterotrophic feeding may help *P. cylindrica*survive and grow in the absence of autotrophic energy. Unbleached and heat bleached corals where kept under four different feeding treatments (particulate or dissolved organic carbon, glucose and not fed) and two light regimes (light/dark or dark only). Coral survival was the same across all treatments, however some bleached corals maintained in the dark showed signs of disease. Different food groups had no significant effect on calcification rates measured as changes in buoyant rate. An interaction between light and coral bleaching status was observed with only unbleached corals exposed to light/dark cycles showing significant calcification over the 14-day experimental period. Tissue properties will be analyzed to determine whether *P. cylindrica* trades calcification for tissue growth in the presence of food when photoassimilates are absent. The results obtained to date consistent with the hypothesis that the promotion of coral calcification by dinoflagellates is not solely based on the provision of energy to the host.

PETER MINSHALL'S WATER COLOURS: AN INNOVATIVE APPROACH TO CORAL REEF CONSERVATION AND CONSERVATION FINANCING IN TOBAGO (Abstract ID: 28740)

The Buccoo Reef Marine Park (7km2 of coral reefs, seagrass and mangroves) is Tobago's biggest tourist attraction, earning an estimated US$43.5 million (40% of the island's tourism income) annually. It was designated as a protected area in 1973; a RAMSAR site in 2005; and an Environmentally Sensitive Area under Trinidad's 2001 Environmentally Sensitive Area Rules. As legal protection has increased mean live coral cover has decreased, with the greatest decline in shallow water (<3m), from 23.20% in 1985 to 5.63% in 2009. Lack of funds to manage the Park has contributed to these declines. Government funding for the Park was just US$56,000 in 2009. A 2010 willingness-to-pay study suggested that US$11.72 could be charged to visit the reefs. However, charging for previously free activities has proved difficult (e.g., imposition of a US$3 access fee at Pigeon Point, the Park's beach, led to protests and the fatal shooting of a fisherman in 2000). In an effort to independently and sustainably finance the Park, Trinidadian Carnival Artist Peter Minshall, creator of the Opening Ceremonies for the Barcelona, Atlanta, and Salt Lake City Olympics, is making Water Colours—an undersea artwork at Buccoo. This new, culturally-appropriate tourist attraction will raise funds through admission fees and memorabilia sales. This paper describes the IADB-funded first phase of the project including: the design of the sculptures; the creation of the Water Colours Trust Fund; and the socio-economic and marketing studies for the attraction.

FUNCTIONAL BIOGEOGRAPHY OF NOMINALLY HERBIVOROUS FISHES (Abstract ID: 28649)

Herbivorous fishes are known to be important components of reef systems worldwide, but to date no comprehensive large-scale study of their functional structure has been performed. Here, we describe the global distributional patterns of herbivorous fishes on tropical reefs, and the relative importance of their main feeding modes according to large-scale biogeographical variables. We compiled a database on the occurrence of 550 herbivorous fish species at 170 sites worldwide. Each species was classified according to six functional traits and functional entities (FEs) defined as a combination of each one of these traits. We found markedly differences on richness and proportion of herbivores among region, with higher values in the Indo-Pacific (IP), in contrast with Eastern Pacific (EP) and Atlantic. The functional structure of the herbivore assemblages presented a similar pattern with functional richness positively related to richness. Browsers exhibited higher proportions in EP and Atlantic and peripheral areas of the IP, and scrapers were more important in the Western Atlantic and EP. The results suggest that different environmental and historical factors have shaped the present day structure of herbivorous fishes assemblages. Patterns of functional structure observed may have important implications for coral reef conservation and management.

TEMPORAL VARIATIONS IN PHOTOCHEMICAL EFFICIENCIES OF ALGAL SYMBIONTS IN BENTHIC FORAMINIFERA AND ANTHOZOANS IN THE FLORIDA KEYS (Abstract ID: 29391 | Poster ID: 286)

Pulse-amplitude modulated (PAM) fluorometry is widely used to study photochemical efficiency in photosynthetic organisms. This project compared photochemical efficiencies of the algal symbionts of reef organisms by time of year and habitat depth. Maximum quantum yields (Fv/Fm) were measured from visibly healthy colonies of three species of zooxanthellate anthozoans (in situ) and specimens of the foraminifer*Amphistegina gibbosa*, which hosts diatoms. Because of their small sizes, data for the latter were taken in the laboratory as soon as possible after field collection. Field work was carried out near the equinoxes and solstices in 2012-13 at Tennessee Reef, Florida, USA, at 6 m and 18 m depths. At 6 m, the Fv/Fm means for *Palythoa caribaeorum* differed only between summer (0.55 +/- 0.01) and fall (0.63 +/- 0.01) 2012. No significant differences with time were found for *Siderastrea siderea* at 6 m (0.64 +/- 0.01). The mean Fv/Fm for *S. siderea* at 18 m was significantly higher in winter 2012 (0.71 +/- 0.01) than in spring 2013 (0.65 +/- 0.01). No significant differences were found for*Montastraea cavernosa* at 18 m over time (0.68 +/- 0.01). The Fv/Fm means for*A. gibbosa* from 6 m (0.719 +/- 0.01) were lower than their counterparts at 18 m (0.735 +/- 0.01). The overall trends in photochemical efficiency of *A. gibbosa*and the anthozoans were lower, more variable yields under higher potential for photic stress, that is, both shallower depths and months with highest solar irradiance.

GENETIC DIVERSITY OF THE SYMBIOTIC DINOFLAGELLATES (SYMBIODINIUM) ON THE CORAL PORITES PANAMENSIS IN THE EASTERN TROPICAL PACIFIC (Abstract ID: 29521)

The reef-building corals have a symbiotic relationship with dinoflagellates of the genus *Symbiodinium*. This symbiosis involves many interactions processes that lead to genetic changes and adaptations. In this study, we describe the genetic diversity of the endosymbiotic dinoflagellates (*Symbiodinium*) within the coral *Porites panamensis* in the Eastern Tropical Pacific. The genetic diversity of symbiont was accesed using the non-coding region of the minicircle of chloroplast PsbA. We analyzed samples from the Gulf of California, West coast of Mexico and Costa Rica. We found four phylogenetic lineages (L1-L4) belonging to *Symbiodinium* Clade C in the Eastern Tropical Pacific. The lineage 1 was composed by six groups distributed in the Gulf of California. We show that the genetic diversity of*Symbiodinium* in *P. panamensis* is high, since we found 35 unique haplotypes in 39 sequences analyzed. Changing environmental conditions across the Eastern Tropical Pacific have led to the existence of distinct symbiont-host combinations. This environmental situation combined with the reproductive form of the coral and the vertical transmission of symbionts (i.e. from parents to offspring) allows the high genetic diversity of*Symbiodinium* in *Porites panamensis*. This could be an explanation of how the host and its symbionts have diverged in many different phylogenetic groups that belong to distinct localities across the Eastern Tropical Pacific.

OPTICAL PROPERTIES INVOLVED IN THE EFFICIENCY OF LIGHT ABSORPTION OF CORAL FAVIA FRAGUM (Abstract ID: 29732 | Poster ID: 45)

The structural complexity of corals provides them the capacity to regulate the amount of light they receive, by absorbing a variable fraction of the photons and transmitting, reflecting or scattering the rest. The aim of this study was to describe the optical properties of Favia fragum at two developmental stages with different skeletal thicknesses: 35 juveniles with skeletal thicknesses less than 0.5 cm and 25 adult colonies with skeletal thicknesses greater than 1 cm were used. Measurements of transmittance and reflectance were performed and from these measures absorbances and absorptances were estimated. The number of symbionts, their chlorophyll a content and the chlorophyll a specific absorption coefficients (a*) were determined. The transmittance value recorded in the skeletons of juveniles was close to 3%. Reflectances at 675 nm was 12% in adult colonies and 37% for the juveniles with absorptance values of 88% and 62% respectively. Juveniles had a higher pigment content/symbiont and lower symbiont densities than adults. Comparison of a* values showed that adults are up to 1.6 times more efficient at absorbing light than juveniles. Loss of light by transmittance is reduced with increasing skeletal thickness and is related to the increased light absorption efficiency in adult colonies. The balance between cell density and symbiotic photosynthetic pigments strongly influence the efficiency of light absorption in corals with different skeletal thicknesses.

A PHYLOGEOGRAPHIC APPROACH TO STUDY CORAL REEF REFUGES IN SOUTHWEST ATLANTIC (Abstract ID: 29031 | Poster ID: 68)

Along Pleistocene, at least 30 cycles of repeated global cooling and warming caused sea level variations that dropped as much as 120 m during the Last Glacial Maximum (~ 21000 y BP). Coral reef ecosystems, which mainly occur in shallow, warm and oligotrophic waters, were drastically affected by these events. For Southwest Atlantic, where reef formations extend mainly in a north-south direction, the Abrolhos Bank has been hypothesized as an important coral reef refuge, a main source of the propagules that formed the present banks. We used phylogeographic tools to a first approach to this hypothesis. We used nuclear DNA fragments (Signal Recognition Particle 54-kDa – SRP54) to analyze 11 samples of the widely distributed Brazilian coral Siderastrea stellata from three localities in a range of 630 Km from Abrolhos Bank to the north. We observed overall high haplotype diversity. Genetic structure was detected, however, no isolation-by-distance was observed. The haplotype network presented two main groups separated by at least 15 mutational steps. Although our results cannot discard Abrolhos as a refuge, they point to the presence of two distinct areas that remained isolated for some time and from where our sampled banks had received migrants. Additional investigations, extending the sampled area, using more loci and coalescence based analysis may provide more details and even may detect other putative areas that might had been suitable for coral species during the periods of lower sea levels.

RAMIFICATION PATTERNS OF THE THREATENED CORAL ACROPORA CERVICORNIS: IMPLICATIONS FOR RESTORATION ACTIVITIES (Abstract ID: 30097)

Acropora cervicornis is a threatened Caribbean coral that depends greatly on branch fragmentation to proliferate. Thus, understanding the patterns of branch formation is essential for the development of management and conservation initiatives. Studies directed at describing the branching dynamics of A. cervicornis are nonetheless, scarce. In this study, we examined the patterns of branch morphogenesis in 100 colony fragments that were transplanted to two reefs with different light regimes. Five morphometric variables (e.g. location of branch formation) were measured for one year. Branching complexity was evaluated by means of two indices: the Horton-Strahler bifurcation ratio (Rb) and the Carrillo-Mendoza branching index (CM-BI). We also constructed a simple discrete model that estimates the number of harvestable branches and contrasted the model's prediction with the observed branching dynamics. In general, we found that 1) growth and branching rates were higher at the site with the lowest light intensities, 2) the CM-BI was more appropriate than the Rb to describe the branching structure of A. cervicornis, and 3) the number of branches formed during the study was accurately predicted by the simple mathematical model. We will discuss how our results can be used to guide management and conservation plans focused on this key species.

THE IMPORTANCE OF LONG-TERM MONITORING TO ASSESS THE EFFECTIVENESS OF SEAGRASS BEDS WITHIN A MARINE PROTECTED AREAS NETWORK IN PALAU, MICRONESIA (Abstract ID: 28580 | Poster ID: 555)

Seagrass beds provide a number of ecosystem goods and services which include nursery grounds, habitat for fish, carbon sequestration, sediment trapping, and nutrient filtration. The loss of seagrass beds often leads to a decrease in fish and invertebrates' populations, increase in sedimentation, and impacts adjacent coral reefs. In Palau, several seagrass beds are protected and are part of the Palau Protected Areas Network (PAN) that aims at effectively conserve marine resources. However, since the implementation of the PAN, few studies have looked at the impacts of protection on seagrass bed communities. With long term monitoring data collected bi-annually since 2011 on fish, invertebrates and seagrass communities, this study showed the effect of protection at four spatially spread seagrass beds. Results demonstrated that protected seagrass beds had higher marine resources than their respective non-protected reference sites. In addition, fish and invertebrates densities and seagrass cover within MPAs showed different trends among the four MPAs. This implies that protection from fishing solely is benefiting seagrass beds but to a certain extent. Other non-measured variables such as water quality should be considered in the future for more effective resource management.

EVALUATING THE CONTRIBUTION OF HOST GENOTYPE, SYMBIODINIUM COMMUNITY, AND BLEACHING HISTORY IN REPEATEDLY BLEACHED ACROPORA CERVICORNIS NURSERIES (Abstract ID: 29840)

*Symbiodinium* community composition, host genotype, and bleaching history play key roles in determining holobiont thermal tolerance and bleaching susceptibility. The hyperthermal events in both summers of 2014 and 2015 severely affected *Acropora cervicornis* propogated within South Florida coral nurseries and provided an opportunity to study these factors. These nurseries rigorously track numerous different clones or genets, each containing many clonal individuals or ramets, allowing for study of diverse genotypes. Bi-monthly to monthly sampling of these corals from June 2014 prior to thermal stress through September 2015 tracked these corals through both mass bleaching events. High throughput sequencing has begun to revolutionize the study of coral associated *Symbiodinium* communities, but it has not yet been applied to temporal studies of coral bleaching recovery, when *Symbiodinium* communities are most dynamic. We employed high-resolution pair-end Illumina sequencing to track *Symbiodinium*communities using the cp23S rDNA through time points before, during, and after the bleaching events. Our study evaluates the roles of coral host genotype, *Symbiodinium* community composition, and bleaching history as potential determinants of bleaching susceptibility. Here we address the relative contributions and interactions of each of these factors. More importantly, this monitoring effort explores the potential for a key reef building coral to adapt or acclimate to increasingly frequent thermal stress imposed by climate change.

TERRIGENOUS SEDIMENT DYNAMICS IN A SMALL, TROPICAL FRINGING-REEF EMBAYMENT, AMERICAN SAMOA (Abstract ID: 30005 | Poster ID: 453)

Watershed disturbance can increase sediment stress on corals, but clearly linking sediment sources to reduced coral health poses significant challenges for environmental managers. This study provides a template for managers in remote, sediment-impacted environments, who wish to quantify relationships between watershed sediment sources, water circulation over the reef, and the spatial distribution of sediment accumulation on the reef. In-stream sediment yields were monitored downstream of undisturbed forest, a quarry, and village, before and after sediment mitigation in the watershed. An event-wise sediment budget showed the disturbed quarry and village contributed about 70% of sediment loading to the embayment. Following sediment mitigation at the quarry, sediment loading to the embayment was significantly reduced. An empirical model of water circulation and residence time over the reef was developed from GPS drifters (5 drifters, 30 deployments) and acoustic current meters. Shortest residence times were on the exposed South Reef near breaking waves, and longest over the reef flat close to shore and sheltered northwest corner of the embayment. This circulation pattern explained the significantly higher accumulation of terrigenous sediment on the North Reef, than on the South Reef, as measured by tubes and SedPods. The sediment plume discharged during storms was deflected over the North Reef, leading to increased sediment accumulation on corals and reduced coral health. Conversely the South Reef remains relatively healthy due to the observed circulation pattern that prevents fine, terrigenous sediment from being transported over the South Reef.

THE ROLE OF LETHAL AND SUBLETHAL PREDATION ON CROWN-OF-THORNS STARFISH POPULATIONS (Abstract ID: 29081 | Poster ID: 208)

The removal of predators through over-fishing has been proposed as one contributing factor in crown-of-thorns starfish outbreaks, but the role of predation in controlling crown-of-thorns starfish populations remains controversial. Here, we explore the frequency of predation events, as well as the consequences of sublethal predation on crown-of-thorns starfish. Based on over 3500 crown-of-thorns starfish collected from the Great Barrier Reef (Australia), approximately 50% of the individuals had missing or short arms (indication of past predation events), irrespective of the level of fishing restrictions placed on reefs. This begged the question at what point predation becomes lethal and what the consequences of sublethal predation are on fecundity. In an experimental trial, sections of crown-of-thorns starfish as small as 1/8 survived over several months and showed signs of regeneration. However, survival of sections appears to be dependent on the size of the starfish, with sections of large mature animals less likely to survive. Additionally, fecundity as a function of arm length was estimated for 40 individuals, but remains to be analysed at the time of abstract submissions. Despite the biological and physical defences of crown-of-thorns starfish, this study showed that predation events are a frequent occurrence. Although fishing restrictions in Australia appear to have little impact on the frequency of sublethal predation, predators are likely to have some impact on crown-of-thorns starfish populations.

STUDYING MULTI-STRESSORS EFFECTS IN CORAL REEF ORGANISMS: PERSPECTIVES RELATED TO THE USE OF RADIOTRACER TECHNIQUES (Abstract ID: 29696)

Marine environmental stressors affecting coral reef ecosystems are numerous: from local contaminants (e.g. land-based pollutants) to global stressors (e.g. increase of temperature, ocean acidification). Some are already well known to impact reef organisms whereas others are about to represent a major concern. Although there are many complex biogeochemical interactions and still a large amount of uncertainties of their combined effects, there is an increasing need to investigate the effects of multiple stressors on coral reefs, one of the richest and most diverse ecosystems. An experimental approach (controlled conditions) presents a series of advantages for such investigation since it allows to gradually understand the effects of stressors on marine organism, one by one and combined. This approach, associated with the use of radiotracers appears to be a unique tool to understand the fate of contaminants and furthermore to clue some physiological reactions to counteract stressors (e.g. delineation of contamination pathways, identification of potential bioindicator reef species or illustration of key detoxification compartment in tropical organisms). Current methodological developments are made to allow studying multi-stressors effects on coral reef organisms at different organizational levels (from the cells to the individuals). This talk presents the perspectives of assessing the effects of multiples stressors on reef organisms by using radiotracers, especially in the context of the future changing environment and will be illustrated through a series of experiments.

GENETIC LINKAGE MAPS ENABLE FUNCTIONAL GENOMICS STUDIES OF CORAL THERMAL TOLERANCE (Abstract ID: 29731)

Modern sequencing technologies have led to an explosion of studies aiming to identify the genomic basis for phenotypic variation. These approaches have been very successful in model systems where the positions of genetic markers can be readily compared, associating genomic regions and genes with phenotypes, but have remained challenging in non-model systems because of limited genomic resources. Here we demonstrate the value of genetic linkage maps for studying the genomic basis of thermal tolerance in reef-building corals. We present a linkage map developed from 2bRAD genotyping of *Orbicella faveolata*, a threatened Caribbean coral. We also genotyped adult coral colonies and measured the bleaching response of each in a controlled thermal stress experiment. The linkage map provided a framework for identifying several genomic regions associated with thermal tolerance, and comparisons with the draft genome assembly are providing insights into biological processes underlying thermal tolerance phenotypes. We also describe a linkage map we are developing for *Platygyra daedalea*, using larvae produced by crossing colonies from the thermally extreme Arabian Gulf. Larval families produced from different colonies show striking differences in thermal tolerance, and we are using the linkage map to identify genomic regions underlying these differences by testing for associations between allele frequency and thermal tolerance. Together, these studies highlight the potential of linkage mapping for functional genomic studies of thermal tolerance in corals.

MICROBE-MICROBE INTERACTIONS IN THE ESTABLISHMENT OF BLACK BAND DISEASE (Abstract ID: 27880)

Coral diseases are often associated with the appearance of polymicrobial disease consortia that replace stable commensal microbiota. The polymicrobial disease consortium of Black Band Disease (BBD) is dominated by filamentous cyanobacteria of the genus Roseofilum. The recent application of high-throughput sequencing has demonstrated that BBD is highly localized and in as little as 10 cm from the leading edge of the black band layer, the microbial community in the surface mucus layer is indistinguishable from that of healthy corals. Deep sequencing has also uncovered that Roseofilum is a rare but ubiquitous member of healthy Caribbean coral microbiota, implying that the growth of Roseofilum and other members of the disease consortium is constrained in healthy tissue until these undefined restrictions are removed. Here, we present the metagenomic analysis of BBD samples from Florida, Belize, and Guam. We assembled 26 draft genomes from the metagenomes, including five genomes of Roseofilum, nine genomes of Proteobacteria, and twelve genomes of Bacteroidetes. The draft genomes suggest that Roseofilum may be a net source of organic carbon, amino acids and/or vitamins for the heterotrophic bacterial associates in the black band consortium, as well as a source of novel natural products that may influence interactions between microbes.

LONG-TERM MONITORING REVEALS COMPLEX SPAWNING IN HIGH-LATITUDE ACROPORA SPP. (Abstract ID: 29151 | Poster ID: 175)

Acropora spp. reproductive patterns have been well-documented in reefs from tropical and sub-tropical areas and has shown a synchronous pattern in the gamete release. However, there are few observations from high-latitude locations. Acropora species diversity and spawning patterns in, Nishidomari (32°N), Otsuki, Kochi, Japan differ from those in major coral reef areas in GBR, Australia and Okinawa, Japan where species diversity is relatively high. Most of Acropora species at high latitude are less synchronous and are not associated with a particular lunar phase when compared to corals in the reefal area. Here, we document the reproductive pattern of Acropora species at Nishidomari from early to late summer in 2005 to 2015 in situ. Spawning of 16 Acropora species were observed, starting from the middle of June to the beginning of September. The major spawning day of Acropora spp. in Nishidomari ranged from 5 days after full moon to 5 days after New moon in 2005 to 2015. However, from our records through 11 years, Acropora spp. spawned not only during the major spawning period from 5 days after full moon to 5 days after New moon but also all other lunar phases. These spawning patterns suggest that Acropora spp. at high latitude may have an ability to spawn at every lunar phase.

BIODIVERSITY ESTIMATION FROM INDIVIDUAL SAMPLES AND METABARCODED COMMUNITY SAMPLES (Abstract ID: 28851)

Documenting marine diversity is challenging because most species are rare, many habitats are difficult to sample, and sampling techniques provide a lot of material that is time consuming to sort through. Accurate and efficient methods to evaluate biodiversity are particularly crucial when sampling remote areas where time in the field is limited,

and historical knowledge sparse. In more accessible locations, having efficient methods to evaluate biodiversity could facilitate monitoring of biodiversity. Metabarcoding, the high-throughput parallel sequencing of DNA barcodes in whole community samples, is emerging as a powerful method to provide biodiversity estimates, as standardized, quantitative samples can easily be compared across space and time. Here, we report how biodiversity estimates from the fauna associated with dead coral heads, and in plankton tows, vary among the Southern Line Islands and the Phoenix Islands. In particular, we evaluate how diversity estimates correlate and complement each others, between individually sampled, visually identified, DNA barcoded animals (> 2mm), and metabarcoded community samples (fractions between 2mm and 500µm, < 500µm, and plankton tows). We also explore how these community level data can be used to gain insights into the unraveling of biogeographic patterns across taxonomic groups.

## EVALUATION OF THE SOCIO-ECONOMIC BENEFITS AND ROLE OF STAKEHOLDERS IN STRENGTHENING THE MARINE PROTECTED AREA NETWORKS OF SELECTED SITES IN THE PHILIPPINES (Abstract ID: 29328)

Various studies on marine protected area networks have focused on its managerial and biophysical aspect. However, the segmentation of stakeholders and the local communities and the understanding and application of information on the value of the socioeconomic features is crucial in enhancing their performance. This study aims to assess the pivotal functions of each stakeholder groups within the Batangas, Oriental Mindoro and Lanuza Bay Networks. Determination of the relative contribution of their socioeconomic benefits was used to analyze the stakeholders' performance and classify tasks, responsibilities, capacity potentials and limitations of accountable members. The socioeconomic assessment tool and network effectiveness assessment tool accompanied by secondary data collection were used to examine the socioeconomic and general network diffusion of information of the three sites. Local government units possessed the most crucial role in the network acting as direct influence to civil society. The socioeconomic evaluation suggested that the output indicators were associated with the input indicators such as budget and revenue allocation. Moreover, stronger network yields better performances on the identified network management criteria. This indicates that the communication and feedback of socioeconomic benefits with clear stakeholders' functions generally strengthen the marine protected area network. The vitality of network connectivity studies at the municipal-scale scenario highlights the bottom-up approach in contributing to the goals for sustainable development.

## FISHERIES COMPLIANCE AND MPA EFFECTIVENESS: AN INVESTIGATION IN THE VERDE ISLAND PASSAGE, PHILIPPINES (Abstract ID: 29291)

Marine Protected Areas (MPAs) are used globally as a conservation tool in response to anthropogenic impacts. Compliance of local stakeholders and fishing communities as resource managers contributes to MPA success; however, there is a variety of factors that influence its effectiveness. This study investigates the relationship between MPA effectiveness and compliance defined as the observance to the rules and regulations of the fisher populations including significant variables that contribute to their defiance within the municipalities of Calatagan and Tingloy, Batangas. Moreover, a proposed regulatory framework is presented for validation by the local community in order to enhance stakeholder compliance. The use of the MPA Effectiveness Assessment Tool (MEAT) and key informant interviews provided insights on MPA management effectiveness, socio-economic benefits and other related information for compliance. MPAs in Calatagan had a higher level (3 and 4) of effectiveness compared to Tingloy (level 0); yet compliance between the two MPAs did not vary substantially as both municipalities displayed a similar percentage of violators (<10% of the population fished inside the sanctuaries). However, reduction of other illegal fishing activities was still observed since the establishment of MPAs. Continuous and collective efforts in capacity building, planning, policy, conservation and management strategies among the stakeholders and coastal populations should be addressed to maximize conservation and socio-economic benefits derived from MPAs.

## HIGHER LEVEL SYSTEMATICS OF THE WALKING, SWIMMING, AND BURROWING HOLOTHUROIDEA (ECHINODERMATA): A SIX-GENE MOLECULAR PHYLOGENETIC APPROACH (Abstract ID: 28518)

Sea cucumbers (Holothuroidea) are some of the most morphologically diverse, ecologically important, and economically valued echinoderms; however, the higher-level systematics of the class remains controversial. Here, we present a phylogeny of the extant Holothuroidea estimated with maximum parsimony, maximum-likelihood, and Bayesian approaches using approximately 5.1 kb of mt- (COI, 16s, 12s) and nDNA (H3, 18s, 28s) sequences from 80 holothuroid terminals representing 23 of the 27 families. We found that three of five orders are non-monophyletic. Apodida is sister to the rest of Holothuroidea. Apodida and Elasipodida lack respiratory trees and lie paraphyletic below a clade with respiratory trees. Elasipodida is polyphyletic. Aspidochirotida is paraphyletic with representatives from three orders (Molpadida, Dendrochirotida, and Elasipodida in part) nested within it. Dactylochirotida is at least in part of derived dendrochirotes. Molpadida's position is least certain; it unstably groups with Dendrochirotida or two other mixed clades that are dominated by members of Aspidochirotida. These results indicate that there has been rampant homoplasy in the anatomical features used as traditional taxonomic characters, necessitating a major systematic revision of Holothuroidea and a new perspective on the evolution of the class.

## SEAGRASS AMELIORATES CORAL PHYSIOLOGICAL PERFORMANCE UNDER OA CONDITIONS (Abstract ID: 29520 | Poster ID: 374)

Coral reefs are the most biologically diverse and economically important ecosystem on the planet; however they are sensitive to impacts from human activities like ocean acidification. Ocean acidification lowers the saturation state of calcium carbonate utilized by calcifying organisms, potentially leading to dissolution of skeletons and reduced ability to form new calcium carbonate structures, as well as impacting general health and physiology. Seagrass meadows, sometimes found adjacent to coral reefs in the Florida Keys, are mostly net autotrophic as a carbon sink and use the excess bicarbonate for growth. This presents the possibility of locally mediating ocean acidification effects on corals downstream of seagrass meadows. This study tested the impacts of the presence of seagrass (*Halodule wrightii* and*Syringodium filiforme*) on carbonate chemistry and coral health (*Acropora cervicornis*, *Porites porites*, and *Porites astreoides*) in ocean acidification

scenarios expected to occur in this century and present day conditions in land-based experimental settings. Physiological and functional responses measured include chlorophyll *a*, total protein, zooxanthellae counts, photosynthesis, respiration, and net calcification. Physiological responses were variable among species; however, coral respiration was consistently higher in the presence of seagrass. Results presented here describe the potential for seagrass to buffer against negative effects from OA.

MANIPULATION OF THE ASSOCIATED MICROBIAL COMMUNITY BY THE CORAL HOST IN THE ACROPORA MILLEPORA HOLOBIONT (Abstract ID: 27917)

Corals live in close association with complex and diverse bacterial communities, but little is known about the roles of the bacteria in the diseased and healthy states of corals. Some bacteria are thought to play important roles in coral nutrition and shifts in the abundance of specific bacteria that are normal associates of corals may underlie some coral diseases. Many organisms manipulate their associated bacterial communities by producing anti-microbial peptides (AMPs), and this is also the case in corals. We have identified a novel family of AMPs in anthozoan cnidarians and shown that the Acropora protein is highly active, particularly against gram-positive bacteria. The Acropora AMP is expressed in larvae and all later developmental stages. As gram-negative bacteria dominate the microbial communities associated with "healthy" corals, the novel AMP presumably functions in limiting the growth of gram-positive bacteria. Immune challenge experiments imply that corals are also capable of interfering with bacterial communication systems, potentially providing another means by which control can be imposed on the resident bacterial communities.

A 25-YEAR MONITORING PROGRAM REVEALS SIGNIFICANT DECREASES IN CORAL BUT INCREASES IN REEF FISH ABUNDANCE AND BIOMASS ON REEFS IN ST. JOHN, US VIRGIN ISLANDS (Abstract ID: 29619 | Poster ID: 573)

Analysis from a 25-year annual fish and benthic monitoring program at 4 sites in St. John, US Virgin Islands (3 sites in Virgin Islands National Park), revealed that despite significant declines in coral cover (>60%, $p<0.05$) primarily from hurricanes, coral bleaching and disease, reef fish abundance and biomass have increased significantly. Permanent benthic transects sampled from 1989 to 2014 revealed significant declines in coral cover, but increases in gorgonian and crustose coralline algae. Macroalgal cover varied over this period. Total reef fish biomass increased across all sites pooled ($p<0.05$), although no significant trends were observed in species richness or abundance. Herbivore increases were primarily driven by parrotfishes (Scaridae) the family with the highest biomass and second highest abundance, for both metrics increased at all sites pooled and individually ($p<0.05$). Secondary consumers increased in abundance and biomass at three sites ($p<0.05$), and biomass increase at all sites pooled was driven by increases of snappers (Lutjanidae) and grunts (Haemulidae). Large predators (primarily piscivores) showed no change in abundance at all sites pooled, but increased at one site in abundance and biomass. Grouper (Serranidae) and jack (Carangidae) biomass increased at all sites pooled and individually (except groupers at one site). The use of standardized monitoring co-located at permanent reef locations over multiple decades provides managers in Virgin Islands National Park and the Caribbean with long term trends in these valuable reef resources.

IMPROVING ESTIMATES OF LARVAL PRODUCTION, SURVIVORSHIP, AND COMPETENCY IN TWO IMPERILIED CARIBBEAN BROADCASTERS (Abstract ID: 27893)

Knowledge of coral early life-history (e.g., fertilization, pelagic larval duration, survivorship or competency curves) is based largely on laboratory observations and presumptions. We present recent data on two Caribbean keystone broadcasting corals, Acropora palmata and Orbicella faveolata, from the Florida Keys. Pairwise fertilization rates and larval survivorship and settlement/competency curves were determined over their full pelagic duration. For both species, known parental genets that spawn on the same night show dramatic variation in pairwise fertilization assays at high sperm concentration. This implies substantially lower larval production than would be presumed from simple spawning output at a given parental density. Larval survivorship and competency curves were substantially different between species. Peak settlement response (in the presence of positive cue) was observed at day 8-9 after spawning for A. palmata, at which time approximately 75% of fertilized embryos survive. In contrast, O. faveolata has a much less entrained competency curve. Settlement response (with positive cue) is well-developed earlier, by day 4-5, although only 50-60% of fertilized O. faveolata embryos survive at this time. O. faveolata settlement response persists at a similar rate for up to 48 days. Although additional data is needed from other areas/populations, contrasting early life history characteristics suggest strong differences in potential connectivity between these imperiled keystone species and need to be considered in management and recovery planning.

SHOULD I STAY OR SHOULD I GO? PHENOTYPIC AND ENVIRONMENTAL DETERMINANTS OF LARVAL DISPERSAL (Abstract ID: 28464)

Environmental changes have caused the destabilization of many of the world's ecosystems. In order to cope with environmental change, organisms may adapt by selection or adjust their phenotypes. Organisms may alter the dispersive potential of their offspring to track the movement of favorable environments in space and time. Different dispersal strategies are widespread in animals and plants, enabling species to respond to environmental change. However, despite extreme temporal and spatial variability in coral reef environments, phenotypic plasticity associated with dispersal is virtually unknown among coral reef organisms. We will present the latest findings of our project, ANR funded research co-written with Glenn on his arrival at CRIOBE in Perpignan, which uses clownfish as a model species to unravel the causal mechanisms underlying dispersal. We will present the effects of anthropogenic and environmental stressors on parental behaviour and stress hormone levels, and their impacts on spawning frequency, fecundity and larval traits associated with dispersal.

REEF FLAT RECOVERY FOLLOWING LARGE-SCALE REMOVAL OF INVASIVE ALGAE (Abstract ID: 29060 | Poster ID: 475)

The invasive alien alga (IAA) *Avrainvillea amadelpha* has fundamentally altered the shallow reef flats of Maunalua Bay, Hawaii, transforming a diverse, productive mosaic of native algal and seagrass communities into a sediment-laden monoculture of alien algae. Between March 2010 and May 2011 the local community and The Nature Conservancy, along with government, academic, and conservation partners, removed 10.9 ha and over 1.3 million kg of invasive algae. Following removal, cover of *A. amadelpha*dropped from 57.9(2.7)% [mean (SEM)] to 5.9 (2.4)%. Silt entrained in the IAA initially remained trapped within the project area, but eventually flushed from the bay following a series of high wave events. For approximately 20 months post-clearance, recovery was on the desired trajectory toward a native-species dominated reef flat community. At 24-months, however, while the majority of the project area remained clear of *A. amadelpha*, significant patches were regrowing and becoming dense in the vicinity of a storm drain that is a source of fine sediment. In response, the community targeted volunteer clearing efforts at these high density areas. After 70 months post-clearance, cover of *A. amadelpha* across the project remains spatially patchy but low (15.5 (1.0)%), while native algae cover has increased from 10.5 (1.8)% post-clearance to 27.8 (1.6)%. Data also suggest that *A. amadelpha* cover has stabilized, indicating that large-scale removal of *A. amadelpha* may be a viable restoration option for reef flat communities in Hawaii.

NEARSHORE CURRENTS AND POPULATION CONNECTIVITY AROUND OKINAWAN FRINGING REEFS — A DRIFTER STUDY (Abstract ID: 28263)

Ocean circulation processes are one of the major factors that determine connectivity, recruitment, and isolation of populations of reef organisms. It has been demonstrated that ocean models can account for (or match) genetic patterns among populations

inhabiting distant reefs. However, it is not clear whether ocean models can account for year-to-year connectivity at local reef scales, which is essential for optimal management of reef ecosystems. Many regional ocean models have not fully integrated important nearshore ocean processes (e.g., tides, topographically-driven currents, and wave-current interactions). We deployed 182 GPS-equipped surface-drifting buoys (Pacific Gyre, Microstar drifters) near reef crests (typically ~100 m offshore) of fringing reefs in Okinawa Prefecture. Drifter dispersal trajectories were compared with known recruitment patterns of*acroporid* corals and predatory crown-of-thorns starfish, *Acanthaster planci*, along the Onna village coast of Okinawa Island, as well as dispersal probabilities predicted based upon high-resolution (200 m) regional ocean circulation models. Drifting buoys were typically released monthly or bi-monthly in Spring, Summer, and Fall of 2011–2015 from 5 islands (Okinawa, Zamami, Kume, Ishigaki, and Daito). Larger drifter releases were conducted on coral spawning days. Our study suggests that proper inclusion of nearshore circulation processes is important to accurately estimate year-to-year connectivity of corals and populations inhabiting fringing reefs.

DECIPHERING CELL CYCLE REGULATION IN ZOOXANTHELLAE (Abstract ID: 27794 | Poster ID: 113)

A critical relationship exists between reef-building corals and symbiotic zooxanthellae residing within them. These photosynthetic algae (*Symbiodinium* spp.) harvest energy from sunlight and share it with their coral hosts. In return, corals provide them with metabolites, a stable position in the water column, and protection from grazing. This relationship, which is critically important for reef health, is delicate. Exposure to temperatures only marginally above the average maximum can cause corals to expel their residents. To establish symbiosis, corals produce a signal that forces*Symbiodinium* into a non-motile, dividing state. Other signals then coordinate coral-algal cell divisions to maintain the proper density of symbionts. Evidence suggests that failure of the host to maintain proper control of zooxanthellae cell divisions at high temperatures may cause bleaching. Unfortunately, little is known regarding cell cycle regulation in*Symbiodinium*, so this host-mediated control is poorly understood. Using computational methods, we identified putative cell cycle genes in the recently published genome of *Symbiodinium minutum*. We then correlated expression of these genes with cell cycle phase in cultured *Symbiodinium*. With these data, we will begin deciphering zooxanthelale cell cycle regulation to understand how corals and algae coordinate life cycles to maintain a proper balance for symbiosis.

CARBONATE CHEMISTRY OF REEFS ALTERED BY MACROALGAE: A SNAPSHOT STUDY OF HOW INVASIVE ALGAE CHANGE THEIR PH ENVIRONMENT (Abstract ID: 29911 | Poster ID: 85)

Non-native macroalgal species have been introduced to Hawaii since the 1950's, and have spread throughout the reefs of the Main Hawaiian Islands. It has been suggested that marine alga are not only resource competitors to reef-building corals, but can also change their local pH environment through photosynthesis and respiration. The resilience of corals is continuously being challenged by climate change, and understanding how coral reefs respond to their changing environment must include looking at how other reef organisms influence their local environments. This study investigated whether invasive algae inhabiting the surfaces of coral reefs could alter the carbonate chemistry environment surrounding reef-building corals. Water samples for pH and total alkalinity (TA) were collected from immediately below algal mats and from the water column on a patch reef in Kaneohe Bay, Hawaii. No relationship was found between percent algal coverage and TA, however, there was a positive correlation between pH and percent algal coverage. These data indicates that macroalgae mats covering coral reefs could be creating distinct pH environments, dissimilar to the surrounding coral reef habitat.

SEASONAL VARIATION OF THE ANTIOXIDANT ENZYME ACTIVITY IN THE HERMATYPIC CORALS (Abstract ID: 29214 | Poster ID: 125)

Recently an increased frequency of coral bleaching events have been reported in coral reefs around the world. Coral bleaching is caused by stresses such as high temperature, which lead to an increased production of reactive oxygen species. Superoxide dismutases (SOD) are antioxidant enzymes which protects the cell from oxidative stress. Several forms of SOD, harboring different metal co-factors: Cu/Zn, Mn and Fe, are present in animal and vegetal cells including corals and their zooxanthellae. An increase of the amount of SOD enzymes in coral tissue under thermal stress in the field and an increase of total SOD activity in corals experimentally stressed by high water temperature, have been reported. However, literature on natural variations of the different SODs activities in coral is still scarce. The activity of the different SOD for the coral Montipora digitate was monitored for more than a year under natural conditions at the Sesoko Island, Okinawa, Japan. Cu/Zn-SOD and, Mn and/or Fe-SOD activities were assayed by the nitrite method in the host tissue and zooxanthellae. Most of the SOD activities of the coral host and the zooxanthellae showed seasonal variations with increased activities in summer and decreased in winter. During summer, Cu/Zn represented the major contribution to the total SOD activity while in winter it was MnSOD. These results confirm the previously observed variation of amount and activities of SOD in corals under thermal stress. In addition, it shows that the different SODs have different responses against stressors such as high and low temperature.

40 YEARS OF ENVIRONMENTAL DISTURBANCES AND MOLLUSK COMMUNITIES IN THE INTERTIDAL ZONE OF OKINAWA ISLAND, JAPAN. (Abstract ID: 30059 | Poster ID: 455)

Conservation of biodiversity is an important issue, especially in coral reef ecosystems. On Okinawa Island, Japan, the coastal area has continuously been exposed to artificial disturbances such as landfill, seawall construction, soil run-off, and water pollution. However, how local marine organism communities respond to such long-term disturbances and what factors determine local community structure are hard to assess due to a lack of past environmental and faunal data. In this study, we investigated the presence/absence of mollusk species in the intertidal zone in 2015 at 91 sites located at 5 km intervals along the coastline of Okinawa I., and then compared with unpublished results from 1974. Fourteen sites (=15%) disappeared between 1974 and 2015 due to construction of seawalls, fishery ports, or landfill. For environmental data set, we obtained data on soil run-off, nutrients, and river pollution from Okinawa Prefectural Institute of Health and Environment, geological features from the Geological Survey of Japan, and calculated shore direction and openness to the ocean from Google Earth, along with other values such as distance from shoreline, type of substrate, etc. We then analyzed the influence of geological and physiological environmental factors on mollusk community structure using principal component analyses. Although we are unable to directly compare 2015 data to 1974 data due to differences in survey efforts, comparative analyses will provide us important information in understanding changes in the environment and biodiversity over the last 40 years.

JUVENILE CORALS ARE AFFECTED BY LOW SEDIMENTATION RATES: THE FIRST WEEKS ARE CRUCIAL (Abstract ID: 28758 | Poster ID: 430)

Increased sedimentation due to anthropogenic activities is a threat to many near-shore coral reefs. The effects on adult corals have been studied extensively and are rather well-known. Studies about the impact of sedimentation on the early life stages of scleractinian corals, however, are rare although recruitment is essential for conserving and restoring resilient coral reefs. Laboratory and in-situ experiments with recruits of different age classes focused on the broadcast-spawning species Acropora hyacinthus, and the brooding coral Leptastrea purpurea. Recruits were exposed to different sediment loads over a time-span of three to five weeks. Applied sediment loads were more than one order of magnitude lower than those known to affect survival of adult coral colonies. The results show that growth and survival of newly settled recruits were negatively affected by sediment loads which had no effect on the growth and survival of one-month old recruits. All experiments indicate that newly settled coral recruits are most sensitive to sedimentation within the first two to four weeks after settlement. The co-occurrence of moderate sedimentation events during and immediately after periods of coral spawning can therefore reduce recruitment success. These findings provide new information to develop comprehensive sediment management plans for the conservation and recovery of coral reefs affected by chronic or acute sedimentation stress.

ECOSYSTEM APPROACH TO FISHERIES MANAGEMENT FOR LEADERS, EXECUTIVES AND DECISION-MAKERS (LEAD) (Abstract ID: 29074 | Poster ID: 574)

Given the global need for more holistic and balanced fisheries management through an Ecosystem Approach to Fisheries Management (EAFM) and requests from fisheries managers across Southeast Asia to gain support of leadership to implement an EAFM, a consortium of international fisheries management organizations joined forces to develop the "EAFM for Leaders, Executives and Decision-makers (LEAD)" toolkit. The EAFM LEAD toolkit provides leaders in fisheries and other sectors and throughout levels of government with an improved understanding of, and ability to initiate EAFM, and more broadly ecosystem-based fisheries management (EBFM). The LEAD toolkit was designed to help facilitators educate and engage leaders in an EAFM/EBFM so that they will then empower their people to implement an EAFM. By using the appropriate, situation-based tools, the toolkit helps leaders: 1) understand why EAFM leads to more sustainable fisheries management and can improve the well-being of their people; 2) understand what an EAFM is; 3) recognize and discuss human, ecological, and governance issues and concerns relating to their fisheries and how an EAFM can help; 4) understand in general how the EAFM Planning Process works; 5) recognize that they have the legal and institutional ability to engage in an EAFM; 6) communicate EAFM across sectors and throughout levels of government; and 7) understand the need for developing capacity and taking steps toward the implementation of an EAFM.

STATUS OF CORAL REEFS IN SRI LANKA: A MICROBIAL PERSPECTIVE (Abstract ID: 27946 | Poster ID: 148)

Coral reefs have suffered from a range of impacts from local anthropogenic influence to global climate change. These changes adversely affected to switch coral dominated reefs systems to algae dominated systems. However the mechanisms related to these global changes in coral reefs is not well understood to date. We hypothesis that microbial activity in reef waters could be a possible lower scale indication to explain mechanisms related to global change in coral reefs. Reef benthic monitoring, water chemistry (Dissolved Organic Carbon - DOC) and higher Dissolved Inorganic Nitrogen - DIN) and abundance of microorganisms (Bacteria and Virus) performed 08 coral reef sites around Sri Lanka from February 2014 to April 2015. Results show that the coral reefs in north are dominated by living corals whereas reefs in south dominated by algae. Algal dominant reefs represented by higher microbial abundances with relation to lower concentrations of DOC and higher DIN. These results suggest that potential connectivity to changes of reef systems with the microbial activity. Further analyses are in progress to explain how microbes structuring reef in Sri Lanka

MOLECULAR MECHANISMS UNDERLYING ESTABLISHMENT OF CORAL-SYMBIODINIUM SYMBIOSIS: A TRANSCRIPTOMIC APPROACH (Abstract ID: 27923)

Despite the ecological significance of coral-Symbiodinium symbiosis, very little is known about the molecular mechanisms involved in the establishment of the relationship. Gene expression studies based on microarrays have led to the assumption that host transcriptome is largely unresponsive during the establishment of symbiosis with competent Symbiodinium. In the present study, Illumina RNA-Seq was used to investigate transcriptome changes in Acropora digitifera larvae during exposure to competent Symbiodinium (a clade B strain). A transient period of differential expression involving a small number of genes (1073 transcripts; <3% of the transcriptome) was detected very early in the infection process i.e. 4h after infection. This phenomenon has not previously been detected as a consequence of both the lower sensitivity of the microarray approaches used and the sampling times used. The transcriptome data imply that translation and oxidative metabolism are supressed in the coral host during the infection process, and altered expression of some apoptosis-related genes was also observed. The results also suggest the involvement of both partners in the establishment of the symbiosis; there is an active response on the part of the host in recognizing the symbiotic partner, but an apparent suppression of host immune responses may be initiated by the symbiont. The results are also consistent with the hypothesis that the symbiosome is a phagosome that has undergone early arrest, raising the possibility of a common mechanism of symbiont infection in corals and symbiotic sea anemones.

HOME RANGE, ACTIVITY PATTERNS AND INDIVIDUAL HABITAT TRANSITIONS OF DUSKY PARROTFISH SCARUS NIGER ON INTACT AND TYPHOON-IMPACTED CORAL REEFS (Abstract ID: 29359 | Poster ID: 516)

Parrotfishes mediate competition between corals and macroalgae, and their role in algal removal will be influenced by changes in movement patterns on reefs in different states. Acoustic telemetry was used to understand movement of Dusky parrotfish Scarus niger at Apo Island, Philippines. We established an array of acoustic receivers on the south-eastern side of Apo where coral cover was very low (5%) due to severe damage caused by two typhoons (in 2011 and 2012). Another array of receivers was established on the opposite side of the island where the reef was intact (60% coral cover). Ten S. niger were captured, tagged and released on each side of the island. Data was available from 17 out of the 20 tagged S. niger. Fourteen fish yielded longer-term data (2–3 months). Individuals with home ranges in typhoon-impacted habitat visited intact habitat on the opposite side of the island, and vice versa. Most fish remained on their respective side of the island and displayed activity spaces that were usually smaller than receiver arrays (400 m wide). Depth data was used to examine individual activity by calculating daily metrics for vertical migration, mean depth and standard deviation of depth. Activity patterns were similar in both habitats, with larger mean depth in intact habitat, and more vertical activity in larger fish. Daily movements of parrotfish observed over the long term ranged from a few 10s to several 100s of m. The longer-range movements indicate that some individuals may be able to adjust their home range and activity patterns in response to large-scale changes in the benthos that may influence grazing patterns.

BIOGEOGRAPHIC ASSESSMENTS: A FRAMEWORK FOR INFORMATION SYNTHESIS IN THE MANAGEMENT OF CORAL REEF ECOSYSTEMS (Abstract ID: 29589)

This paper presents NOAA's Biogeographic Assessment Framework (BAF), a decision support process for ecological forecasting and environmental management with emphasis on the spatial management of resources in coral reef ecosystems. Spatial planning is a considerable challenge for marine stewardship agencies because of the need to synthesize and model information on complex socio-ecological patterns across geographically broad spatial scales. The BAF provides a multi-disciplinary approach to integrate geospatial information into formats and visualization tools readily useable for marine resource management. The BAF is comprised of four components: (1) Planning; (2) Data Evaluation; (3) Ecosystem Characterization; and (4) Management Applications. Regardless of the approach taken to fill data gaps, errors in the source data or errors accumulated during processing can proliferate during data synthesis that generate complex spatial patterns of uncertainty. To aid managers in understanding data reliability, BAF

quantifies and documents errors and uncertainties throughout project development. Three major sources of uncertainty in the BAF are: (1) measurement or observation error, (2) errors arising from assumptions and approximations made in the statistical modeling process, and (3) inherent variability in ecological processes. Through applied case studies this paper presents the structure of the BAF framework and the associated analytical techniques applied to management information needs.

STUDIES ON EFFECT OF CLIMATIC CHANGES ON SCLERACTINIAN CORALS THROUGH LONG TERM PERMANENT MONITORING PLOTS IN ANDAMAN AND NICOBAR ISLANDS (Abstract ID: 27961)

A total of 579 species of scleractinian corals under 94 genera and 19 families with 127 threatened species under IUCN were recorded from extensive 1962 km. coastline and adjoining continental shelf region of Andaman and Nicobar Islands against the India's data base of 611 species belong to 98 genera and 19 families. To assess the status of corals in A&N Islands, 10 Long Term Permanent Monitoring Plots (LTPMPs) have been established with an area of 100 sq. m. per plot since 2009. The data on inter- and intra-species cohesion and the adaptive features for the acquisition of development in association with ecological parameters and associated faunal communities are being collected in a regular interval.A total of 254 species of scleractinian corals under 50 genera and 12 families were recorded from 10 LTPMPs areas. The mean live coral cover was 57.65±5.99% with mean density of 22.98±2.65 colony/10 sq. m. was recorded during 2009. Due to rise of abrupt Sea Surface Temperature (SST) about 3.7°C against the normal average temperature, massive bleaching was recorded throughout Andaman Sea during April-May 2010 and resulted with 86.94±6.27% of bleaching exclusively in the LTPMPs. The resilience of scleractinian corals against bleaching was recorded during 2011 due to conducive environment and it recovered to the extent of 21.40±13.87% followed by recruitment of new colonies or coralla of scleractinian corals with the mean of 18.6±8.85%. LTPMPs of South Andaman region faced maximum stresses during the climatic alteration followed by Middle and North Andaman region and Nicobar group.

INTEGRATING TRADITIONAL CUSTOMARY LAW, KNOWLEDGE AND PRACTICE WITH CONSERVATION IN THE BIRDSHEAD SEASCAPE, THE HEART OF THE CORAL TRIANGLE, INDONESIA (Abstract ID: 30001)

As the world's largest archipelagic nation and custodian of 18 percent of the world's coral reef area, Indonesia has made huge strides in creating a national system of nearly 37 million acres of marine protected areas during the past two decades. But enforcement in these reserves is not always effective, and illegal fishing continues. To address this problem in the Raja Ampat Archipelago in the West Papua province of Indonesia, teams of citizens actively patrol the area, working to decrease illegal fishing. However, the legal basis for enforcement by communities is unclear: many of these communities follow a system of "adat" law, the set of largely unwritten, cultural customs and practices dating to the 15th century that have under-pinned management of marine resources. These customs and laws have not previously been consistent and integrated with national level legislation. Two key approaches are being used to address these challenges: i. documenting the customary laws and then developing a policy framework for their legal application and enforcement by communities; ii. building a targeted team and road map for stakeholder engagement in the formal codification and strengthening of adat law on marine resource management. We are already seeing strong support and commitment at the grass-roots and regional government levels, with presumed benefits for marine resources and ecosystems.

THE EXPOSURE OF THE GREAT BARRIER REEF TO OCEAN ACIDIFICATION (Abstract ID: 29104)

The Great Barrier Reef is founded on reef-building corals. Corals build their exoskeleton with aragonite, but ocean acidification is lowering the aragonite saturation state of seawater (Ωa). The downscaling of ocean acidification projections from global to GBR scales requires the set of regional drivers controlling Ωa to be resolved. Here, we use a regional coupled circulation–biogeochemical model and observations4, to estimate the Ωa experienced by the 3,581 reefs of the GBR, and to apportion the contributions of the hydrological cycle, regional hydrodynamics and metabolism on Ωa variability. We find more detail, and a greater range (1.43), than previously-compiled coarse maps of Ωa of the region (0.4), or in observations (1.0). Most of the variability in Ωa is due to processes upstream of the reef in question. As a result, future decline in Ωa is likely to be steeper on the GBR than currently projected by the IPCC assessment report.

GENETIC DIFFERENTIATION OF THE CORALS STYLOPHORA PISTILLATA AND POCILLOPORA VERRUCOSA ACROSS MULTIPLE SPATIAL SCALES IN THE RED SEA (Abstract ID: 29272)

Observing populations at different spatial scales gives greater insight into the specific processes driving genetic differentiation and population structure. Here we assessed connectivity across multiple spatial scales in the Red Sea to determine the population structures of two reef building corals Stylophora pistillata and Pocillopora verrucosa. The Red sea is a 2,250 km long body of water with extremely variable latitudinal environmental gradients, where genetic isolation by environment and distance has previously been found in other organisms. Mitochondrial and microsatellite markers were used to determine lineages and to look for genetic differentiation among sampling sites. No distinctive population structure across the latitudinal gradient was discovered for P. verrucosa, suggesting a phenotypic plasticity to various environments. This is corroborated by a lack of genetic differentiation at a fine scale. S. pistillata displayed a heterogeneous distribution of three distinct genetic populations on both a fine and a large scale. Fst, Gst, and Dest were all significant (p-value<0.05) and showed moderate genetic differentiation between all sampling sites. However, this seems to be a byproduct of the heterogeneous distribution, as no distinct genetic population breaks were found at the large scale. Greater population structure was found on a fine scale for S. pistillata suggesting genetic selection based on fine scale environmental variations. However, further environmental and oceanographic data is needed to make more inferences on this structure at small spatial scales.

THE ROLE OF THE SCLERACTINIAN-ASSOCIATED HYDROZOANS IN THE CORAL COLONY HEALTH STATE (Abstract ID: 28343)

Scleractinian reef corals have been acknowledged as the most numerous host group for associated hydrozoans belonging to the genus *Zanclea*. However, the benefits and costs of this symbiosis are still not clear. Although trophic and/or protection mutualism seems a plausible explanation of the association, a possible relationship between the occurrence of hydrozoans and coral diseases has also been proposed. The objective of this study is to test if *Zanclea* hydrozoans significantly influence the health of the reef-building corals. To do that, we test the relationship between the occurrence of *Zanclea* hydrozoans on corals in relation to different colony conditions: healthy, stressed (bleaching, algae overgrowth, fishes and gastropods feeding scars), and diseased (WS, SEB, BrB, BBD). Our preliminary field surveys revealed as the association is widespread in the coral communities of Maldives and Red Sea. A total of 29 scleractinian genera were found in association with *Zanclea* hydrozoans. The overall *Zanclea*-scleractinians prevalence resulted very low in the coral reefs, but significant differences were observed between scleractinian genera and coral communities. Furthermore, no positive implications were found for both diseased and stressed corals, although a positive effect against predation (fish bites) was observed for scleractinians hosting *Zanclea*. In conclusion, the potential implications of the hydrozoan–scleractinian symbiosis for coral health, its wide distribution, and the number of species it involves indicate urgent need for further investigations.

THE DEVELOPMENT AND IMPLEMENTATION OF MARINE HABITAT MAPPING TOOLS AS A MECHANISM TO ENCOURAGE IMPACT AVOIDANCE AND MINIMIZATION TO CORAL REEF RESOURCES (Abstract ID: 29284)

Planned water development projects can provide vital infrastructure to the public. However, these projects can have significant impacts to coral reef resources. Under the Environmental Protection Agency and U.S. Army Corps of Engineers' 2008 rule for Compensatory Mitigation for the Losses of Aquatic Resources as well as the mitigation policy for the U.S. Fish and Wildlife Service, the avoidance and minimization of impacts to resources is required prior to compensatory mitigation for the permanent loss of resources. Prior to finalizing the project design, information such as the type, abundance, and distribution of resources within and nearby a proposed project can be valuable in determining project alternatives. The development of acceptable project alternatives provides maximum avoidance and minimization benefits. Obtaining this information in a rapid and spatially explicit manner can be a cost effective method that can help provide balance between development and resource protection. Historically, tools to provide this basic information within a specific project area have been lacking, limited in utility, and/or expensive. Here, I describe a process and suite of tools that produce standard map products with data on all major groups of coral reef organisms and their relative abundance. The process includes using standard field protocols, terminology, data entry with quality control, data processing, and final map production. This standardized process produces maps in a rapid and cost effective manner that is comparable across projects and geographic regions.

A NETWORK APPROACH TO IDENTIFY SUCCESS AND GAPS IN CORAL DISEASE SCIENCE OVER FIVE DECADES OF RESEARCH (Abstract ID: 28165 | Poster ID: 154)

Here we used a network approach to determine the achievements and gaps of coral disease research. For this, two networks were built based on the answer to 5 questions in peer-reviewed coral disease papers published from 1965 to 2015: Which coral genera are being studied? Where was the sampling performed? Does it include temporal or seasonal patterns? What was the aim of the study? Where the institutions involved were based at? We detected 7 communities (i.e, group of nodes) indicating an apparent bias to disease prevalence studies, whereas other fields such as pathology, microbiology and immunology have received attention for few diseases in a limited number of coral genera and sites. The results indicated that the top 5 locations receiving more attention were Australia, USA (Florida Keys), Hawaii, Puerto Rico and Israel. Concomitantly, the leader institutions are based at USA (continental territory), Australia, Hawaii, Puerto Rico and Israel. Also, the analysis showed a 17% of reciprocity between study sites and the institutions participating in the research, and a negative correlation in the association of the institutions and locations (i.e. locations with few studies conducted by leader institutes and vice versa. Furthermore, the network shows that 77% of sites did not include local institutions in half of the papers published. We conclude coral disease science must focus to fill out existing gaps, increase efforts in poorly understood syndromes and to improve the integration of ecological, epidemiological and molecular studies.

CORAL GARDENING AS A MPA MANAGEMENT TOOL: A SUCCESS STORY IN THE REPUBLIC OF SEYCHELLES (Abstract ID: 29441)

Marine Protected Areas (MPA) promote coral reef recovery, however this is slow and limited in most occasions. Natural and human-made threats continue and MPAs might not be enough to assist in the recovery of coral reefs. More active conservation measures are needed. We used "coral gardening" as an active conservation measure to speed up coral reef conservation in the no-take MPA Cousin Island Special Reserve, Republic of Seychelles. First, we harvested coral fragments from donor colonies or corals of opportunity in nearby areas and reared them in mid-water rope nurseries for about 1 year. Second, we transplanted the nursery-reared corals to a degraded reef site within the MPA. A total of 24,431 corals were transplanted to 0.52 ha of degraded reef site from December 2012 to April 2014. This resulted in a 300% increase in coral cover by the end of the project. We compared the fish and benthic community structures of a degraded control site and the transplanted site before-during-after transplantation. We observed a five-fold increase in fish species richness, a three-fold increase in fish density, and a two-fold increase in coral settlement and recruitment at the transplanted site. We also analysed the costs of transplantation and the life cycle of coral reef restoration technology. Our results support the application of large-scale, science-based coral reef restoration projects with long time scales to assist the recovery of damaged reefs. We propose large-scale coral reef restoration as a cost-effective tool to include in the MPA manager's toolbox.

EXTREME 2011 LA NIÑA EVENT DRIVES CORAL RANGE EXPANSION ALONG THE WEST AUSTRALIAN COAST (Abstract ID: 28294 | Poster ID: 308)

The concept of range shifting offers a ray of hope for the future of coral reefs that are under increasing threat from climate change. The likelihood of coral range expansion depends upon the availability of source larvae, the presence of suitable, non-degraded habitat and the incidence of favourable ocean currents to transport larvae. For many marine species including corals, pole-ward range expansions have been documented and here we report a new example of climate-driven range expansion along the West Australian (WA) coast. In January 2015, during an island wide survey of coral diversity, a small colony of A. digitifera was observed growing on an exposed intertidal rock platform, at the western tip of Rottnest Island (32˚S). Based on WA and Queensland Museum specimen records the most southerly record of A. digitifera is currently North Island, Houtman Abrolhos (~28˚S), almost 450 km north of Rottnest Island. We estimate the colony (10 cm by 15 cm) to be approximately ~4 years old, based on a temperate water growth rate estimate of <5 cm/year. The coral age suggests settlement occurred during the 2011 unprecedented La Niña event when sea surface temperature (SST) anomalies up to 5˚C above average were recorded along the WA coast and contributed to strengthening the Leeuwin Current. This unusual climatic event coincided with the annual spring coral spawning along the WA coast enabling larvae transportation further south than usual. Although recruitment success appears to have been extremely low, further range expansions may be expected in future extreme La Niña years.

SPATIAL PATTERNS IN FISHERIES, POPULATION STRUCTURE AND DEMOGRAPHY OF A HEAVILY EXPLOITED CORAL REEF FISH IN THE TROPICAL PACIFIC (Abstract ID: 29821)

Coral reef fish provide a significant source of food and economy of Pacific Island peoples, yet relatively little is known on their life history in the region. Here, spatial patterns in fisheries, connectivity and demography of a heavily exploited lutjanid, *Lutjanus gibbus*, are explored across multiple locations in the tropical Pacific. Creel surveys highlighted the species' importance to artisanal and subsistence fishers in the region, with this single species constituting >30% of total landings by abundance and >25% by weight at certain locations. Preliminary examination of microsatellite markers revealed little genetic variation amongst locations. Demography, in particular age and growth relationships, maximum age and mortality estimates, differed considerably across locations, with latitude (as a proxy for water temperature) and human population density appearing as significant drivers of the observed spatial patterns. Initial results indicate a strong relationship between otolith morphometrics (weight, length, width, thickness) and age estimated from sectioned otoliths, suggesting that these indices may provide a reliable estimate of age in the absence of sufficient resources to section otoliths for age estimation. These results provide critical information for monitoring and management of this key reef fish across its distribution.

USING THE ENDANGERED SPECIES ACT TO ACHIEVE CORAL CONSERVATION (Abstract ID: 29378)

In 2006, elkhorn coral Acropora palmata and staghorn coral A. cervicornis were listed as threatened species under the U.S. Endangered Species Act (ESA), and in March 2015, NOAA Fisheries adopted a recovery plan for the two coral species. While NOAA Fisheries is mandated to recover these species, we do not have all the resources or authorities to implement all the activities necessary to meet the recovery goals. Thus we must rely upon partnerships to implement recovery actions. However, the ESA does provide several tools, which we have been using since the species we listed to promote recovery. This paper will focus on how the ESA can be used a a tool for coral conservation. We will present several case studies where regulatory and voluntary actions have resulted in conservation.

CURRENT STATE OF THE CORAL REEF ECOSYSTEMS IN IRANIAN COASTS OF THE PERSIAN GULF: ANTHROPOGENIC EFFECTS AND AN UPDATED CHECK-LIST OF THE SCLERACTINIAN CORALS (Abstract ID: 27849 | Poster ID: 346)

Persian Gulf is regarded as a unique marine ecosystem, from an ecological point, it is dominated by some extreme environmental conditions; air temperature can rise to above 55oC heating up the Gulf water by over 40oC and elevating its salinity to up to 45ppt. Despite such extremes, the Gulf is a vital habitat for thousands of marine creatures, many of which displaying remarkable adaptations to its harsh environment. Numerous studies have been performed on the impacts of human activities on the coral communities of the southern part of the Gulf in Arabian states, but less is known about these impacts in Iranian shores, In this study, we have reviewed the available data to analyze the current situation of the corals in northern Persian Gulf in relation with anthropogenic and natural alterations. While coastal pollution by extended urbanization, petrochemical and fisheries activities in the recent years has negatively affected the coral lives across all coastal lines of the Gulf, compared to the southern part, there has been less an attempt or substantial strategies to protect or restore coral biodiversity in northern Persian Gulf. Nevertheless, the Iranian waters still have a considerable contribution to the world coral diversity by hosting more than 40 species of hard corals which have so far been documented even from, more or less, polluted zones; yet more species are to be discovered. Porites seems to be the most susceptible form being the dominant coral in areas distantly located from human activities, whereas Acropora is frequently found in more disturbed grounds.

STRUCTURAL AND FUNCTIONAL ANALYSIS OF CORAL HYPOXIA INDUCIBLE FACTOR (Abstract ID: 28309)

Oxygen plays a pivotal role in the physiological adaptation of metazoans to a broad range of terrestrial and aquatic environments. It is known that symbiotic cnidarians are submitted to wide, rapid and daily variations of oxygen concentration. Indeed, during daytime, intracellular $O_2$concentrations increase due to the symbiont photosynthetic process, while during night, respiration of both host cells and symbionts leads to intra-tissular hypoxia. It is well established that, in higher eukaryotes, maintenance of oxygen homeostasis and adaptation to hypoxia require HIF that is a heterodimeric transcription factor composed of a &alpha a &beta subunit. Whereas HIF &beta is stable, HIF &alpha is sensitive to oxygen concentration due a specific domain called ODD. Here, we carried out a mechanistic study of the hypoxic response of the model coral Stylophora pistillata. We cloned and characterized the coral HIF &alpha and &beta genes, and determined their expression and physiological regulation. We performed structural and functional analyses by transfecting coral HIF &alpha and HIF &beta in mammalian cells. Our results indicate that coral HIF subunits share functional similarities with human HIFs. Although HIF &alpha has an incomplete ODD domain relative to its human homolog, its protein level is increased under hypoxia when tested in mammalian cells. Furthermore, we tested HIF expression and DNA binding activity in hospite over a diel cycle (dark / light) and in artificial hypoxic conditions.

EXTENSIVE REEF DEVELOPMENT WITHIN THE "MESOPHOTIC" NEARSHORE GREAT BARRIER REEF: EVIDENCE FOR INTRA-REGIONAL VARIATIONS IN CORAL RESILIENCE (Abstract ID: 27826)

Mean coral cover on Australia's Great Barrier Reef (GBR) has reportedly declined by over 15% during the last 30 years. Climate change events and outbreaks of coral disease have been major drivers of degradation, often exacerbating the stresses caused by localised human activities (e.g. elevated sediment and nutrient inputs). Here, however, in the first assessment of nearshore reef occurrence and ecology across meaningful spatial scales (15.5 sq km), we show that areas of the GBR shelf have exhibited strong intra-regional variability in coral resilience to declining water quality. Specifically, within the highly-turbid "mesophotic" nearshore (<10 m depth) of the central GBR, where terrigenous seafloor sediments are persistently resuspended by wave processes, coral cover averages 38% (twice that reported on mid- and outer-shelf reefs). Of the mapped area, 11% of the seafloor has distinct reef or coral community cover, a density comparable to that measured across the entire GBR shelf (9%). Identified coral taxa (21 genera) exhibited clear depth-stratification corresponding closely to light attenuation and seafloor topography. Reefs have accreted relatively rapidly during the late-Holocene (1.8-3.0 mm/y) with rates of vertical reef growth influenced by intrinsic shifts in coral assemblages associated with reef development. Indeed, these shallow-water reefs may have similar potential as refugia from large-scale disturbance as their deep-water (>30 m) "mesophotic" equivalents, and also provide a basis from which to model future trajectories of reef growth within nearshore areas.

LABORATORY INDUCED ESTRADIOL EXPOSURE STIMULATES TRANSCRIPTIONAL RESPONSES IN THE SEA ANEMONE EXAIPTASIA PALLIDA (Abstract ID: 28125)

Endocrine disruption is suspected in cnidarians but no direct hormone interactions have been identified. Pathways associated with hormone biosynthesis and signaling are an understudied area in cnidarian biology. Sea anemones (Exaiptasia pallida) were exposed to 20ppb estradiol for 4 hrs. Representational Difference Analysis (RDA) was used to isolate differentially expressed transcripts associated with estradiol exposure. RNA samples were extracted after a 4hr exposure as well as after subsequent recovery periods of 4hrs, 24hrs, 96hrs, and 7days. Quantitative Real-Time PCR quantified the expression of 17β-hydroxysteroid dehydrogenase, Niemann-Pick, Equastatin, C3, Cathepsin, and interleukin-6. These genes are known to be associated with steroid metabolism and transport, immunity, lysosomal proteases/inhibitors, and inflammation. These genes were used to characterize the expression profiles of laboratory induced exposures of estradiol at 20ppb, 2ppb, and 0.2ppb. Post-exposure expression profiles provide insight into how the organism recovers from an acute exposure. These genes were also used to screen for the specificity of response. Other anemones were exposed to 20ppb testosterone or 20ppb cholesterol for 4 hrs. This suite of genes can generate expression profiles capable of differentiating exposures to different sterols.

AN EXAMINATION OF VARIATION IN BENTHIC MEGAFUANAL COMMUNITY STRUCTURE WITH DEPTH AND SIDE OF A SEAMOUNT (Abstract ID: 30025 | Poster ID: 322)

Increasing evidence suggests that seamounts communities are not homogenous across a given feature, harboring a number of habitats that increase the overall diversity of seamount communities. A number of environmental parameters may influence the distribution of benthic species on seamounts. As part of a larger project to examine the effects of trawling on seamounts, we conducted AUV Sentry photo transects along 3 sides of Pioneer Bank Seamount in the Northwestern Hawaiian Islands. A total of over 90,000m of transects were conducted at depths from 200-700m. Environmental data including depth, substrate type, slope, slope orientation, rugosity, salinity, temperature, and oxygen data were collected simultaneously. We present a preliminary analysis of the benthic megafauna communities present on the seamount and correlate variations in community structure to variations in measured environmental parameters to gain a better understanding of the scale of variability that occurs on a single feature. Our results add further evidence to the growing body of literature that demonstrates the variability found on seamounts. These scales of variability need to be incorporated into science and management plans.

IMPROVING CORAL RESTORATION THROUGH PRIOR KNOWLEDGE OF ACCLIMATION OR ADAPTATION TO LOCAL ENVIRONMENT: A COMMON GARDEN EXPERIMENT IN A NATURAL BLEACHING EVENT (Abstract ID: 30157)

One of the primary values of understanding climate resilience of naturally growing corals is the opportunity to use this information to enhance the success of future restoration efforts. Here we test if prior knowledge of a coral's experimental heat tolerance or microhabitat allows us to predict colony-level differences in thermal tolerance that are retained in common gardens after transplantation and acclimatization. In American Samoa, we characterized microclimate, acute stress performance and transcriptome response for 80 coral colonies across four species and then transplanted 800 fragments of these corals into a common garden nursery. After a natural bleaching event in 2015, we evaluated how bleaching severity correlated with expectations from prior knowledge and with the observed performance of the original colonies on the reef. After 12 months,

corals with higher stress tolerance or from warmer microhabitats bleached less and survived better than conspecifics with lower stress tolerance from cooler microhabitats. Knowledge of microhabitat structure or variation in acute stress tolerance could provide tools for active management to protect and restore reefs before the worst impacts of climate change.

THE META-GOVERNANCE OF CORAL REEFS (Abstract ID: 28029)

Over the last two decades of environmental governance scholarship, the traditional conceptualisation of resource governance (as undertaken by top-down governments) has given way to a more networked understanding of resource governance (involving a variety of public and private actors). The devolution of governance to lower orders of government (decentralised governance) was based on the understanding that government functions more responsively and effectively at local levels. The delegation of policy decisions to individual resource users (privatised governance) was based on the understanding that private actors supplement governmental capacity and authority. The coordination of actors at this level (networked governance) was based on the understanding that involving a wide range of actors enhances the certainty and legitimacy of governing. Yet, despite the magnitude of these reforms, and their significance for efficiency, accountability and efficacy, there has been very little academic consideration of how these new arrangements work beyond an acknowledgment of the new complexities of governing. This paper examines the role and tools of the state, and other 'metagovernors', in organizing both the conditions for effective network governance, and the broader enabling fiscal, administrative and democratic pre-conditions. It seeks to cut through the dominant discourse on governance complexity and explore the transformations necessary to avert governance failure and achieve environmental sustainability.

DIAZOTROPH DIVERSITY AND THEIR POTENTIAL ROLE AS CORE MEMBERS OF THE CORAL HOLOBIONT (Abstract ID: 27988)

Corals thrive in nitrogen (N) limited habitats and have therefore acquired a number of strategies to derive N from organic (e.g. heterotrophic feeding) and inorganic sources. Diazotrophs, defined as bacteria and archaea capable of fixing nitrogen, can supplement the coral holobiont with N in the form of ammonia (NH3). Diverse diazotroph assemblages have been found in a limited number of coral species, in both adult and larval life stages. Thus further investigation is needed to elucidate the ubiquity of diazotrophs as part of the core coral microbiome, and their role in contributing essential N products to both the coral host and Symbiodinium. The current study utilized gene-targeted Illumina sequencing coupled with rates of 15N2 uptake and translocation within the holobiont to illuminate the extent of ongoing N2 fixation within six coral species on the Great Barrier Reef, Australia. Coral samples were collected from 15-18 m near Heron Island Research Station and amplified using primer sets that target both the nitrogenase gene (i.e. nifH) and the universal bacterial/archaeal 16S rRNA gene. The microbial community associated with one coral species (Stylophora pistillata) will be further interpreted in the context of concurrent measurements of 15N2 fixation rates. Results provide expanded insight into the taxonomic diversity of coral-associated diazotrophs as well as the potential for N2-fixation within a set of globally important coral species.

SCIENCE FOR STAKEHOLDERS IN MPA DEVELOPMENT AND MANAGEMENT (Abstract ID: 28394)

Florida Keys National Marine Sanctuary (FKNMS) is undergoing its first comprehensive review of its network of marine zones and regulations. This review is founded upon addressing the status and trends identified in its 2011 Condition Report which documented more than a century of pressures, including a history of discharges, coastal development, habitat loss, and over exploitation of large fish and keystone species. The report details how human actions — such as poaching, vessel groundings and discharging of marine debris — continue to negatively affect the habitat and living resources of the sanctuary, but that resource condition may be improved with long term management efforts, regulatory compliance and community involvement. Since 2012, the National Oceanic and Atmospheric Administration has been working with the Florida Keys National Marine Sanctuary's Advisory Council – made up of more than 50 members of the Florida Keys marine community and government agencies – to set goals, objectives, and then identify potential programmatic, regulatory, and zoning changes based on the research and monitoring conducted in FKNMS over the last 25 years. This presentation will examine the use and digestion of scientific findings by the public, community advisory council, and issue specific working groups in decision-making and consensus building during the 2013 & 2014 FKNMS stakeholder process. The presentation will also explore opportunities for use in other communities and applicability to other processes - past, present and future.

QUANTITATIVE ASSESSMENT OF THE IMPACT OF NOISE IN A SPACEBORNE HYPERSPECTRAL SENSOR ON THE REMOTE DETECTION OF CORAL REEF HEALTH REGIMES (Abstract ID: 28080)

Conventional in situ monitoring of coral reef health by underwater surveys are spatiotemporally limited and cannot be relied upon to provide regular synoptic coverage of coral reef health. The Hyperspectral Infrared Imager (HyspIRI), with high spatial (60 m) and spectral (10 nm) resolutions in the 380-2500 nm spectral region, provides a promising option for remotely monitoring coral reef health. However, remotely sensed data are inevitably affected by sensor noise. We have quantitatively assessed the impact of sensor noise on remotely detecting coral health status. Coral reefs can be classified based on their health status as follows: (i) healthy calcifying corals, (ii) turf and coral rubble, and (iii) fleshy macroalgae. We used a large dataset of reflectances collected in the Bahamas from all three reef regimes to create representative reflectances for each regime. A robust radiative transfer model was used to propagate the reef reflectance up through the water column and the atmosphere to the sensor platform. We used published values of the expected Signal-to-Noise Ratio (SNR) of HyspIRI to model sensor noise and its effect on the received signal. We considered various ratios of mixed reef regimes for a range of water quality and atmospheric conditions typically expected in coastal waters with coral reef bottoms and quantitatively assessed how the sensor noise affects the ability to spectrally distinguish reef health regime and, given a particular set of water quality, atmospheric, and reef regime mix conditions, what level of SNR is required to detect coral reef health.

THRESHOLDS IN THE BENEFITS OF BIODIVERSITY FOR MAINTAINING FISH BIOMASS ON CORAL REEFS (Abstract ID: 28774 | Poster ID: 473)

In studies of biodiversity and ecosystem function relationships there has been a disconnect between the results from experimental low-diversity systems and those from high-diversity natural ecosystems. This discord is exacerbated by discussion over the most useful metrics of biodiverseity, while empirical studies have been challenged by the overarching effect of humans on biodiversity loss. Using Pacific-wide surveys of reefs fishes we show that the apparent disconnect between studies of low and high diversity systems may arise as a result of a distinct threshold in biodiversity-ecosystem function relationships. At low diversities biomass increases rapidly, above a low threshold level subsequent increases in biodiversity have moderate benefits. This threshold is seen in all richness metrics while the evenness of phylogenetic diversity provides the best overall predictor of biomass. Our results provide a empirical explanation for the apparent paradox of contrasting BEF relationships in low vs. high diversity systems. Furthermore the findings emphasise the importance of phylogenetic information and the utility of traditional taxonomic groups in identifying practical measures to manage complementarity and maximise potentially harvestable biomass on coral reefs.

RECOVERY PLAN FOR ACROPORA PALMATA AND ACROPORA CERVICORNIS (Abstract ID: 28161)

In 2006, elkhorn coral Acropora palmata and staghorn coral A. cervicornis were listed as threatened species under the U.S. Endangered Species Act (ESA), and in March 2015, NOAA Fisheries adopted a recovery plan for the two species. The recovery plan identifies a strategy for rebuilding and assuring the long-term viability of elkhorn and staghorn corals in the wild, allowing ultimately for the species' removal from the list of threatened and endangered species. The plan contains ten criteria which are targets by which to gauge species' recovery and identify when they no longer require the protection of the ESA. Twenty-four actions provide direction for achieving the recovery criteria and include research and monitoring, reduction or elimination of threats, and enhancement of the population by growing and actively putting corals back on the reef. Federal resources to implement recovery plans are often very limited. Therefore, communication, coordination, and collaboration with a wide variety of stakeholders are needed to effectively implement recovery actions. Although recovery plans are developed under U.S. law, the recovery plan for elkhorn and staghorn corals can be used as a guide for conservation of

the species in other countries. Because threats to elkhorn and staghorn corals are both local and global in nature, recovery will require concerted effort on the part of domestic and international communities.

RAPID ACCLIMATION OF JUVENILE CORALS TO CO2-MEDIATED ACIDIFICATION BY UP-REGULATION OF HEAT SHOCK PROTEIN AND ANTI-APOPTOTIC BCL-2 GENES (Abstract ID: 28197)

Corals play a key role in ocean ecosystems and carbonate balance, but their molecular response to ocean acidification remains unclear. In this study, whole-transcriptome analysis was used to compare the effects of acute (3-d) vs prolonged (9-d) exposure to elevated pCO2, in juveniles of Acropora millepora. Acute exposure shows extensive disruption of gene expression, particularly of genes involved in calcification and metabolism. In contrast, the expression of most genes was at control levels after the 9-d treatment, indicative of a rapid molecular acclimation to the altered environment. Heat shock proteins and heat shock factors were over-represented amongst the genes responding to both treatments. The most obvious feature of the molecular response in the 9-d treatment was the up-regulation of five distinct Bcl-2 family members. Our efforts to understand the functional significance of this response led to the characterization of the Bcl-2 and caspase gene repertoires of A. millepora, discussing these in an evolutionary context. The pro- or anti-apoptotic activities of coral Bcl-2 proteins were investigated by expression in mammalian cells. Our results showed that most of the differentially expressed Bcl-2 genes were anti-apoptotic. This suggests that an important component of the corals' longer term response to elevated CO2 is the suppression of apoptosis. Therefore, it appears that juvenile A. millepora have the capacity to rapidly acclimate to elevated CO2, a process mediated by up-regulation of specific HSPs and anti-apoptotic Bcl-2 family members.

MANGROVE-CORAL HABITATS AS A NOVEL REFUGE FROM CLIMATE CHANGE (Abstract ID: 29603)

More than 90% of the world's coral reefs will be threatened by climate-associate stressors and local anthropogenic impacts by 2030 under "business as usual" emissions scenarios. Increasing temperatures and solar radiation cause coral bleaching that has resulted in extensive coral mortality. Increasing carbon dioxide reduces seawater pH, slows coral growth, and may cause loss of reef structure. Management strategies include establishing marine protected areas where environmental conditions promote reef resiliency. However, few resilient reefs have been identified, and resiliency criteria are poorly defined. We characterized mangrove communities that serve as a novel coral refuge from thermal stress and ocean acidification for more than 30 species of scleractinians growing directly on and under mangrove prop roots in Hurricane Hole, St. John, US Virgin Islands. We identified resiliency factors for these mangrove-coral habitats and show that a combination of substrate and habitat heterogeneity, proximity of different habitat types, hydrographic conditions, and biological influences generate biogeochemical conditions that buffer against ocean acidification. Furthermore, these corals are thriving in low-light conditions from mangrove shading and at higher temperatures than nearby reef corals. In the Florida Keys, red mangroves line 29,000 km of shoreline, thus representing a major potential area of refuge for reef corals. The potential and evidence for mangrove-associate coral refugia in other locations within Atlantic, Caribbean, and Pacific regions will also be discussed.

THE EFFECTIVENESS OF LOCALLY MANAGED MARINE PROTECTED AREAS FOR CONSERVATION OF COMMERCIALLY IMPORTANT CORAL REEF FISHES IN THE PHILIPPINES (Abstract ID: 28540 | Poster ID: 634)

The Philippines has more than 1,600 locally managed marine protected areas (MPAs), the most in the world. However, most of these MPAs are very small (i.e. average of 0.15 km2) and threats from overfishing are high. In this study, we assessed the effectiveness of 54 locally managed MPAs in the Philippines for conservation of commercially important coral reef fishes. We used the fish biomass level at the nationally managed, large (332 km2), remote (no human settlement), old (established in 1988) and well enforced (i.e. protected for >20 years) Tubbataha Reefs National Marine Park (TRNMP) as a proxy for "unfished" ecosystems (Bo). We also considered fish biomass levels between 25-50% of Bo as biomass "within" the maximum sustainable yield for multi-species coral reef fisheries (BMMSY). Results showed that fish biomass levels in 7%, 25% and 68% of the surveyed MPAs were "above BMMSY", "within BMMSY" and "below BMMSY", respectively. All of the reefs outside MPAs were either "within BMMSY" (16%) or "below BMMSY" (84%). We also observed signs of "fishing down the food webs", wherein the proportion of high trophic fishes decreased with the increasing levels of exploitation rate. Overall, the current locally managed MPAs in the Philippines are not effective enough for coral reef fish conservation but, nonetheless, better than no MPAs at all. Tradeoffs between fishing and conservation, particularly in setting fisheries management targets that would take into consideration both the social and ecological sustainability of coral reef fisheries will be discussed.

ANTI-PATHOGENIC ACTIVITY OF CORAL BACTERIA AGAINST WHITE PLAQUE DISEASE OF CORAL FAVIA SP. FROM TENGAH ISLAND KARIMUNJAWA INDONESIA (Abstract ID: 29447)

Coral disease is main factor of degrading coral reefs, such as White Plaque (WP) disease that cause loss of epidermal tissue of coral. The purposes of this research were to identify the bacteria associated with White Plaque Disease of coral Favia sp. and to investigate coral bacteria that have antipatogenic potency against White Plaque Disease of Coral Favia sp. Sampling was carried out by purposive method in Tengah Island, Karimunjawa on March 2015. Streak method was used to isolate and purify coral bacteria, while overlay and agar diffusion method were used to test antibacterial activity. Identification of selected bacteria were conducted by biochemical and molecular methods. Polyphasic identification of bacteria associated with diseased coral White Plague of Favia sp. showed that TFWP1, TFWP2, TFWP3 and TFWP4 were closely related to Bacillus antracis, Virgibacillus olivae, Virgibacillus salarius and Bacillus mojavensis, respectively. While antipatogen activity bacterial isolates, NM1.3, NM1.8 and NM2.3 were closely related to Pseudoalteromonas flavipulchra, Pseudoalteromonas piscicida, Vibrio azureus, respectively. Phylogenetic data on microbial community composition in coral will help in the knowledge on the biological control of coral diseases.

MOLECULAR DIVERSITY AND HOST SPECIFICITY OF CRUSTACEAN COPEPODS LIVING IN SYMBIOSIS WITH TWO CO-OCCURRING SPECIES OF GALAXEA (SCLERACTINIA) FROM AUSTRALIA (Abstract ID: 28848)

Copepods may be found living in symbiosis with invertebrates of many different taxa, including scleractinian corals. 18 species from 9 genera of copepods representing three orders (Siphonostomatoida, Poecilostomatoida and Cyclopoida) have previously been recorded as symbionts of three species of Galaxea corals (G. astreata, G. clavus and G. fascicularis) from New Caledonia, Indonesia and Madagascar. We studied Galaxea copepod symbionts from three widely separated sites in Australia: Heron Island and Lizard Island (Great Barrier Reef) as well as Ningaloo Reef (Western Australia). Although abundant, many of these symbiotic copepods were previously unknown for Australia. Corals were collected with their symbiont communities using SCUBA at depths from 5 to 21 m. Copepod DNA was extracted using a new method that preserved copepod exoskeletons (body length typically 1-2 mm), enabling morphological study. We analyzed nuclear (ITS2, 18S) and mitochondrial (COI) markers of 337 specimens of all morphotypes

of copepods from 8 colonies of two co-occurring species of Galaxea (G. fascicularis and G. astreata) using specifically-designed primers, revealing a highly diverse fauna of symbiotic copepods. Molecular diversity of these symbiotic copepods, patterns of their distribution and levels of host specificity will be discussed.

DYNAMICS OF CARBONATE CHEMISTRY, PRODUCTION AND CALCIFICATION OF THE FLORIDA REEF TRACT (2009-2010): EVIDENCE THAT HETEROTROPHY IS DRIVING SEASONAL DISSOLUTION (Abstract ID: 27865)

Are the reefs of the Florida Reef Tract currently in a state of positive carbonate balance? The seasonal variability in the carbonate chemistry of the waters the FRT was followed over a two-year period. Seven surveys were performed at approximately quarterly intervals in 2009-10 across seven onshore-offshore transects comprised of 3-5 stations spanning the upper (UK), middle (MK) and lower Keys (LK). Rates of NCP and NCC were positive during the spring/summer, 50-72 mmol C $m^{-2}$ $d^{-1}$ and 13-20 mmol $CaCO_3$ $m^{-2}d^{-1}$, respectively. During the fall/winter NCP became negative and exhibited a strong north-south gradient (UK -58.3, MK -27.3 and LK -12.4 mmol C $m^{-2}$ $d^{-1}$). This trend was mirrored in the rates of NCC (UK -20.0, MK -6.1 and LK 5.4 mmol $CaCO_3$ $m^{-2}$ $d^{-1}$). A significant correlation was observed between NCC and NCP suggesting that heterotrophy could be a driving factor accounting for the patterns in NCC (NCC=0.0002+0.29*NCP, $r^2$=0.53, P<0.0001). There was also evidence that NCP could be driving some of the temporal and spatial variability in NCC indirectly as &Omega$_{ar}$ was significantly correlated with NCP (&Omega$_{ar}$ =3.65+0.0052*NCP, $r^2$=0.46, P<0.0001). We conclude that the upper Keys are experiencing net dissolution on an annual basis (-0.24±0.2), the middle Keys are in an intermediate state (0.49±0.1) and the lower Keys are in the best condition (0.80±0.2 kg $CaCO_3$ $m^{-2}$ $y^{-1}$).

EFFECTS OF LIGHT, NUTRIENTS AND THE CIRCADIAN CYCLE ON QUANTITY AND QUALITY OF DISSOLVED ORGANIC MATTER RELEASED BY CARIBBEAN BENTHIC PRIMARY PRODUCERS (Abstract ID: 28743)

Benthic primary producers (BPPs) release a substantial part of their fixed carbon as dissolved organic matter (DOM). This DOM plays a crucial role in the element cycling on reefs, and particularly algal-derived DOM stimulates the growth of opportunistic microbes. While several studies focus on the fate and consumption of DOM, the effects of environmental factors on the DOM release by BPPs are less understood. We thus investigated the effect of light intensity, inorganic nutrient availability, and the circadian cycle (day vs night) on the DOM release of selected BPPs from Curaçao, Southern Caribbean. All macroalgae (*Cladophora* sp., *Dictyota menstrualis, Lobophora variegata*) and turf algae tested at ambient nutrient conditions released DOM, and this release increased with increasing light intensity. When inorganic nutrients (N and P) were added, DOM release by turf algae at low and high light intensities was comparable to those at high light without nutrient addition. Both light and nutrient availability affected DOM release of turf algae, and nutrient availability determined whether light had a positive effect on this release. Benthic cyanobacterial mats (BCMs) and turf algae released large amounts of DOM during the day, but even twice that much at night. Yet, turf algal DOM released during the day stimulated the growth of planktonic microbial communities more than that released at night, suggesting a different quality of the released DOM. Here presented results can help us to better understand DOM dynamics on reefs and to improve carbon flux estimations over diurnal cycles.

CORAL REEF CONSERVATION AND MANAGEMENT CHALLENGES IN SOUTH ASIA (Abstract ID: 28521)

South Asia is home to over 250 species of coral reef, over 1200 reef associated fish species, around 10 % of the world mangroves and over 100 globally threatened species are recorded from coastal and marine habitats and is hosting the Maldives-Chagos-Lakshadweep Atolls which is the largest atoll system in the world. South Asia has 19,210 km² of coral reef which is about 6% of the world's coral reefs. Coastal and marine ecosystems support very rich species diversity in South Asia. South Asian region having extensive river deltas and diverse marine and coastal habitats supporting marine biodiversity, however coral reefs are facing numerous threats due to natural and anthropogenic factors. Nearly one third to half of coral reef resources of South Asia are now effectively dead and further 30 percent are threatened. Consequently, livelihoods of many reef dependent communities are at risk. The management and conservation of coral reefs is one of the most challenging tasks for conservationists and marine bio-resource managers in South Asia. The South Asia Coral Reef Taskforce (SACRTF) was established in five South Asian countries sharing the Indian Ocean to facilitate and coordinate in the management of coral reefs and associated ecosystems at national level and to promote collaborative action at the regional level aiming at encouraging trans-boundary responses to shared environmental challenges and raising South Asia Cooperative Environment Programme (SACEP) is the regional coordinating agency of SACRTF.

MESOPHOTIC CORALS OF NORTHEAST AUSTRALIA: INITIAL ESTIMATES OF THE POTENTIAL FOR DEEP-REFUGE (Abstract ID: 28484)

Northeast Australia has a rich diversity of coral reef systems that includes the Great Barrier Reef and atolls of the western Coral Sea. While the shallow reefs are relatively well studied in the region, mesophotic coral communities (>30-40 m depth) are not well documented. Here we present results obtained from the study of a large coral collection compiled over eight expeditions from 2007 to 2014 that used deep diving, remotely operated vehicles and dredge sampling to investigate the mesophotic zone. The collection, housed at the Queensland Museum Townsville, includes at least 59 genera and 165 species (including five potential new species), with 93% of species depth generalists (occurring in both shallow and mesophotic zones) and 7% restricted to the mesophotic zone. Approximately 28% of the depth generalist species were only rarely observed in the mesophotic zone and the possible origins and significance of these records are discussed. Recent studies suggest a relatively large area of mesophotic coral habitats in the GBR region, and while our sampling effort was relatively small, these initial results suggest that the mesophotic zone has potential for providing deep-refuge for up to 37% of shallow-reef coral species in the region. Further work on the ecology, reproduction, physiology and phylogenetics of these species are urgently required to assess the potential for deep-refuge as the shallow reefs of the region are widely predicted to be subjected to increased coral bleaching and damage from tropical storms in coming decades.

MICROBIAL COMMUNITIES ASSOCIATED WITH SPONGE ORANGE BAND DISEASE IN THE GIANT BARREL SPONGE, *XESTOSPONGIA MUTA*(Abstract ID: 27928 | Poster ID: 151)

The giant barrel sponge, *Xestospongia muta*, represents an ecologically important species of Caribbean coral reefs. In April 2012 Sponge Orange Band (SOB) Disease spiked highly in Southeast Florida. The disease began with typical mesoyl bleaching, necrosis and often total sponge disintegration. Near the outbreak peak, 20 *X. muta* individuals were collected from two diseased populations to examine the etiology of the disease microbiomes of diseased and healthy sponges. From each diseased individual, three different morphological stages of SOB disease were collected and compared: visually healthy mesohyl from diseased sponges (HoD); the boundary layer (BL) of healthy and diseased mesohyl; and diseased mesohyl from diseased sponges (D) (N=14). Additional healthy controls (HC) mesohyl from adjacent non-diseased sponges (N=6), ambient seawater and sediment were also collected and compared. A total of 51 distinct 16S rRNA amplicon libraries were constructed with V4 primers, yielding a total of 228,315 pyrosequence reads. Beta-diversity analyses showed that healthy mesohyl had less microbiome variability than BL and diseased *X. muta* mesohyl. Although specific SOB pathogens were not confirmed, we found 22 OTUs clearly associated with SOB disease. These taxa included significant increases in *Flavobacteria, Verrucomicrobia, Plantomycetes, WPS-2* and *ZB3*. Two OTUs were always detected in the BL, while *Poribacteria* disappeared in D and BL. This study provides an extensive profile of microbial communities within X. muta with implications of a possible polymicrobial origin for SOB.

THERMAL STRESS CAUSES A SIX-FOLD INCREASE IN THE RISK OF DISEASE INFECTION IN ACROPORA CERVICORNIS (Abstract ID: 27830)

Over the last several decades diseases have caused significant declines in coral populations throughout the Caribbean. Yet we know little about the proportion of populations that are resistant to disease, and even less about the influence of the environment on disease virulence and host vulnerability. The objectives of the present study were to: i) determine whether different genotypes of Acropora cervicornis from the Florida Keys were resistant to disease, and ii) quantify the change in disease risk when corals were bleached. Five replicates of 15 genotypes were exposed to tissue slurries created from corals showing signs of disease in August 2015, before thermal stress and bleaching. The same 15 genotypes were again exposed to disease tissue slurries in late September 2015, during peak bleaching. A set of controls, which used tissue slurries created from apparently healthy corals, were paired with each experimental treatment. The relative risk of tissue loss, using a Bayesian framework, determined the risk of disease after exposure to the disease slurry, and quantified whether bleaching significantly increased disease risk. Disease exposure prior to bleaching doubled the risk of disease for twelve genotypes, whereas after bleaching the median risk increased six-fold. When bleached, eighty percent of the genotypes had a significant increase in risk of disease. Interestingly, two genotypes remained disease resistant even after bleaching. These results signify the critical role that both genetics and the environment play in coral-disease dynamics.

TESTING MITIGATION TECHNIQUES TO STOP THE PROGRESSION OF CARIBBEAN YELLOW-BAND DISEASE ON ORBICELLA FAVEOLATA (Abstract ID: 29017 | Poster ID: 474)

Caribbean yellow-band disease has caused extensive mortality of Orbicella faveolata, often affecting colonies that were hundreds of years old. The slow progression of yellow-band disease, however, provides an opportunity to test methods to mitigate disease progression. We tested three different mitigation techniques to determine whether the progression of the yellow band could be slowed or stopped using applied approaches, including: 1) the application of a shade cloth, 2) the aspiration of diseased tissue, and 3) the creation of a physical trench, or firebreak, between the diseased and healthy tissue using a hammer and chisel. Each technique was tested on three replicate colonies, and another three colonies with yellow bands were monitored as controls. The colonies were revisited after four and seven months to determine rates of success. Disease progression under the shade cloth was similar to the controls, and all aspirated corals regrew the diseased tissue, indicating that these two mitigation methods were ineffective. However, two of the three chiseled colonies showed no apparent signs of disease within the isolated healthy tissue after seven months. One colony showed small patches of discolored tissue, where the trench was likely created too close to the yellow band, suggesting that the barrier may need to be widened, removing both diseased and some healthy tissue to increase effectiveness. These results indicate that creating a firebreak between diseased and healthy tissue, which takes minimal effort and resources, may prolong the life of long-lived coral colonies.

HIGH-RESOLUTION BATHYMETRY IN SELECT PHILIPPINE REEFS AND THEIR IMPLICATIONS ON THE LATE PLEISTOCENE-HOLOCENE SEA-LEVEL CHANGES AND REEF DEVELOPMENT (Abstract ID: 29201 | Poster ID: 400)

Coral reefs provide an effective archive to past sea levels because reef-forming corals grow at a limited depth range and have a good geologic preservation. High-resolution multibeam bathymetry to a depth of 70m show a series of terraces and steep scarps in Apo Reef, Occidental Mindoro; Masinloc, Zambales; and Patnanungan, Quezon in the Philippines. Diver and drop-camera observations indicate the proliferation mesophotic corals especially along the edges of terraces. The terraces are interpreted to represent reef flat to reef crest environments and scarps as reef fronts. These are possibly the back-stepping reefs that were drowned during the overall rise of sea level. Mounds with reliefs of 2-10 m along the edges of terraces in Apo Reef and Patnanungan may represent catch-up growth. This may have been made possible by a deeper photic limit, greater depth range of coral assemblage and relative protection from wave action in the sites. Comparison of the distribution of the depths of the terraces across reefs shows clustering in three depth ranges which may correspond to three sea-level stillstands in the past 12-14 ky in the South East Asia. Variations in depth and number of terraces may indicate local tectonic influence. This provides an opportunity to extend the sea level record in the Philippines towards the Late Pleistocene.

ADAPTING BIOPHYSICAL PRINCIPLES FOR MARINE RESERVE DESIGN FROM CORAL REEF ECOSYSTEMS TO ROCKY REEFS IN A TEMPERATE SYSTEM IN THE GULF OF CALIFORNIA (Abstract ID: 29824)

The Gulf of California is a biodiversity hotspot and supplies more than half of Mexico's fisheries. We adapted biophysical marine reserve design principles originally developed for coral reefs to the unique evolutionary, oceanographic and ecological characteristics of the Gulf of California. While the amount of habitat representation and replication within reserves could be similar to that recommended elsewhere, this approach would need to be replicated within three well-defined biogeographic sub-regions. Unique sites for protection include hydrothermal vents, the northern most coral reef in the eastern tropical pacific, places showing exceptional richness of endemics and overall species diversity and sites with high productivity year-round. Given that strong, unidirectional oceanographic currents reversing direction twice a year characterizes the area and larval dispersal is ~100 km, reserves should be spaced 50-100 km apart and the location of reserves should consider the reproductive timing of the focal species (e.g. locate reserves upstream of fishing sites in relation to the direction of the predominant flow). Recovery times should be similar to other places (20-40 years), but consider local baselines. In terms of climate change, habitats and species more likely to be resistant should be prioritized. Climate change might affect larval dispersal, species' distribution, growth, reproduction, and ecosystem function and dynamics, which may require modifying recommendations about habitat representation and replication, size, spacing duration and location in future.

INFLUENCE OF PHYSICAL AND STRUCTURAL HABITAT VARIABLES IN ECOLOGICAL COMMUNITY INDICATORS AND BLEACHING OF CORALS IN A PROTECTED AREA OF THE GULF OF MEXICO (Abstract ID: 29350 | Poster ID: 350)

Coral reefs offer many ecological services; yet, these are affected by various stressors causing impacts that decrease the resilience of these ecosystems. The main objective of this study is to relate the influence of physical and structural factors of the habitat, in the composition, structure and the condition of bleaching of hermatypic corals (Anthozoa:Scleractinia and Hydrozoa:Milleporina), in order to develop an ecological resilience index. The research was conducted in the National Park Arrecife Alacranes (NPAA), a natural protected area considered one of the largest reefs in the Gulf of Mexico. Due to its geographical location, it has a relatively low human impact, so it is of great importance for the study of the potential impact of natural stressors. The methodology implemented was the BLAGRRA optional belt transect (slightly modified), remote sensing data (SST by the AVHRR sensor and diffuse attenuation coefficient K490 AQUA-MODIS sensor) and spatial information obtained by previous works in the NPAA. The results suggest that species *Siderastrea siderea, Porites astreoides, Millepora complanata* and the *Orbicella* and *Undaria* genus are the most affected in the study area. In general, it is not considered that there is an event of mass bleaching in the NPAA, however, the variability in the SST and the K490 can be of great relevance in coral bleaching at the local level.

EXPLORING THE FUNCTIONAL ROLE OF A COMMON HERBIVORE IN MOOREA, FRENCH POLYNESIA (Abstract ID: 30108 | Poster ID: 248)

Understanding mechanisms that contribute to coral persistence is recognized as a high priority research topic. Herbivory is an important mechanism that prevents macroalgae from dominating disturbed coral reefs. In this study, we focused on the feeding ecology of herbivorous fish species in Moorea, French Polynesia. Using video recording and field assays, we analyzed the foraging behavior of common herbivores in the lagoon

reef habitat. Our results show that 7 of 8 herbivorous fish species fit conventional Indo-Pacific functional group classifications, with the exception of the bullethead parrotfish, *Chlorurus sordidus*. Previous research has classified the bullethead as an excavator of epilithic turf algae, however our results show this species takes 40% of bites on macroalgae. Additional foraging observations of 138 individual bulleteads of various sizes suggest this species may be more of a generalist herbivore, consuming multiple species of macroalgae in addition to turf. Creating a selectivity index based on food availability and mass specific bite rates will confirm if the role of the bullethead can be context dependent on fish size, reef habitat, and benthic cover. As one of the most abundant herbivores in Moorea, the bullethead likely plays a major role in coral reef communities. The results of this study contribute to the understanding of how different functional groups drive community composition and function.

A GEOSPATIAL ASSESSMENT OF COMMUNITY CARBONATE PRODUCTION AND BIOEROSION ON THE SOUTHERN AND WESTERN COASTS OF GRAND CAYMAN (Abstract ID: 28367)

Calcium carbonate production and bioerosion are key factors controlling coral reef growth and the maintenance of reef structural complexity. Thus, ecosystem services dependent on physical reef structure are influenced by changes to the balance between these controlling factors; a carbonate budget is used to determine this balance. Recent research has identified a dramatic decrease in carbonate production on Caribbean coral reefs in response to declining coral cover and reef carbonate budgets may not be sufficiently net positive to continue providing these essential ecosystem services. Here we present a geospatial assessment of carbonate production and bioerosion by biological communities along 26 km of coastline on Grand Cayman. Census surveys allowed the calculation of carbonate budgets at 23 sites within the major habitat types found on Grand Cayman – hardgrounds, relict Acropora palmata reef and Orbicella reef. Habitats were mapped using ground-truthed aerial images and net carbonate production characterised within the investigated area, from the reef crest to a depth of 15 m. Mean net carbonate production was positive on Orbicella reefs, but only marginally so on relict A. palmata reefs (1.26 and 0.34 kg CaCO3/m2/yr respectively). Hardgrounds were net erosional (mean = -1.05 kg CaCO3/m2/yr). The results highlight reef sites which have become net erosional and can no longer maintain their structural complexity, while also identifying coastal locations that may be at risk from flooding as sea level rises and reef habitats produce less calcium carbonate.

ANALYSIS OF ANTIOXIDANT ENZYME EXPRESSION OVER REPRODUCTIVE TIME POINTS IN POCILLOPORA DAMICORNIS (Abstract ID: 28478)

Continued degradation of coral reefs around the world, particularly within NOAA's Hawaii National Marine Sanctuary, is an alarming call for action towards the identification of stressors and subsequent rehabilitation of these national resources. Aligned with the goals of NOAA's National Marine Sanctuary to protect areas of the marine environment that are of special national significance to cultural, scientific, educational, and ecological values, this research targets addressing and standardizing antioxidant enzyme stress levels in Hawaiian coral over reproductive cycles in order to increase management aptitude and efficiency. By developing a greater understanding for biochemical biomarkers of stress in corals, specifically through the study of superoxide dismutase, catalase, glutathione peroxidase, and glutathione reductase activity and expression, this research will aid in the adaptation and further development of biochemical tests to understand baseline thresholds of stress on coral reefs within Sanctuary waters. Although findings suggest that reproductive cycling may not be a significant factor affecting the activity and expression of this suite of enzymes, these baseline findings will be further applied to diagnostic tests describing the effect of different physical environmental factors and chemical pollutants on coral health. Through this application we look to improve our ability to identify ecological issues and expand the knowledge of local communities and NOAA, so that steps can be taken to mitigate human Sanctuary impacts.

SUPPORTING COASTAL COMMUNITIES TO ACHIEVE A SUSTAINABLE AQUARIUM TRADE (Abstract ID: 29739 | Poster ID: 602)

Harvesting fish and invertebrates from coral reefs to supply the global aquarium trade is driven by the aquarists' desire to showcase the most diverse and rare ornamental reef species in their home aquaria. As a luxury hobby the industry is highly controversial. It has contributed to species over-exploitation (e.g. clown fish following "Finding Nemo") and has been identified as a causal factor in habitat loss and degradation through the use of damaging and illegal fishing practices. However, many advocates of the industry believe that if well-managed, it could provide economic stability in low-income coastal communities whilst incentivising the maintenance of a healthy marine ecosystem. Research conducted in the Philippines found that aquarium fishers still receive minimal margins for their catch despite the expansion of the global market. They are also driven to fish with increasing distance from their local reefs where reef stocks have already been depleted, raising operational costs and further pressurising the small financial margins within which aquarium communities operate. Few alternatives to wild collection exist and development of aquaculture is limited by the costs associated with rearing tank bred fish compared to one harvested from the wild. Through engagement with local communities of aquarium fishers, an assessment of how "fair" the trade currently is in combination with socio-economic and biodiversity assessments are being trialed to develop a framework to aid local governments in the management of aquarium fisheries to provide a sustainable future.

CORAL DIVERSITY AND THREATS IN THE INTERTIDAL ZONE OF WATAMU MARINE NATIONAL PARK, KENYA (Abstract ID: 29205 | Poster ID: 627)

Research in tropical marine protected areas tends to focus on relatively deeper coral reefs, neglecting potentially biodiverse habitat such as the rocky intertidal zone. The high diversity and interesting features of Watamu Marine National Park, Kenya, attracts wildlife tourism. These intertidal habitats have been overlooked by research and management of this no-take MPA, with more effort directed towards lagoonal patch reefs. The aims of this study were to assess the population patterns and ecology of a rare coral Anomastraea irregularis, document coral diversity, and assess threats to these species in these habitat in the park. Belt transects were used to assess the number and surface area of colonies of Anomastraea. Percentage composition of substrate type was estimated. Coral condition was noted. Colonies of other coral genera were recorded. Participatory observation was used to assess threats posed by use of these habitats. 156 colonies of Anomastraea were recorded in an area of 1500 m2. The southern part of the park, near a tidal inlet, had the highest number of colonies, the largest colony and the widest size range of colonies. Thirteen other coral genera were recorded. Tourists interacted with the habitat through guided tours by local untrained guides, and involved touching, poking and feeding species such seastars and moray eels. The lack of biological knowledge and awareness of the sensitivity of the habitats poses a risk to the wildlife. There is an urgent need for training of guides, sensitization of tourists, and a management plan for this habitat.

COMMUNITY FISHERS' FORUM AS A MEANS TO FACILITATE THE UPTAKE OF SCIENCE INTO SMALL-SCALE FISHERIES CO-MANAGEMENT (Abstract ID: 29965)

Co-management is a key approach that is increasingly being used to manage small-scale fisheries (SSF) across the western Indian Ocean (WIO). This is resulting in increased responsibility on fishers who previously were not involved in management, yet there are few examples of learning programs in the WIO that provide scientific information that meets fisher management capacity needs. Uninformed fishers will not be able to play their part in co-management, reducing the benefits of this governance system. We describe here a co-management partnership, the Fishers' Forum, aimed at promoting the use of scientific information in the management and conservation of coral reefs in Kenya. The forum, a partnership between fishers through their Beach Management Units and other associations, the State Department of Fisheries and the Wildlife Conservation Society, has over a 15-year period grown to an annual event of more than 150 actors and practitioners in the coastal SSF sector across the Kenyan coast. We describe the adoption, outcomes and challenges of fisheries management measures discussed at the forum during this period. Learning was achieved through an iterative process that involved scientists presenting findings annually from monitoring and research studies on coral reefs and making management recommendations, and fishers using the platform to discuss the feasibility of management options and implementation of solutions. This resulted in increased fisher community participation and the use of science in the management of SSF. The Fishers' Forum, can serve as a useful model for the WIO where governance of SSF is increasing being restructured towards co-management.

SKELETAL PROPERTIES AND MECHANICAL STRENGTH OF KENYAN SCLERACTINIAN CORALS UNDER SEDIMENT DISCHARGE (Abstract ID: 29191 | Poster ID: 440)

Coral reefs are maintained by the close balance between constructive and destructive processes. However, disturbances that impair carbonate production or facilitate carbonate destruction can potentially push coral reefs into states of degradation. There is growing concern that rapid changes in global and local environmental factors are increasing the severity of reef damage, particularly in nearshore reefs adjacent to modified catchment areas. Mechanical properties of coral skeletons are important determinants in the survival of corals by limiting colony or branch size, range of hydraulic conditions colonies can withstand, selection of suitable habitat and influencing growth form characteristics. Skeletal properties also play a significant role in the ability of corals to compete for space and light, repair structural damage, and withstand the impacts of hydrodynamic energy and bioeroding organisms as well as the maintenance and structuring of coral assemblages. Predicted increases in SST, atmospheric CO2 and water quality changes will potentially combine to modify coral calcification and coral skeleton properties consequently undermining coral fitness and resilience. Previous studies have shed some light on the consequences of skeleton property modification and morphology. However, few studies have been undertaken to elucidate the influence of sediment concentration on the consequences of coral skeleton modifications. Here we report on the response of coral skeletons (skeleton properties and mechanical strength) to the influence of sediment discharge.

IMMUNITY TO COMMUNITY: WHAT CAN IMMUNE PATHWAYS TELL US ABOUT DISEASE PATTERNS IN CORALS? (Abstract ID: 28202)

Not all coral species are affected by disease equally. Some species are host to different diseases, but seem to successfully fight them reducing mortality. Other species are disproportionately infected on any given reef and experience high mortality due to disease. We are interested in the role immunity can play in directing these patterns and are evaluating coral immunity using several novel approaches. We exposed 4 species of coral, Orbicella faveolata, Pseudodiploria strigosa, Porites porites and Porites astreoides, to the immune stimulator, LPS and quantified the changes using a combination of full transcriptome sequencing and protein activity assays for gene to protein analysis. We mapped gene expression changes using KEGG pathway tools onto key immune pathways including melanogenesis, complement cascade and Toll-like receptor (TLR). We found many differences among species in the presence of certain pathway components, and in expression with LPS exposure. For example, O. faveolata down-regulated many genes in the melanogenesis cascade and TLR pathway while P. strigosa up-regulated much of these pathways. O. faveolata also had many 'dysfunctional' regulated genes, while both Porites species had far fewer identified genes in these pathways with little to no change in their average expression. We will present our data for these species of coral and assess how these transcriptional and protein responses are related to disease susceptibility in nature.

ENSURING EFFECTIVE CO-MANAGEMENT OF MARINE PROTECTED AREAS IN THE MESOAMERICAN REEF: STRATEGIES FOR INVESTING IN LOCAL MANAGEMENT (Abstract ID: 29822)

Marine protected areas (MPAs) are a common strategy used worldwide to improve coral reef health. However, MPAs are only successful if they are effectively managed, which requires local capacity and sustainable financing. On the island of Roatan in Honduras, the Sandy Bay West End MPA was declared in 1989, but lack of adequate funding, personnel, and capacity resulted in little-to-no management of the MPA. In order to fill this gap, the Government of Honduras created a co-management scheme that allows local NGOs to manage MPAs in collaboration with the government. The Roatan Marine Park (RMP), a local NGO co-manager, was legally established in 2008 to manage the Sandy Bay West End MPA. The Coral Reef Alliance, an international NGO, has supported RMP since its establishment and has strategically invested in its growth with the long-term goal of creating a self-sufficient and autonomous local management entity. As a result, RMP is now effectively managing the west end of Roatan and is 86% independent. CORAL's strategic support for RMP through sub-grants, capacity building, and strategic planning has progressively helped them to gain financial and management sustainability. The end result that the reefs within the MPA are healthier reef than adjacent areas. Our inclusive, thorough and collaborative process for empowering local co-managers in the Bay Islands, particularly RMP, has successful emergent properties that can be applied to strengthen management of other MPAs within Honduras and beyond.

SHOALING REDUCES METABOLIC RATE IN A GREGARIOUS CORAL REEF FISH SPECIES (Abstract ID: 28897)

Many coral reef fishes live in cooperative groups due to the benefits that sociabillity can confer, such as reduced energetic requirements to fuel a variety of basic processes. Most studies on this topic have focused on the reduced costs of locomotion in collectively moving fish, in which trailing individuals can take advantage of the vortices produced by leading fish to maintain swimming speed with reduced effort. Theory suggests that individuals in social groups may also be able to reduce their energy spent on vigilance, as fish groups exhibit improved threat detection by having "many eyes" to scan for predators. In addition, individuals accustomed to a social environment may exhibit reduced stress levels when exposed to shoaling conditions. How these effects may influence overall metabolic demand, however, remain poorly understood. In this study, we quantified the impacts of shoaling on the metabolism and body condition of a gregarious coral reef fish species, the shoaling damselfish *Chromis viridis*. Using a novel respirometry method, we found that the presence of shoal-mate cues led to a significant reduction in the standard metabolic rate (SMR) of individuals. Although all fish were fed a body-mass specific feeding regime, fish held in isolation exhibited a significant reduction in body condition following one week in treatment when compared to those held in shoals. As environmental disturbances like tropical cyclones have the potential to induce social isolation, these results could have ecological consequences for gregarious fishes on coral reefs.

ASSESSMENT OF DATA-POOR CORAL REEF FISH POPULATIONS USING LIFE HISTORY PARAMETERS OBTAINED THROUGH A STEPWISE MONTE CARLO SIMULATION APPROACH (Abstract ID: 29613)

Coastal fisheries in tropical areas usually target dozens, sometimes hundreds, of species and are typically managed with limited resources. Some parsimonious stock assessment approaches rely on easily obtainable length data and are useful in data-limited situations. However, these methods still require information on key life history parameters (growth, natural mortality, and maturity) which is missing for the majority of exploited tropical species. We present a new approach to obtain life history data by using information on maximum length, taxonomic group, and the relationships between key life history parameters to obtain probability distributions of these parameters for unstudied species. We used this approach, combined with length data obtained through commercial and diver surveys, to calculate probability distribution of fishing mortality rates and spawning potential ratios (SPR) for 25 species of Hawaii coral reef fishes. For 17 of those species, we had actual life history parameters obtained from the literature which we used to conduct regular assessments and compare the results from the data-poor approach. We obtained good agreement between the data-poor approach and the results obtained with actual life history parameters: the status of 15 of the 17 previously assessed stocks was correctly classified using this method. Of the 25 species assessed in this study, slightly less than half were classified as having SPR < 30%. The longer-lived species (surgeonfishes and snappers) typically had lower SPR values in contrast to shorter-lived ones (goatfishes and jacks).

RELATIONSHIP BETWEEN SUBSTRATA DISTRIBUTION AND AMOUNT OF PRIMARY PRODUCTION: ITS SPATIO-TEMPORAL CHANGE (Abstract ID: 30094)

The primary production of each substratum: sediment or benthic communities, on coral reefs have been measured. For example, Nakamura et al. (2016) in this ICRS measured on Sesoko Island reef in Ryukyu Islands. Using these data, this study examines relationship between substratum distribution and primary production on 2 fringing reefs in

Ryukyu Islands: Sesoko reef in Okinawa Island and north eastern reef in Yoron Island. The procedure is as follows: (1) Substrata distribution pattern and its area were obtained by field survey and aerial photo reading. (2) Based on amount of primary production per unit area among each substratum, total amount of primary production was calculated about each reef. In the case of Yoron Island, we obtained aerial photographs of three eras. The oldest era was 1945, the reef flat was covered with rich coral communities. The middle era was 1960s, because of the typhoon disturbance, most reef flat was covered by sand and gravel. The last era was 1977, coral communities recovered from typhoon disturbance. Using these aerial photographs, the change of substratum distribution and the amount of primary production on Yoron Island's reef for the past 70 years was considered. In addition, using similar method, the evaluation about the loss that occurred for reclamation work on coral reef was considered in the case of Ishigaki new airport construction that was planned before.

POPULATION GENETIC ANALYSIS AT VARIOUS SPATIAL SCALES OF THE BROADCAST-SPAWNING CORAL, *GALAXEA FASCICULARIS*, IN THE NANSEI ISLANDS, JAPAN (Abstract ID: 28277 | Poster ID: 181)

Estimation of species diversity and genetic connectivity is essential for management of coral populations. At various spatial scales, we analyzed sequence types of the mitochondrial DNA (mtDNA) non-coding region and microsatellite multilocus genotypes of the broadcast-spawning coral,*Galaxea fascicularis*, in the Nansei Islands, Japan. Two morphological types are known in *G. fascicularis*, and these are strongly correlated with the length of the mtDNA sequence. Using microsatellites, significant genetic differentiation was detected between mtDNA sequence types. We also found a third genetic cluster, and this unexpected mtDNA type may be a cryptic species of *Galaxea*. Furthermore, significant genetic differentiation within mtDNA types was found among four geographic regions spanning 750 km. Nevertheless, intraspecific genetic diversity and connectivity have been maintained in the Nansei Islands. For fine scale analysis within a site, spatial genetic structure was analyzed based on location of each colony at four sites in the Nansei Islands. Clonal diversity was calculated in both mtDNA types; however, values differ among sites. Using both sexual and asexual reproduction, this species apparently has the potential to recover populations damaged by anthropogenic insults.

CORAL FARMING AND OUT-PLANTING BY MEANS OF CORAL REEF PRESERVATION AND REHABILITATION IN OKINAWA (Abstract ID: 28545 | Poster ID: 486)

The number of reef-building coral species distributed in Okinawa is approximately 380, which occupies approximately 95% of the total number of species known from the Japanese waters. In 1998, Ministry of the Environment Government of Japan reported that Okinawa possesses a total of 28,235 ha of coral reefs, which occupies approximately 84% of all coral reefs in Japan. According to the Okinawa Prefectural Government's coral reef survey in 2012, average coral cover in Okinawan reefs remained very low. Coral cover was below 10% in a large part (nearly 80%) of Okinawan reefs. Most coral communities have not recovered to the pristine level that was observed in early 1970s. The causes of this degradation in coral communities are thought to be; repeated outbreaks of the Crown-of-Thorns Starfish (Acanthaster planci), mass coral bleaching events, heavy soil runoff and deterioration of water quality. In Okinawa, coral out-planting to rehabilitate coral communities was implemented though these activities were carried out in a small scale. Therefore, Okinawa Prefectural Government launched the Coral Reef Preservation and Rehabilitation Project in 2011. The project comprises research on genetic structure of corals, coral seed production using sexual and asexual reproduction and field tests on large scale coral propagation by out-planting. As of March 2015, 75,000 coral seeds were out-planted in a total of 1.72 ha reef area. Approximately 140,000 more seeds are projected to be planted in a total of 3.3 ha reef area, which could be the world's largest attempt in coral out-planting.

POPULATION DYNAMICS OF THE CROWN-OF-THORNS STARFISH ALONG THE WEST COAST OF OKINAWA ISLAND VIEWED FROM LONG-TERM REMOVAL DATA (Abstract ID: 28298)

Coral communities along the coast of Onna village, the central west of Okinawa Island, have suffered from predation by chronically high-density populations of the crown-of-thorns starfish, *Acanthaster planci*. To protect corals, Onna Village Fisheries Cooperative began eradication programs in 1989. The cooperative has been recording size-frequency of removed starfish individuals in five different areas along the coast since 2003. Using these data, we previously revealed that successive recruitment could be one of the driving factors maintaining *A. planci* population at high density. Here, we re-examine the removal data of Nakamura et al. (2014) in addition with data of year 2013–2015 in order to establish a prediction model of *A. planci*population along the coast. Fluctuations in population size for each of the five areas shows different patterns over the years. Assuming that a majority of juvenile individuals stays during their growth in the same area along the coast, the number of juveniles which survived removal due to their small size could appear in the following year. In fact, the number of individuals < 15 cm in Year(t) (generally younger than two years-old; Okaji et al., unpubl. data) well reflects the total number of removed individuals born in Year(t–2). These findings could allow us to predict the number of individuals and to make appropriate budget projections for an eradication program of *A. planci*in the future.

MEASUREMENT OF CARBON PRODUCTION BY PHOTOSYNTHESIS AND CALCIFICATION OF SHALLOW LAGOON IN SESOKO (Abstract ID: 28611)

The lagoons in Okinawa also, were affected by a large-scale coral bleaching in 1998. Some of the lagoons have been recovering until now. However, there are any lagoons that have not recovered yet. Sesoko beach lagoon locating at north part of Sesoko Island in Okinawa, Japan is known to be one of the not recovered lagoon. Carbon production of calcification and photosynthesis can be an indicator of a state of the coral reefs to observe the recovery processes quantitatively from the bleaching event. It is important to estimate the production at each different benthic community to integrate as a whole lagoon metabolism since reef community has extremely heterogeneous structures. In this study, photosynthesis and calcification rates at each different substrate in Sesoko beach lagoon were measured for a year to see the recovery state of this lagoon. Clear acrylic domes with sampling bottle were deployed on three different bottom types in a mort of Sesoko beach every month for about a year from 2014. Dissolved oxygen, pH, salinity and total alkalinity of the collected seawater were measured. Calcification and photosynthetic rates per unit area were calculated in each dome from the change in total alkalinity and total inorganic carbon. A decrease trend was seen at community production rate obtained through one year, suggesting the possible decline of reef community. As the rock and gravel substrates showed higher reduction rate of carbon production than coral substrate, indicating that this lagoon was irreversibly deteriorate as a whole reef system after bleaching event in 1998.

REEF-SCALE MODEL SYSTEM FOR EVALUATING AND PREDICTING CORAL RESPONSES TO OCEAN ACIDIFICATION AND SEA-LEVEL RISE (Abstract ID: 29282)

For evaluating and predicting coral responses to future environmental changes in the reef scale, the coral polyp model developed by Nakamura et al. (2013), which can well reconstruct the coral responses to ocean acidification, flow conditions and others, was incorporated into a reef-scale model based on a 3D hydrodynamic model (ROMS) following the Carbonate System Dynamics (CSD) model (Watanabe et al. 2013). The developed modeling system was applied to the Shiraho fringing reef, Ishigaki Island, Japan, and it was confirmed that the model system well reconstructed the spatiotemporal variations of the reef environmental parameters. A scenario analysis under several $pCO_2$ and sea-level conditions, following IPCC scenarios, was conducted by using the modeling system. The simulation results indicated that the coral calcification rate will decrease with increasing $pCO_2$. On the other hand, when the sea-level will increase, the calcification rate especially in the inner reef area will increase because both the mass exchange between the corals and their ambient seawater and that between inside and outside of the reef will be enhanced under higher flow conditions. When both $pCO_2$ increase and sea-level rise will concurrently occur, basically calcification rate will decrease due to ocean acidification effect, but only under the best case scenario (RCP2.6), calcifica-

tion rate in some inner reef areas will increase because positive effect by sea-level rise prevails against negative effect by ocean acidification.

CHALLENGES FOR CONSERVING PALAU'S CORAL COMMUNITIES BY P-CORIE (Abstract ID: 28123)

A joint research project called P-CoRIE (Palau Coral Reef Island Ecosystem) has started in April 2014 under the umbrella of JST/JICA SATREPS scheme. During the project, permanent quadrats were established and monitored at 14 sites pallalel to the temperature monitoring around Palau since 2014. The preliminary results from first two years showed that inner reef sites were predominated by massive Porites spp. while the outer or near-outer reef sites were mainly consisted by tabular or branching Acroporid corals. The average coral cover at the sites varied between <5% to >85% with most of the sites kept >70% coral cover. However, with site-by-site uniqueness, the coverage changed drastically in several sites within a few years period. In addition to the aspects of natural science field, we'll further discuss how we can utilize these results in terms of integration with social aspects of reef conservation.

THE IMPACT EXTENT OF REGIONAL ENVIRONMENTAL FACTORS IN THE RECOVERY PROCESS OF THE CORAL COMMUNITY IN TERRAINS ESTABLISHED VIA DIFFERENT GEOLOGICAL HISTORIES. (Abstract ID: 29135 | Poster ID: 414)

Okinawan coral communities (CCs) suffered catastrophic impacts in the large-scale bleaching event of 1998 and subsequent repeated bleaching events. The recovery processes of CCs varies by location. In more detailed observations, the degree of recovery of the microtopography of coral reefs within the same location is different. This difference is due to the interactions among the following elements; physiochemical environment, relationships with other organisms, and the ecology of coral itself. In many cases researchers have monitored the recovery process of some elements of CCs, but whole ecosystems have not evaluated. To undertake a comprehensive evaluation of ecological areas by performing a correlation calculation between elements, it is necessary to select the elements with the strongest impact. However, coral reefs have different development histories in each region, and for each microtopography, and current CCs reflects these histories as a succession. In succession of CCs, the degree of impact of each environmental factor is different. In our project, we evaluated the interaction of physical and chemical environmental factors and coral-associated bacteria, and attempted to evaluate the degree of influence of the environment on the coral and CC by analyses of coral-associated bacteria. First of all, we evaluated the impacts of environmental factors in the succession of CCs in different terrain environment. Physical factors were suggested to have the greatest effect on the determination of the recovery of community structure.

ELUCIDATING FOOD SOURCES FOR LARVAL STAGE OF CROWN-OF-THORNS STARFISH BY STABLE ISOTOPE ANALYSIS (Abstract ID: 29120)

It has been a center of interest for decades to understand the mechanism by which the crown-of-thorns starfish (COTs), *Acanthaster planci*, explosively increases their population in natural environments. One of the major hypotheses is that the increase in phytoplankton abundance induced by eutrophication of coastal waters contributes for their higher larval survival rate. However, such an explosive increase has been often reported without high phytoplankton biomass during their spawning seasons, implying that other organic particles like detritus could be their food sources. This study intended to elucidate food source(s) of the COTs larvae fed by size-fractionated particulate organic matter (POM). The incubation experiments were conducted for two weeks at Sesoko Island, Okinawa, Japan in July 2015, and the specimens were collected at each developing stages for stable isotope analysis. Most larvae fed POM smaller than 20 μm developed to either the late bipinnaria or the early brachiolaria stage, and their stable isotope ratios shifted to the similar values to those of POM. The larvae without POM degraded within a week, and their isotopic value did not change from those of unfertilized eggs. On the other hand, the larvae fed POM smaller than 2 μm did not develop beyond the early brachiolaria stage but succeeded to survive for two weeks, and their isotopic ratios also became similar to those of POM. Our results indicated that organic particles other than phytoplankton seemed to contribute for the survival and development of COTs larvae.

ANALYSIS OF THE DISTRIBUTION OF SPECIALIZED HERBIVOROUS REEF FISHES THROUGHOUT THE PACIFIC (Abstract ID: 30000 | Poster ID: 412)

The importance of niche width and specialization has been discussed for years, and the concepts are fundamental to ecological theory. Despite historic attention, questions still remain about the ways in which humans may be affecting specialization in coral reef communities. To explore this question, this meta-analysis examines how human impacts are shaping the composition of herbivorous reef fish assemblages on a Pacific-wide scale using fish abundance data for sites at over 40 islands collected by the Coral Reef Ecosystem Division (CRED) at the National Oceanic and Atmospheric Administration. Using diet data obtained from the literature, each species referred to as an herbivore by CRED is classified along a continuum of specialization. Comparing the abundance of fishes at each site to the human population within 200 km, as well as other variables (e.g., benthic cover, geographic location, human health and economic metrics), this study aims to determine which factors are most responsible for driving trends in the distribution and abundance of dietary specialists among herbivorous reef fishes in the Pacific. Understanding the characteristics of reef communities in which specialists thrive will assist in the identification of areas that may be particularly vulnerable to anthropogenic stressors.

SPAWNING AGGREGATION OF WHITE-STREAKED GROUPER*EPINEPHELUS ONGUS*: SPATIAL DISTRIBUTION, ANNUAL VARIATION AND SEX-SPECIFIC DIFFERENCE IN ARRIVAL TIMING (Abstract ID: 27824)

Groupers (family Epinephelidae) are an impor¬tant fishery targets in coral reefs. *Epinephelus ongus* is a major fishery target that forms spawning aggregations at specific spawning grounds in an Okinawa coral reef. The aims of the present study were to investigate the spatial distribution, annual variation and sex-specific difference in arrival timing of this species. Underwater observations were conducted at a spawning ground in the spawning season (May between 2011 and 2015) in Yaeyama Islands, Okinawa. Monthly observations were also conducted during non-spawning seasons (between November 2012 and October 2013). Six to ten 30-min time-transects were set to cover the entire area of the spawning ground. Digital images of the substrates were simultaneously recorded in order to examine any relationships between fish density and environmental variables. Ten replicated 20 × 5 m line transects were established to clarify the daily changes in the male and female density. No individuals were found during monthly survey in non-spawning seasons. In contrast, high density of *E. ongus* was found in the spawning season. Clear spatial variations in the density were found. The highest number (53.6 individuals per 100 m2 in May 2011) was found in one time-transect (defined as "core site"). There were few significant relationships between fish density and environmental variables. Annual variations in fish density at the "core site" were found in May between 2011 and 2015. Males showed earlier arrival and stayed longer at the spawning ground compared to females.

COMPARING DIFFERENTIAL DISEASE AND BLEACHING RESPONSES OF PACIFIC CORALS FROM LELEUVIA, FIJI AND MOOREA, FRENCH POLYNESIA (Abstract ID: 28531)

Increasing frequency and severity of coral bleaching events, often coupled with coral disease episodes, are degrading the health of coral reef ecosystems worldwide. Reefs will be differentially affected as coral taxa have varying susceptibilities to the two types of disturbance. To determine the relative susceptibility of different taxa over large spatial scales, coral bleaching and disease surveys were conducted at 10 sites in Leleuvia, Fiji (2013) and 9 sites in Moorea, French Polynesia (2015) during thermal anomalies. Overlapping photos were taken along belt transects at protected and fished sites in high and low energy settings to collect data on coral abundance and diversity while recording signs of stress such as bleaching and disease occurrence. Overall, Leleuvia showed slightly higher coral genera richness and diversity across habitats compared with Moorea. SIMPER (Similarity percentage) analysis clustered sites in Leleuvia in a single group and sites in Moorea in 2 major groups. Genera abundance within sites showed an

average similarity of 53.7% and 59.5% in Leleuvia and Moorea, respectively. However, between localities there was 52.1% dissimilarity. Average prevalence for bleaching and disease was slightly higher in Moorea (66%, 24.3%) than Leleuvia (8.2%, 7.1%). This distribution pattern was strongly influenced by Acropora, Montipora, Pocillopora, and Porites (cumulative contribution ~70%), indicating that these key genera have similar susceptibility to bleaching and disease over larger scales.

REEF FISH ASSEMBLAGES IN FISHED AREAS WITH MPAS IN TOURIST AND NON-TOURIST DESTINATION SITES IN SOUTHERN MINDANAO, PHILIPPINES (Abstract ID: 29450)

MPAs have shown significant contribution in maintaining species diversity and in some cases supporting sustainable fisheries in the Philippines. Known tourist destinations sites in the country also found to contribute for the protection of endangered species (e.g. Tubbataha Reefs Natural Park, Palawan for Cheilinus undulatus) and sometimes reducing fisheries threats (e.g. EL Nido, Palawan) thereby help in maintaining reef integrity. But in some cases, tourists were the source of reef destruction and increase in fisheries harvest because of the clamour for sea foods. In this paper, we hypothesize that tourist and non-tourist destinations sites have no significant impact on reef fish assemblages. Results indicated that presence of MPAs at least under level 2 (effectively strengthened/enforced) occupying no less than 10% of the total reef area has a greater positive impact on the fish assemblages (i.e. high species diversity, >20mt/km2 of fish biomass) compared to areas with <10% reef area as MPA even with the presence of tourists. Impact of reef fisheries found to have lesser influence due to almost the same fishing pressure for the areas examined.

STRENGTHENING LOCAL LINKS BETWEEN SCIENCE AND MANAGEMENT. BUILDING LOCAL STAKEHOLDERS INVOLVEMENT IN SCIENCE FOR CORAL REEF MANAGEMENT IN INDONESIA (Abstract ID: 29233)

Despite a plethora of coral reef studies in Indonesia, only a fraction of them are informing coral reef management. Thus, a rapid analysis was conducted in 2013 to identify the identify examples of success and failure and propose mechanisms for improvement. The analysis interviewed 75 respondents from 45 institutions and reviewed 5 marine national park strategic planning documents. We found that the need for science to support management is rarely expressed and often not well communicated by reef managers. The science generated in many cases is largely initiated or led by implementation partners (national/international NGOs or government projects). The study proposed a (1) strengthened structured collaboration between authorities, local strategic partners and implementation partners to identify information needs and develop appropriate studies; (2) its translation/integration into coral reef management; and (3) increased capacity building efforts. To ensure success, this needs to be supported by policies, regulations, and a clear exit strategy from implementation partners. A pilot project is being implemented in Buleleng Regency aiming at a development of coral reef science platform within the marine and fisheries agency (MFA) since 2014. In this early phase, MFA coordinate efforts from two implementation partners and local universities to identify and implement strategic coral reef research, provide expert support, and develop management recommendations based on sound science. The lessons from Buleleng would be used to strengthen the model and apply it to other places.

ARE ZANZIBAR'S REEFS UNDERGOING ECOLOGICAL CHANGE? FORAMINIFERA BIO-INDICATORS FOR MONITORING AND ASSESSMENT OF REEF ECOSYSTEMS IN THE WESTERN INDIAN OCEAN (Abstract ID: 28602)

The reefs of the Zanzibar Archipelago contain high biodiversity taxa and are key ecosystem service providers and resource base generating fisheries and tourist revenue for subsistence-based coastal communities. Zanzibar's reefs remain some of the least studied in the world and face increasing pressure from rapid coastal expansion of urban areas, development of tourist facilities, overharvesting and daily boat/tourist visitations. Here, we provide the first foraminifer community data; their contribution to reef carbonate production; and an assessment of the response of foraminifers to untreated urban wastewater pollution from Stone Town in nearby fringing reefs (Changuu, Bawe and Chumbe). Overall, we find: a high diversity assemblage (130 species) dominated by abundant key symbiont-bearing, large benthic foraminifers (LBFs), particularly Amphistegina spp.; high FORAM Index values ranging from 5.3 to 9.1; and a contribution of as much as 40 to 90 percent to carbonate sand production. Communities at Chumbe MPI are more stable than Changuu Reef, which has higher daily visitations. The concentration of nutrients derived from untreated wastewater from Stone Town is variable but low (< 0.8 umolL-1). However, an increase in urchins and predators (COTS) in reefs closest to Stone Town indicates continuous monitoring and management of benthic communities and water quality changes is needed to ensure long-term protection of Zanzibar's ecological integrity and natural resources. Foraminifera offer a good cost-effective monitoring and management tool for regular, effective assessments.

IMPACTS OF THERMAL STRESS ON THE PORITES SPP. CORAL-POPULATION DYNAMICS IN A SMALL PHILIPPINE EMBAYMENT (Abstract ID: 29056)

The increasing frequency of thermal stress has affected reefs in the tropical seas causing mass coral bleaching. In 2010 and 2013 the western Philippines experienced mass coral bleaching that affected the Porites coral populations, a coral considered to be resistant to many stressors and disturbances. In this study, we examine vital rates of Porites in a small bay in the western Philippines in order to evaluate the changes in the size structure before, during and after the 2010 bleaching event (i.e. the 2013). Photographic censuses were made from 2009-2013 for 658 Porites colonies from three fixed plots in each of four stations in the bay. Two of the four stations with bigger and denser colonies showed significant differences in the size structure of Porites before the 2010 bleaching and one station after the 2013 bleaching but not after the 2010 bleaching. The dominance of small colonies in all the stations was not due to recruitment but due to partial mortality and fission. The transition matrices indicated that the Porites population have declining population growth rates (lambda=<1). This suggests that the population was already in decline before the 2010 bleaching and exhibited further decline after the 2013 bleaching event. To reduce the vulnerability of Porites populations in the bay it would require reducing exacerbating threats in the face of more frequent thermal stress. This is to allow establishment of new resistant and persistent individuals into the population in order to enhance survivorship.

MANAGING CORAL REEFS FOR FISHERIES AND ECOSYSTEM RESILIENCE OBJECTIVES (Abstract ID: 27894)

On coral reefs, little work has examined the relative effects of fishing and other drivers, such as habitat change, on ecological fisheries indicators. In light of increasing habitat degradation, this lack of understanding limits the usefulness of indicators for monitoring the effect of fishery management actions. We examined the relative influences of a proxy of fishing pressure and the benthic habitat on 17 indicators that characterise attributes of the fish community important for fishery yields. We found that both habitat and fishing influenced indicators, but habitat effects were particularly strong. This knowledge provides managers with the capacity to implement an array of complementary management actions targeted at maintaining reefs in a coral-dominated state. Critically, these actions may be beneficial both for sustaining ecosystem structure and function, and for supporting characteristics of the fish community that underpin fisheries production. We then explored potentially useful management actions in this context. We examined the relative importance of herbivore biomass, functional diversity and size composition in supporting habitat recovery. We found that having both a diversity of herbivore functions and sizes was important for recovery. Maintaining a wide range of herbivore sizes requires that no size-class is disproportionately depleted by fishing. Balanced harvesting, where species are all fished in proportion to their potential production, would help achieve this and support both fisheries and ecosystem resilience outcomes.

UNEXPECTED CONTROLS ON REEF-BUILDING PROPERTIES OF CORALLINE ALGA POROLITHON ONKODES (Abstract ID: 29712)

Crustose coralline algae (CCA) play a vital role in structural reef-building. They form thick, hard crusts that binds reef skeletal material to form new reef substrate and can build extensive protective algal rims. Porolithon onkodes is the dominant species in the shallow high-energy environment of the fore reef. It has been presumed that their capacity to form a durable crust capable of persisting in the face of incessant high-energy waves is due to their calcified cell walls. We found that unexpectedly, it is secondary mineralization processes that enable the development of their thick, tough crusts. Using nanoindentation, a materials engineering analytical technique, to test the hardness and fracture toughness of the CCA we found that the presence of the mineral dolomite lining the cells, transforms the crust to a super-tough, fracture resistant material. In contrast, crusts without this extra mineral exhibited poor fracture resistance. A most surprising result was the role of endolithic erosive bacterial activity. Usually this is considered a destructive force, however, the nanoindentation testing revealed this to be a key constructive process in reef-building. The findings from this study, together with recently discovered chemical and bacterial erosion resistant properties of CCA dolomite, demonstrate that dolomite formation within P. onkodes is an essential process for modern structural reef development and persistence. Experimental work suggests that dolomite will continue to provide this reef-building service as CO2 rises.

RECORD OF CORAL REEFS STRUCTURAL CHANGES, CORAL BLEACHING IMPACTS AND RESILIENCE FACING CLIMATE CHANGE EFFECTS AT THE SIAN KAAN BIOSPHERE RESERVE (Abstract ID: 29833)

According to the last publication of the Caribbean Coral Reefs Status, three quarters of the locations studied until 2012 reduce their coral cover to half since 1970. In the other hand macroalgae triple its cover, finding in the latest years reefs in severe degradation. In the Mexican Caribbean Sian ka'an Biosphere Reserve (SKBR) is one of the largest areas in Mexico including coral reefs. A first description of the reef structure and condition was done in 1993. Some other studies evaluated the area after this date, however it was until 2011 when an specific monitoring program was implemented with monitoring sites at the back reef, shallow and deep fore reef. Here we analyzed the structural changes found in the reefs of the SKBR from 1993 to 2011 and changes in the reef ecosystem condition from 2011 to 2015. Although coral cover in 2015 register 16.9% without significant changes since 2011, results showed a reduction of coral builders that use to be dominant; it also showed an increase of macroalgae and coralline algae, increase of diseases presence and increase of bleaching episodes related with climatic anomalies. During 2013 recent mortaliy increased in sites near to the bays due to an atypical rainfall. Bleaching during 2015 (August-November) showed an increased in extent and intensity affecting more tan 50% of the coral colonies registered in all sites monitored. With five years data of the monitoring program, including water quality information, we were also able to run a resilience analysis for the monitoring sites for management porpouses.

INDIGENOUS CLASSIFICATION AND UTILIZATION OF THE RED SEA BLACK CORAL (Abstract ID: 28331)

Precious materials, such as red and black coral, have gained in value because they are natural organic resources living in the deep-sea environment, which, for a long time, have presented humans with considerable difficulties in collecting them. Despite their economic and cultural importance, little is known about the basic biology and ecology of black corals (Cnidaria: Anthozoa: Hexacorallia: Antipatharia) because most species inhabit deeper-water environments (>50 m), which are logistically challenging to study (Wagner et al. 2012). In the Red Sea area, black coral has been known to, and valued by, local people for a considerable period. The axial skeleton of black coral is formed by a brown or black extremely hard proteinaceous material which, when cut and polished, is used for making jewelry and prayer beads (Vine 1986). Prayer beads made of black coral are known as "yusr", an Arabic word meaning "ease" or "well-being". Based on my field study in Sinai, Egypt, fishermen of the Red Sea viewed black corals as living creatures because they wrapped themselves around the men when they moved close to the coral. The fishermen shaved their bodies and removed all their clothes before diving and recited the "basmalah" when cutting the coral. Humans believed they could only reach the precious material, and overcome their fear of water, when they invoked divine protection. There is an undersea world that lies out of reach of the knowledge and activities of helpless humans, even though it is included within the range of marine resource conservation or ecosystem-based management.

THE XL CATLIN SEAVIEW SURVEY: MEASURING BLEACHING AND COMMUNITY RESPONSE IN HAWAII IN 2015 WITH HIGH-DEFINITION IMAGING AND SEMI-AUTOMATED IMAGE PROCESSING (Abstract ID: 28886)

Coral reefs worldwide are suffering dramatic declines, with an estimated 40% of coral reef habitat degraded within the last 50 years due to a suite of factors, including pollution, overfishing, destructive fishing and climate change. This degradation will affect the ~500 million people globally who utilize coral reefs for food, tourism income and coastal protection, along with the potential future losses to the still partially unknown biodiversity of these ecosystems. The XL Catlin Seaview Survey is a multiyear program creating a baseline record of coral community composition over 150 worldwide coral reef locations, using multi-camera, high-resolution, panoramic underwater imaging. These images are processed by a novel, computer-vision driven, automated benthic image analysis system capable of producing summary statistics of population and community composition in less time than manual annotation. We deployed this camera system in Maui, Hawaii to measure community response and bleaching rates before and during the autumn 2015 bleaching event, and will present a summary of these methods and findings.

CORAL RESTORATION FOUNDATION: A 15 YEAR STUDY IN BUILDING A LARGE SCALE, REPLICABLE RESTORATION MODEL (Abstract ID: 29957)

Coral reef ecosystems are declining worldwide due, ostensibly, to direct and indirect anthropogenic stressors. The Caribbean reef biota's decline has been further accelerated by loss of keystone species, principally Diadema antilarum, widespread coral disease, and successive, regional bleaching events, each confounding the accelerated loss of crucial reef building corals: Acropora sp. Although water quality in many regions remains suitable for coral growth and reef development, reef ecosystems continue to collapse – or not recover – due to low coral recruitment or an inability for new recruits to become established. During the last 20 years various coral propagation and reef restoration techniques have been explored and refined. Some of these projects led to the development of community-based restoration programs that have had varying degrees of success and persistence. The transference of any such project from proof-of-principal to a regional restoration program faces challenges of scalability and sustainability. At the Coral Restoration Foundation we set out to develop a large scale, community based program. Integrating restoration, science and education programs we have built a model that is scalable, suitable of generating and planting large numbers of corals, and integrates community-level volunteers and partners in an active, self-sustaining manner. Now, 15 years following our origin, we present a complete overview of our methodologies, lessons learned, successes and how the model has been adopted in various partnerships and stand-alone programs internationally.

TROPICAL ECOTOXICOLOGY FOR OIL AND GAS (Abstract ID: 29243)

Risks posed by oil spills to coral reefs are difficult to evaluate, primarily due to the absence of studies adequately assessing toxicity to relevant reef species. Furthermore, comparison of the available data is impractical owing to fundamental inter-study differences including: oil types; inclusion of chemical dispersants; methods of preparing water accommodated fractions; durations of exposure and accurate quantification of toxic aromatic hydrocarbons. Here we present a model ecotoxicological workflow for laboratory exposures of tropical reef species to oil and gas contaminants for use by regulators, managers and industry. To illustrate this approach, a series of experiments with coral and sponge larvae is presented to compare the toxicity of light crude oil in the presence and absence of UV

and to compare the toxicity of a range of chemical dispersants to coral larvae. We also present the development of species sensitivity distributions using tropical taxa to progress water quality guidelines for oil and gas contaminants. Whilst traditional ecotoxicology incorporates ecologically relevant endpoints including reproduction, growth and mortality; we show how molecular level responses are also emerging as sensitive indicators of exposure impact. With increasing oil and gas extraction, shipping and coastal development, incorporation of standardised and relevant ecotoxicological methods will be critical to inform spatial risk assessments, management decisions, guidelines, policy development and ultimately the protection of high conservation value coral reefs.

CORAL REEF RESTORATION THROUGH MANAGEMENT OF THE ALIEN INVASIVE THROUGH THE USE OF MECHANICAL REMOVAL AND BIO-CONTROL EFFORTS (Abstract ID: 28944 | Poster ID: 472)

For several decades, invasive macroalgae (Acanthophora spicifera, Gracilaria salicornia, Kappaphycus spp., Eucheuma denticulatum) have posed a serious threat to coral reefs in Kaneohe Bay, Hawaii. To address this ecological threat a consortium of researchers and managers developed a novel approach to control invasive algae by combining mechanical removal and biocontrol techniques. Invasive algae are manually removed by divers equipped with an underwater vacuum system. Then, hatchery-raised native sea urchins (Tripneustes gratilla) are outplanted to graze remaining holdfasts and control algae re-growth. These techniques have been evaluated at the experimental level, but have not been thoroughly tested at the reef-wide scale as a management technique. Here, we conducted benthic surveys on two patch reefs and two control reefs in Kaneohe Bay and tested the effectiveness of mechanical removal and biocontrol of invasive algae in a natural reef ecosystem. We analyzed the change in percent cover of invasive algae before (2011-2012) and after (2014) algae removal and urchin outplanting. Mechanical removal and biocontrol reduced invasive algae percent cover by 85%. Our results show that mechanical removal in combination with sea urchin biocontrol is an effective management approach for controlling invasive algae at the reef-wide scale.

PELAGIC BIOGEOCHEMISTRY OF SHALLOW CORAL REEFS IS DISTINCT FROM THE SURROUNDING OCEAN (Abstract ID: 29864)

The persistence of productive coral reefs in relatively oligotrophic waters of the surface tropical oceans implies that reef ecosystems retain and recycle nutrients such as nitrogen, phosphorus and organic carbon. Describing the nutrient regime of reef waters is important for understanding reef metabolism and productivity, but measuring and differentiating biogeochemical parameters of reef waters from the surrounding ocean requires high resolution sampling and analytical precision. We used an unprecedented opportunity to conduct a high-resolution synoptic oceanographic profile survey of the offshore and nearshore reef waters surrounding Mo'orea, French Polynesia to couple a suite of biogeochemical measurements with physical oceanographic parameters and detailed bathymetric mapping. We established consistently significant differences between backreef and offshore surface waters in a suite of biogeochemical parameters, with elevated concentrations of inorganic nutrients (nitrate, ammonium and phosphate) and depleted concentrations of dissolved organic carbon and bacterioplankton in the reef water column. We also show that reefs maintain a unique signature of fluorescent dissolved organic matter composition enriched in humic and protein components. By sampling the circumference of the island we captured onshore-offshore patterns across very different wave energy regimes and benthic community structures, and we present our biogeochemical data in the context of both synoptic and long term understanding of the physical forcing and community ecology of reefs around Mo'orea.

INTEGRATION AND ALLOMETRY CONSTRAIN CARIBBEAN OCTOCORAL MORPHOLOGY (Abstract ID: 28828)

As stony corals continue to decline in abundance, there is interest in the potential of other macroinvertebrates, such as octocorals, to play a stronger role in the structure and function of future reefs. While it is well known that arborescent octocorals exhibit complex geometries with variation at the polyp, branch, and colony level, the factors constraining colony morphology remain unclear. To examine the role of integration among traits and allometry in controlling variation within and among Caribbean octocorals species, we compared five morphological traits (colony height, branch length, branch thickness, number of branches, and polyp density) among eight species of the common octocoral *Eunicea*. Principal components analysis (PCA) revealed that some traits were tightly correlated, with variation in morphology between species constrained to a linear gradient. This gradient was comprised in one direction of species with many, thin, short branches with a high polyp density, and in the other direction with species having few, long, thick branches with a low polyp density. Interestingly, this gradient was independent of the effects of colony size on octocoral architecture. Morphological traits either didn't scale with colony size (e.g., polyp density, branch thickness) or scaled allometrically with size in such a way that the differences in morphology between species were maintained along the aforementioned gradient. Differential scaling of traits among species may drive species coexistence by allowing species to exploit different resources in the same place.

CONTINUOUS IMAGING FLOW CYTOMETER – FLOWCAM - FOR THE STUDY OF PHYTOPLANKTON (Abstract ID: 29617 | Poster ID: 528)

Responding to the need for the "rapid counting and measurement of individual plankton cells in natural populations", researchers at the Bigelow Laboratory for Ocean Sciences in 1999 developed an imaging flow cytometer (FlowCam) designed specifically to support aquatic microbial research. Over the past 15 years over 300 FlowCAMs in 50+ countries have been put to use for the purpose of the study and monitoring of microorganisms in both fresh and marine systems. Building upon advances in technology, input from the user community, and expanded resources, engineers at Fluid Imaging Technologies, manufacturer of the FlowCAM, have transformed the FlowCAM of 1999, and now build an instrument that is vastly improved when compared to the first unit built. We present here a brief evolution of the FlowCam, focusing on the current state of the instrument's technology, with particular emphasis on new capabilities of the FlowCam's software to with regard to image recognition, classification of taxa, and estimation of plankton biovolume.

SEAFOOD CONSUMPTION PATTERNS IN FISHERY-DEPENDENT HUMAN COMMUNITIES: ECOLOGICAL RELATIONSHIPS IN A CORAL REEF SOCIO-ECOLOGICAL SYSTEM (Abstract ID: 30038)

The human inhabitants of Falalop, Asor, Mogmog and Federai (Ulithi Atoll, Yap State, Federated States of Micronesia) enjoy differing levels of access to fishable reefs and imported goods. The health of their coral reefs and the abundance and community composition of associated fishes also vary. We sought a better understanding of the relationship between the status of these resources and fishing activities on these four islands. We also sought insight into reports of food insecurity. To complement underwater surveys of reef fish populations and fishery landings data, we tracked seafood consumption in 53 households over a 28 day period using a calendar that enabled participants to record meals at which seafood was consumed, the seafood source, fishing activity and the distribution of seafood captured but not consumed by that household (i.e., shared with other households or shipped off the atoll). We found significant differences in the frequency of seafood consumption within and between communities at least partially attributable to the health of community-controlled reefs and their associated fish stocks. The health of these resources and their ease of access were reflected in patterns of seafood consumption as well as the frequency and characteristics of fishing activities. Fishing prowess and access to resources, but not household size, affected sharing of resources. Coral health, fish abundance, and food security co-vary on Ulithi Atoll; seafood consumption estimates offer a powerful new perspective on the ecological relationship between reefs and human communities.

THE STRUCTURE OF FISH ASSEMBLAGES ON RESTORED AND UN-RESTORED CORAL REEF HABITATS IMPACTED BY SHIP GROUNDINGS (Abstract ID: 29929)

We conducted an experimental study using both B.A.C.E. and comparative designs in order to evaluate how fish assemblages responded to active coral reef restoration work at two large ship grounding sites in Guayanilla, Puerto Rico. Restoration of the impacted coral reef habitat involved out-planting of*Acropora cervicornis* from nurseries to restore areas where the reef topography was flattened. Also emergency restoration was conducted to salvage detached corals, octocorals and sponges to recover lost habitat from groundings. Data on reef fish density, species diversity and size structure were collected from four experimental treatments: *A. cervicornis* outplants, emergency restoration areas, non-restored impacted areas and reference natural reef habitat including A. cervicornis thickets. The benthic community at each treatment was sampled to evaluate correlations between the fish assemblage, sessile biota and rugosity. Fish assemblages within restoration sites were more similar to reference sites than un-restored treatments. *Acropora cervicornis* restoration sites exhibited a temporal change in fish habitat utilization and had a higher relative abundance of early juvenile life stages of reef fishes. These results provide information for understanding the dynamics of reef fish habitat value related to coral reef restoration efforts.

APPLICATION OF ACOUSTIC TELEMETRY TO ADVANCE SCIENTIFIC UNDERSTANDING AND INFORM MANAGEMENT OF SPECIES THAT FORM SPAWNING AGGREGATIONS IN THE US VIRGIN ISLANDS (Abstract ID: 29527)

Acoustic telemetry has provided new insights into the movements of aquatic organisms. Drivers of animal movements can include foraging, reproduction and ontogeny that can encompass multiple habitats and various spatial scales. Environmental variability is a fourth driver of movement that has become more important as climate change intensifies. This paper reports on the dynamic application of acoustic telemetry as an essential tool to discover novel behaviours that advance scientific understanding and inform management. Emphasis will be placed on several fish families that migrate to spawning aggregation sites or forage across various habitats (i.e. Epinephelidae, Lutjanidae, Megalopidae, Scaridae) and how acute environmental change may modify behavioural patterns.

MORE THAN JUST A PRETTY MANTLE: THE ECOLOGICAL SIGNIFICANCE OF GIANT CLAMS IN CORAL REEF ECOSYSTEMS (Abstract ID: 28243)

Giant clams are large and colourful bivalves closely associated with Indo-Pacific coral reefs. They are thought to play various ecological roles but these have not yet been fully elucidated. In this study, we show how giant clams are important providers of food and shelter, and function as reef builders and shapers. Giant clam tissues are attractive to predators and scavengers, while opportunistic feeders exploit their discharges of live zooxanthellae, faeces and gametes. The shells of giant clams provide hard substrate for colonization by epibionts, while various commensal and ectoparasitic organisms live within their mantle cavities. Populations of giant clams can enhance the topographic relief of reefs, act as reservoirs of zooxanthellae, and potentially counteract eutrophication via water filtering. Lastly, giant clams can produce large quantities of calcium carbonate shell material that eventually becomes part of the reef framework. As with many benthic species, giant clams are facing pressures of overfishing and habitat loss, resulting in extirpations that are likely to affect coral reefs negatively. Identifying the ecological roles of giant clams is an important step in strengthening the case for their conservation.

SYMBIODINIUM DIVERSITY IN PORITES COMPRESSA FOLLOWING A NATURAL BLEACHING EVENT (Abstract ID: 29747 | Poster ID: 356)

Climate change has led to increases in coral bleaching worldwide. The question of why corals expel their symbiotic zooxanthellae (Symbiodinium) has been studied from the perspective of the coral host as well as the symbiont. While progress has been made toward understanding the physiological and cellular mechanisms that cause bleaching, Next-generation sequencing (NGS) permits further investigation of genetic explanations for variations in bleaching response across the entire genome. This work is focused on identifying genetic factors from the coral genome that are associated with bleaching variation, as well as the composition of Symbiodinium communities within corals during and after bleaching. To address the question of Symbiodinium clade composition, we compared Symbiodinium in colonies of Porites compressa that varied in their response during the 2014 bleaching event in Hawaii. Although other species of Porites have been shown to host thermally-tolerant clade D zooxanthellae, previous studies have found that P. compressa only host a single clade (C), even among colonies in habitats that have a history of high temperatures. For this work, we genetically analyzed colonies of P. compressa sampled from October 2014 through November 2015 from four sites in the Main Hawaiian Islands. Our approach is to use restriction site-associated DNA sequencing (RADseq) to analyze genomes of the coral holobiont and identify symbiont clades, and we will discuss progress in using NGS to characterize symbiont diversity among colonies with different bleaching phenotypes.

TEMPERATURE AND SALINITY EFFECTS ON THE ONSET OF SYMBIOSIS BETWEEN *ACROPORA VALIDA* AND VARIOUS SUBCLADES OF*SYMBIODINIUM* (Abstract ID: 30017)

Larvae of most broadcasting corals do not contain symbionts. They have to establish symbiosis by uptaking symbionts from the environment. This process is likely to be affected by environmental factors. To study the possible consequences of global climate change on coral-algal symbiosis establishment, *Acropora valida* recruits were exposed to different temperatures (24, 27, 30 and 32°C), salinities (22, 27 and 32psu) and symbiont treatments (subclades C1, C15 and D symbionts). The success of symbiosis establishment was recorded in terms of infection percentage and visual ranking on symbiont density. Results showed that all the three symbiont types could infect *A. valida* recruits, with symbiont D showing the highest infection percentage in the first three weeks, though only C1 could be found in local adult *A. valida*. High temperature impaired infection ability of C1 and C15 but not D. Lowered salinities showed little effect on infection percentage. Recruit mortality was also monitored. D-infected recruits showed no significant difference in mortality from C1-infected recruits under elevated temperatures. Clade D symbiont has been reported to be less photosynthetically efficient and contributed to lower growth rate in coral juveniles. So the result of this experiment suggested that increasing seawater temperature may drive the coral recruits to form symbiosis with less favorable symbionts and thus affect the growth of the next generations of corals in the future. This project is supported by RGC-GRF 460013.

BIODIVERSITY OF GIANT CLAMS (TRIDACNIDAE) IN THE SPERMONDE ARCHIPELAGO, SOUTH SULAWESI, INDONESIA (Abstract ID: 29738 | Poster ID: 52)

Wild population of clams under family of Tridacnidae has been declined and even gone to extinct in some areas of Indonesian water. For that reason, there is a strong need to determine its current condition in the Spermonde Archipelago. The study was conducted on 11 islands that represent three zones of Spermonde Archipelago using Belt Transect method. The results are presented descriptively in the form of tables, figures and graphs. There are four species of clams (Tridacnidae) found in the research area, namely Tridacna crocea, T. maxima, T. squamosa, and Hippopus porcellanus. The highest density was found on the island of Lumu-Lumu, Barrang Lompo, and Bone Tambung respectively. The shell size of T. crocea found dominantly in a range of 1-3 cm and 3-6 cm. In contrary, T. maxima are dominated by population with shell size 7-10 cm and 4-6 cm, while the phase of juvenile shell size 1-3 cm and 11 cm in the population were found in low density. T. squamosa population is dominated by larger shell size (70-20 cm) while size 1-3 cm is rarely found. This implies that the rate of recruitment and reproduction of T. squamosa is very small, which most probably caused by the reduction of adult population in the wild.

DISEASE ECOLOGY AND TRANSMISSION PATTERN: A CASE STUDY OF BROWN BAND AND BLACK BAND DISEASE ON THE GREAT BARRIER REEF (Abstract ID: 28021)

Managing diseases in nature requires understanding how pathogens are transmitted among hosts. We summarise field and aquarium studies aimed at understanding transmission patterns and vectors of black band disease (BBD)and brown band disease (BrB), two coral diseases on the Great Barrier Reef. In aquarium studies testing the vector potential of two corallivores, the butterflyfish *Chaetodon plebeius* and the snail *Drupella* sp, we found that chaetodontids did not transmit either disease, even when fish fed directly on both infected and healthy nubbins for extended periods of time. In contrast,*Drupella* transmitted BrB to healthy corals in 40% of cases; however, the snail was unable to transmit BBD. Although we observed selective predation by chaetodonids on BBD and BrB lesions, we found no evidence that removal of pathogens by butterflyfish decreased disease progression rates. These results demonstrate that fish are unlikely to influence the dynamics of these diseases, either by slowing disease progression rates or by increasing pathogen transmission among corals. *Drupella* snails however, have the potential to transmit BrB between coral colonies in the field, but not BBD. A 2-year field study of temporal patterns in the spatial distributions of BBD and BrB confirmed that both diseases behaved as infectious diseases, clustering in restricted areas of the available space. Collectively these results indicate that pathogens are transmitted from a source colony to adjacent hosts, possibly with the help of vectors such as *Drupella* snails.

LEPTASTREA PURPUREA: A POSSIBLE MODEL ORGANISM FOR CORAL REPRODUCTION AND PHYSIOLOGY (Abstract ID: 28762 | Poster ID: 173)

Sexually produced larvae are used in various fields of coral research. Because the vast majority of scleractinians reproduces only once or a few times a year and an ex-situ spawning induction is still very hard to achieve, obtaining planula larvae is still very labor intensive. Larvae of brooding corals can be used but are oftentimes clonal and differ in various traits, e.g. settlement behavior, from most spawning corals. Other cnidarians, such as Aiptasia spp. have been substituting scleractinians as model organisms in coral research. Admittedly, the transferability of conclusions obtained from these species can be questionable. This study examines the potential of Leptastrea purpurea as a reliable source of larvae for coral research. L. purpurea is a small (approx. 10 cm) encrusting faviid coral that occurs from the Red Sea to Easter Island. It is common on reef flats and can also be found in depths of up to 30 m. Larval output throughout the year as well a1s settlement behavior of planulae was investigated with corals from Guam. Our results show that L. purpurea releases larvae in a nonperiodic manner allowing permanent access to planulae. The settlement behavior of L. purpurea is similar to many spawning species which increases the transferability of conclusions. We discuss the aptitude of L. purpurea for research on scleractinian physiology, reproduction and ecology and conclude that L. purpurea is an adequate candidate as model organism that could accelerate progress in many fields of coral research.

BULELENG MARINE MANAGE AREAS NETWORK DEVELOPMENT. JUST DO IT. LESSON ON HOW TO INITIATE MARINE MANAGE AREA (MMA) WITH LOCAL RESOURCES (Abstract ID: 28672 | Poster ID: 679)

Buleleng Regency is working on establishing an MMA network of 14,000 ha. The network was design to include already established local MMAs : Pemuteran, Les, Bondalem, Tejakula, Penuktukan villages. Local stakeholders that have specific interest on conservation led the initial development of the MMAs: the tourism sector in Pemuteran, and fishing communities in other villages, in partnership with NGOs. It is important to note that the MMAs were initiated under significant resource support from the communities. The NGOs mainly focused on structuring the community's work, building collaboration within them, and bridging them to strategic partners. The NGOs also connect themself to share program and resources. Buleleng government has been embracing the effort consistently over time with policy support, financial resources, and dedicated staffs. They actively involved MMA's community management bodies in the process. This builds a significant leverage to the conservation. Interests from community are increasing, more partners are connected and supports are rising. Third party funding for Tejakula were US0$ in 2008. In 2009, it raised to US$39,917. In 2016, at least 8 NGOs are partnering with government and local community to support the MMA network development. Buleleng has shown that to develop an MMA, we can rely on local resources. This is not only economically efficient, but also create independency. Thus, it gives a higher assurance of a development of a strong and sustainable adaptive co management system.

DIVERSITY OF GORGONIANS AND GAMETE DEVELOPMENT OF GORGONIAN, DICHOTELLA GEMMACEA IN THE UPPER GULF OF THAILAND (Abstract ID: 29681 | Poster ID: 53)

Gorgonian is one of the most abundant organisms, and has an important role in coral reef ecosystem. In this study, the diversity of gorgonians at Laem Pu Chao, Amphoe Sattahip, Chon Buri Province in the upper Gulf of Thailand was investigated. In addition, the gamete development of Dichotella gemmacea was observed. The results showed that a total of nine genera of gorgonians, i.e. Ctenocella, Dichotella, Echinogorgia, Euplexaura, Junceella, Melithaea, Menella, Rumphella, and Subergorgia were found in the area. From the field observations, the gametes of Dichotella gemmacea in all stages were found year around. However, high maturity stages were recorded from August to September.

SURVIVABILITY OF JUVENILE CORAL IN THE VICINITY OF A SHALLOW WATER THERMAL VENT (Abstract ID: 28989 | Poster ID: 375)

Ocean acidification is a decrease in pH and carbonate ion concentration of the seawater as a response to rising atmospheric carbon dioxide, which expected to have a negative effect on the reef-building corals and calcifying marine organisms. Thus, we evaluated the growth characteristic of juvenile corals in the naturally acidified water of a thermal vent at Pulau Weh, Indonesia. The dominant juvenile corals that were selected for observation were from the genera Acropora, Pocillopora and Porites. The field survey showed a general decrease in the growth and skeletal structure along a decreasing pH gradient, whereby significant effect were observed among juvenile corals that were exposed to pH value 7.7. Growth rate of juvenile corals decreased 20-40% over the study period at the lowered pH condition compared to control condition. The study suggests that juvenile corals at acidified water record a slower growth and a porous skeletal structure. However both field and laboratory experiments will provide a better insight on the susceptibility of coral facing the changing climate particularly ocean acidification.

A RESEARCH FRAMEWORK FOR RESOLVING NICHE DIFFERENTIATION AND SPECIALISATION IN SYMBIODINIUM (Abstract ID: 28879)

The genus Symbiodinium comprises a group of free-living marine dinoflagellate species that have radiated extensively into an endosymbiotic niche. Symbiodinium act as corals' 'solar cells' and ultimately supply a significant portion of all energy used in the formation of tropical reef ecosystems. Vast genetic diversity, heterogeneous populations in symbiosis, and cryptic stages in the life-history (e.g. free-living, sexual reproduction, and endolith formation) make Symbiodinium exceptionally difficult to study and hence coral-Symbiodinium life history dynamics are not currently considered within models of reef-health. Using previously unpublished data of Symbiodinium biology, including: genome size estimation; cell viability ex hospite; interaction with microhabitats as free-living cells; and identification of key traits unique to cryptic stages of the life history; we propose a framework critically needed to expand perception of Symbiodinium functional biology. This new framework will classify variations in life history (e.g. obligate symbiont, transiently free-living, concurrently free-living, or exclusively free-living), thus providing context for specialisation in symbiosis, or alternatively, selection pressures that promote alternative, ex hospite niches of Symbiodinium cells via their free-living phase. Detecting where Symbiodinium lineages are positioned on these evolutionary pathways is ultimately needed to attain a system-wide epidemiology for reefs facing climate change and will isolate 'best candidates' for assisted evolution and reef restoration-based management.

DIVERSITY AND EXTREMELY HIGH ABUNDANCE OF PICOCYANOBACTERIA IN THE TROPICAL LAGOON WATERS OF TONGA (Abstract ID: 29963 | Poster ID: 49)

Flow cytometry enumeration method and high-throughput bar-coded pyrosequencing technique for 16S-23S internal transcribed spacer (ITS) sequences were applied to elucidate spatial changes of picocyanobacterial abundance and diversity in the near

coastal tropical waters of Tonga in November 2013. The samples were collected from 57 stations around Tongatapu Island, main island of Tonga. In most stations, *Synechococcus*was the most abundant picophytoplankton, ranging widely from 0.03 to 150.2 x $10^4$ cells/ml. On the contrary, *Prochlorococcus* abundances ranged from n.d. (not detected) to 7.2 x $10^4$cells/ml. The extremely high *Synechococcus*abundances over $10^6$cells/ml at the upper bay around Fanga'uta Lagoon indicated that there is huge nutrient input from rural and agricultural area to support the high phytoplankton biomass. In addition, dominance of*Synechococcus*clades II, III and VIII in this area suggested that they also actively grow in high nutrient conditions as well, despite clades II and III were known to be dominant in relatively oligotrophic coastal waters. However, in most lagoon waters, *Prochlorococcus* was not detected due to the oligotrophic nature of *Prochlorococcus*. These results suggested that habitat characteristics of the tropical lagoon drive variability in picocyanobacterial diversity. Such tropical lagoon environment might provide an appropriate location for carrying out studies on ecological niche of picocyanobacterial ecotypes.

ARAGONITE SATURATION IN A FRINGING REEF IS STRONGLY INFLUENCED BY OCEANIC CONDITIONS: CABO PULMO, MÉXICO. (Abstract ID: 29724 | Poster ID: 378)

Ocean acidification studies indicate that aragonite saturation (Ωar) will decrease with potential negative effects on reef ecosystems. Reef morphology controls the residence time of seawater, allowing physical or biological control over CO2-system. We test if the CO2-system in a fringing reef is controlled by ocean conditions. Monthly discrete samples were collected from September 2012 to August 2013, pH and dissolved inorganic carbon were used to calculate Ωar. A SeapHOx sensor was deployed in November 2013 to June 2014, at 15m depth and 30min sampling rate. pH was calibrated with discrete samples. This reef has direct communication with ocean, so discrete sampling showed that advection controlled the CO2-system, with presence of Gulf of California Water (GCW,Ωar=2.8±0.1) during winter and Tropical Surface Water (TSW,Ωar=3.2±0.3)the rest of the year. Optimal conditions for coral calcification occur in summer, with 0.5 Ωar between seasons. Sensor data showed a similar seasonal pattern plus the California Current Water, were water-mass intrusions corresponded to oceanic processes. TSW-GCW transition caused a 0.54Ωar decrease. Seasonal presence of water masses indicate a strong oceanic influence, and along with tidal forcing, not allowed to detect dissolution-calcification signals. Our results suggest that: a) fringing reefs might suffer the effects of acidification compared with barrier reefs which modify seawater; b) coral communities in fringing reefs are adapted to a variable Ωar, so it is feasible that predictions of decreasing pH have no direct effect on calcification.

THE NEURAL CIRCUITRY OF PAIR BONDING IN A COMMON BUTTERFLYFISH, CHAETODON LUNULATUS (Abstract ID: 27772 | Poster ID: 505)

While the adaptive significance of coral reef fish social systems is well explored, little is known about their neural basis. Here, we investigated the neurobiology of pair bonding in the monogamous butterflyfish, *Chaetodon lunulatus*. We focused on four neurochemical-receptor systems involved in mammalian pair bonding, including the oxytocin-like receptor, isotocin (ITR); arginine vasotocin V1a receptor (V1aR), dopamine D1 and D2 receptors (D1R, D2R); and the mu-opioid receptor (MOR). To functionally test the involvement of these receptors in promoting pair bonding, we treated paired males with receptor antagonists, which blocked pair bonding behavior. To then examine what brain regions might be involved in this effect, we compared gene expression of these receptors within brain regions between paired and solitary individuals. We found that pair bonding was associated with higher ITR and V1aR gene expression within the Vv/Vl in females but not males, and lower D1R, D2R, and MOR gene expression within several regions that mediates social and reward behavior, including the Dm, Dl, Vs, POA, Vc, and TPp, in both sexes. Our results generate insight into the neural circuitry of teleost pair bonding. More broadly, they show that the neural chemical and anatomical components of butterflyfish pair bonding appear similar to those of mammals, suggesting that the convergent evolution of vertebrate pair bonding has relied on repeatedly co-opting an ancient neural circuitry established in early vertebrates.

THE HERBIVORE-ALGAE-CORAL INTERACTION AND RESILIENCE OF CORAL REEFS: DIADEMA FACILITATE REEF RECOVERY IN TAIWAN (Abstract ID: 27977 | Poster ID: 669)

The current status (2012–2014) of three key functional groups (corals, herbivores, macroalgae) was examined at three representative coral reefs (Kenting, Lanyu, Lyuado) in Taiwan. Results highlighted strikingly low densities of both herbivorous fishes and herbivorous gastropods at all of the coral reefs, suggesting their loss of function as herbivores. Instead, sea urchin, Diadema spp. now became the key herbivore in the coral reefs, enhancing coral juvenile density, and hence coral resilience in the Taiwanese coral reefs. No correlation was observed between macro-algal covers and coral juvenile densities, suggesting that it would be not macro-algae but smaller algae (turf algae) that negatively affect the coral resilience in the Taiwanese coral reefs. Given the abundance and the impact of Diadema, the Diadema herbivory should be proactively incorporated into management planning of coral reefs in Taiwan. In parallel, revival of functional redundancy in herbivores would be urgently needed in order not to repeat the same tragedy happened in the Caribbean, causing the regional decline of coral reefs by the mass mortality of the then dominant herbivore Diadema.

CONTRASTING EFFECTS OF BENTHIC ALGAE ON THE CORAL MICROENVIRONMENT (Abstract ID: 29312)

Although a shift from coral to algal dominance has been documented on reefs around the world, the consequence of such transition for the coral microenvironment is poorly understood. We characterised the oxygen microenvironment at interaction zones between the massive coral Porites and different benthic functional groups using microsensors in a flow cell chamber and compared our results with observed interactions in the field in Moorea, French Polynesia. Turf algae, macroalgae and cyanobacteria were successful competitors against Porites. Their interaction zones exhibited a thick diffusive boundary layer (DBL) and large diel oxygen fluctuations, with anoxic or close to anoxic conditions at night. In contrast, Porites competed better against crustose coralline algae and conspecifics. Their interaction zones had a thin DBL and low diel oxygen fluctuations, with less reduced oxygen concentrations at night. Experiments with turf algae showed that the anoxia at the interaction zone during the night was suppressed by antibiotics, demonstrating that it is mediated by microbes. In addition, DBL thickness at the interaction zone decreased with increasing flow and when Porites was upstream of algae. Our data suggest that shifts towards algal dominance, particularly turf algae, macroalgae and cyanobacteria, create microenvironments which favor the accumulation of harmful metabolites and microbes at the interaction zones between corals and algae, potentially causing coral loss. These effects will be mediated by flow speed and direction.

TEMPORAL DISTRIBUTION ANALYSIS OF PARROTFISH AND SURGEONFISH IN "PARQUE NACIONAL ARRECIFES DE COZUMEL" MEXICO (Abstract ID: 29815 | Poster ID: 228)

Parrotfish and surgeonfish are two of the largest and most conspicuous families of herbivorous fish in the Mesoamerican Barrier Reef System (MBRS). They are a key component in structuring the benthic communities of coral reefs, mainly controlling the algae overgrowth. We evaluated the herbivorous fish assemblage, coral and algae (turf and macroalgae) cover in six fringing coral reef systems in the "Parque Nacional Arrecifes de Cozumel" (PNAC) along 30 m transects at depths of 10 to 15 m, from 2005 to 2011. The relative abundance of fish was variable among reefs and between years: surgeonfish decreased considerably (67%),parrotfish also decreased (50%). The dominant species of herbivorous fish in all reefs of the PNAC were*Acanthurus coeruleus*, *Sparisoma viride* and *Sparisoma aurofrenatum*. The results also showed that through years the cover of coral and algae were inversely proportional in nearly all reefs. There is a positive relationship between the most dominant species of herbivores in the presence of algae. Macroalgae and turf algae increased significantly per reef, while coral cover decreased significantly among years. A proportion of variations per reef in relative abundance of herbivores, coral and algae cover suggest that every reef has a unique biological (coral-benthic algae-herbivorous fish) assemblage. There is evidence that the temporal distribution of parrotfish and surgeonfish among years, affect the coral and benthic algae cover per reef in this period of time.

'STAYIN' ALIVE': MICROBIOME PATTERNS AND PLAYERS RELATED TO CORAL BLEACHING, RECOVERY AND RESISTANCE. A FIELD STUDY AT KANE'OHE BAY (HAWAI'I) (Abstract ID: 29574)

Coral reefs harbor amazing diversity at the macroscopic, microbial, and molecular scale. Coral holobionts generating this richness associate with rich, functionally dynamic microbiomes. Most biochemical diversity resides in microbes, which may engage in symbioses with metazoans, thereby expanding hosts' adaptation capabilities. Symbiodinium dinoflagellate symbionts are for instance crucial as providing metabolic sustenance for corals. Other close associates such as prokaryotes and fungi are less studied, yet are also believed to be vital partners that underpin ecological competence. Under environmental stress, symbioses become highly sensitive, in particular to elevated temperatures, causing corals to bleach, debilitate and eventually die. In the summer of 2014, ~80% of the reefs in Kaneohe Bay paled, representing one of the most intense bleaching events in Hawai'i since 1940. We used next-generation sequencing to track over 6 months the communities of Symbiodinium, fungi, and bacteria in bleached and resistant coral colonies in the field following this devastating episode. Worldwide, reefs are threatened by a warming climate, but the resilience of some colonies after successive bleaching suggests acclimatization, probably involving shifts in coral-associated microbiomes. Corals ability to alter their symbiotic communities in response to external impacts can be passed to subsequent generations, and this might be key in the process of adaptation to a changing world. These data contribute knowledge on the microbial composition that may infer environmental tolerance in corals.

CORAL RECORDS OF SEDIMENTATION AND ITS IMPACTS TO CORAL REEFS IN THE EASTERN MALACCA STRAIT (Abstract ID: 29090 | Poster ID: 434)

The Strait of Singapore situated on the southern end of the Malacca Strait is a one of the world's busiest shipping ports that has been experiencing significant dredging and reclamation activities since its independence in 1960s. These activities along with high runoff from a number of rivers have increased sedimentation pressure on coral reefs environment in this narrow strait of importance to reef connectivity in the region. Here, we present coral-based histories of sediment loading (via measurement of coral Ba/Ca), salinity (via coral-derived oxygen isotopic composition of seawater or d18Osw) and a coral metabolism (via carbon isotopic composition or d13C). These records are accompanied with a 1.5 yr-long monthly seawater Ba, d18Osw and salinity in order to understand their relationships on seasonal timescales. Ongoing analysis of rare earth elements may also be presented herein. Our data shows a steady increase in coral Ba/Ca as a proxy for sediment loading since 1960s with episodes of high Ba/Ca, which are in line with reclamation and other environmental events such as river clean up of the main island. Some of these high Ba/Ca episodes also coincide with higher heavy metal Pb reported in our previous work (Lee et al., 2014). Along with these coral-based environmental records, our data reveals a shift towards depleted coral d13O values suggesting a change toward heterotrophy in coral. Overall, our study shows the utility of coral skeletal geochemistry to provide environmental histories such as sedimentation as well as to infer its impacts of coral reefs.

THERMAL SHOCK INDUCES HOST PROTEOSTASIS DISRUPTION AND ENDOPLASMIC RETICULUM STRESS IN THE MODEL CNIDARIAN*AIPTASIA* (Abstract ID: 29323 | Poster ID: 20)

Coral bleaching has devastating effects on coral survival and reef function, but many of the fundamental cellular effects of thermal stress on cnidarian physiology are unclear. We used label-free liquid chromatography-tandem mass spectrometry to assess the effects of thermal stress on the proteome of the model *Aiptasia* sp. Anemones were allowed to acclimate to elevated temperatures for two weeks or exposed to short-term thermal shock. We identified 2,137 protein clusters in *Aiptasia*, 136 of which were differentially abundant between treatments. There were minimal differences in protein abundances between the control and acclimated high-temperature treatments, indicating that thermal acclimation in symbiotic cnidarians is not primarily regulated at the level of protein expression. Heat shock resulted in significant changes in the abundance of 104 proteins, including those involved in protein folding and synthesis, redox homeostasis, and central metabolism. Highly abundant cytoskeletal and structural proteins showed particularly reduced abundance, demonstrating proteostasis disruption and inhibition of protein synthesis. Heat shock induced multiple mechanisms for stabilizing, degrading and preventing the aggregation of proteins, indicative of endoplasmic reticulum stress. Antioxidant mechanisms and enzymes necessary for redox homeostasis were also upregulated. The effects of thermal shock were most clearly seen at the endoplasmic reticulum, and proteostasis maintenance and protein turnover mechanisms may be essential to cnidarian resistance to thermal shock.

LATITUDINAL DIVERSITY GRADIENTS OF MULTIPLE TAXA IN REEF COMMUNITIES OF SOUTHERN JAPAN (Abstract ID: 28675)

Latitudinal gradients of species diversity are widely recognized among both terrestrial and marine ecosystems. Understanding species assembly dynamics at the boundaries of climate zones is an important theme of biogeography. In this study, we used visual census data to quantify organisms in reef communities at 19 sites along the Pacific coast of Japan, covering a latitudinal gradient from 24° to 35°N. We measured species richness and abundance of multiple epifaunal taxa, such as fishes, echinoderms, octocorals, mollusks and macroalgae, and analyzed the influence of environmental factors and species traits using generalized linear models. We assigned life history traits to species that are available from literature. Different taxonomic groups showed different dynamics along the latitudinal gradient. Species richness and abundance of fishes increased towards low latitudes. Macroalgae clearly showed the opposite pattern, peaking at high latitudes. Species richness and abundance of other invertebrate groups were highest at intermediate latitudes and lower in coral reef areas. Additionally, in some taxa, communities changed with respect to their trait composition along latitudes. For example, fish communities had a longer mean pelagic larval stage with higher latitudes. Algal communities had more fleshy and large-bodied species at higher latitudes, and more encrusting calcareous algae species in the tropics. These results serve to explain and anticipate changes in community structure and biodiversity as a result of environmental change, such as global warming.

**Obura, D. O.**, CORDIO East Africa, Kenya, dobura@cordioea.net

INVESTING IN CAPITAL – CONVERGING ON A DECISION-SUPPORT APPROACH FOR RESOURCE-POOR AND RESOURCE-RICH CONTEXTS (Abstract ID: 29635)

In increasingly populated tropical coastal regions, achieving the "triple bottom line" of sustainable development requires making complex decisions to balance economic, social and environmental needs and limitations. True sustainability occupies the sweet spot between these three domains. This paper merges concepts from the Capitals Approach and Marine Spatial Planning (MSP) to help deal with the problems of system complexity, mixed objectives and uncertainty, providing tools to concretize a stewardship approach. The challenge is to support decision-making that delivers positive change (growth in one or more capitals) and prevents negative change (decrease in one or more capitals). Nature, society and economy can be viewed as capitals, requiring decisions that reject options that result in loss in any capital, and select those that grow capital(s). In MSP, nature, society and economy define the system to be managed; information is needed on multiple aspects of all three, and a supportive governance context is necessary to facilitate decision-making. The Capitals Approach can also view information and governance as capitals to be invested in, rather than degraded. This simple construct can be implemented at a basic level such as in a scorecard approach, with multiple indicators across all the capitals, and their interactions, in a spatial planning context. All indicators need to be improved, not undermined. At higher levels, complex datasets and models can be integrated to identify solutions that increase capital, to guide decision-making across scales.

REVIEW OF CORAL CLASSIFICATION STATUS: A CASE STUDY OF KIUNGA MARINE NATIONAL RESERVE, NORTH COAST KENYA (Abstract ID: 29461 | Poster ID: 623)

Coral classification is a dynamic science which requires regular updates on the species name changes, distribution, threats of extinction and the methods used to detect these changes. Use of a single method of classification either morphological or genetic is not

sufficient to confirm the changes. A review of coral classification for the Kiunga Marine National Reserve (KMNR) in north coast Kenya was conducted during January to August last year to ascertain the current status and assess the coverage on phylogenetic literature; IUCN Red List status and reference to threats facing the species which are locally or elsewhere. Results from this study showed that corals from Kiunga Marine National Park were well covered in all aspects of phylogenetic literature with more than three quarters making it possible to adequately group them to their IUCN Red list categories. However, the analysis detected a group of species which had not been assigned into any status on the IUCN Red list classification, representing less than a quarter. With data and information on such omissions, the species could be faced with several threats hence the need to conduct further studies and analysis focusing on acquiring comprehensive data and information for clear establishment of updated status of the taxonomy of corals so as to correctly label them in the groups. This opens up an opportunity to widen the criteria used when assigning the protection and management level of the coral reef ecosystem in Kenya. Key words: morphological classification, genetic classification, IUCN Red list categories,corals

DIAGNOSING CORAL DISEASE WITH METABOLOMIC MARKERS (Abstract ID: 29430 | Poster ID: 99)

Investigation of coral disease etiology requires multidisciplinary approaches including in-depth molecular analyses. Here, we applied untargeted metabolomics to characterize white syndrome coral disease in the Persian/Arabian Gulf. The Gulf is one of the most extreme environments in which corals occur with high and variable temperatures (23-35°C) and elevated salinity (38-43 PSU).Recent lethality in the branching coral, Acropora, has been caused primarily by a white syndrome disease. We observed tagged Acropora colonies in the Gulf over two years and found that a surprising 63 % of the monitored colonies were visibly infected by white syndrome during summer months. Interestingly, only 5 % of tagged colonies were affected by bleaching during the same period. The syndrome is characterized by fast spreading lesions, which ceased when water temperatures decreased but reappeared on the same colonies in the following summer. To investigate the impact and cause for the disease we apply untargeted ultra-high performance liquid chromatography combined with mass spectrometry from segments of diseased and healthy coral nubbins. Metabolomic profiles show significant differences between infected and healthy parts of the colony. We describe the metabolic pathways impacted by the disease using cross-correlation and comparison with metabolomics databases. Our findings show that untargeted metabolomics is a valuable tool for the investigation of the diseased coral holobiont and improving diagnosis and potential pathogen identification.

PROVIDING ACCESS TO A DISTRIBUTED NETWORK OF RESOURCES: NOAA'S CORAL REEF INFORMATION SYSTEM (Abstract ID: 28768)

The National Oceanic and Atmospheric Administration's (NOAA's) web-enabled Coral Reef Information System (CoRIS) contains over 10,500 catalog entries for coral related data and publications covering a wide variety of topics including: coral reef mapping, monitoring and assessment; natural and socioeconomic research and modeling; outreach and education; and management and stewardship produced through the NOAA Coral Reef Conservation Program (CRCP) and other coral reef projects. Data and information products are published to a variety of different systems throughout NOAA. Through the use of a variety of web services, CoRIS links these systems together to provide a unified single access point for the public to access the organization's coral ecosystem data and publication holdings. The CoRIS catalog is also exposed through a catalog service endpoint to allow developers to access our catalog holdings without having to go through a predefined user interface. CoRIS provides users with various search options to access materials including spatial, temporal, and topical searches. In addition, project pages are used to highlight, promote, and group materials by topic and/or jurisdiction. Finally, the CoRIS Glossary and Acronym list, defines thousands of terms, acronyms, and abbreviations used in coral reef science and management. With over 1.5 million visitor sessions per year we are reaching a wide audience of educators, managers, and scientists interested in coral reef ecosystems. You can begin your search at http://www.coris.noaa.gov/.

EVALUATION OF *ACROPORA CERVICORNIS* PRODUCTION TECHNIQUES IN AN OCEAN-BASED NURSERY WITH CONSIDERATION OF CORAL GENOTYPE (Abstract ID: 27927 | Poster ID: 483)

Staghorn coral *Acropora cervicornis* is widely cultured for active reef restoration using a variety of techniques. We conducted a one-year *A. cervicornis* propagation experiment in an offshore nursery in the Florida Keys. Our objective was to examine benthic-attached (block) versus suspended (tree) growout methods and the effect of coral genotype within and between growout methods. In December 2014, 240 5-cm, non-branching apical fragments were collected from established colonies of four genotypes. For the block method, 10 fragments were affixed to each of 12 cinderblocks (3 cinderblocks per genotype). Three tree structures each had 40 fragments from all four genotypes (10 fragments per genotype) randomly assigned to locations across five depths. Temperature was logged hourly and colony condition was observed monthly. Total linear extension of each colony was also measured monthly until November 2015, when only three colonies had survived an extreme bleaching event that began in August. Statistical comparison indicated that colonies grown on blocks bleached sooner but survived longer than those on trees. Comparisons of growout method were made on pre-bleaching data to exclude confounding effects of this stress event. Colonies on trees grew significantly faster than those on blocks but location on trees did not affect growth. Genotype had a significant effect on colony growth which was determined to be consistent across growout methods by *post-hoc* analysis. These findings should be of use for coral nursery managers throughout the Caribbean.

DEVELOPMENT OF A DEVICE FOR IN SITU COLLECTING, REARING, AND SEEDING CORAL LARVAE (Abstract ID: 28579)

Generally, a shortage of larval supply has been thought a major factor causing delayed coral recovery. In fact, coral eggs and larvae have been found to easily flow out to the outside lagoon among degraded reefs around Okinotorishima, an isolated oceanic island of Japan. Thus, Japan Fisheries Agency developed a device that enables both the in situ seeding and mass culture of coral larvae (hereafter, the device), to promote coral reproduction inside the lagoon. Although this idea had been suggested previously, few studies have addressed the design of such a device at a practical level. We conducted a basic examination for the device's functions using the lattice plate, which enhances the initial survival rate of juvenile corals in Ishigakijima of Okinawa. We also demonstrated the device's durability and effectiveness in Okinotorishima, an isolated oceanic island. We show below the abridged results. a.Appropriate mesh size of the net material of the device: we compared mesh size of the net, an important factor for enhancing survival rate of the enclosed larvae, from 30 to 250 μm. The 30 μm mesh size showed the highest survival rate. b.Quantity of larval collecting and rearing: We assessed the rearing capacity of the device. The maximum number of larvae was 3 million at 4d-old, which they can settle. c.Monitoring the survival of the juvenile corals: We confirmed that the settled corals on lattice plate survived until 18 mo after settlement. d.Demonstration tests in Okinotorishima: We could install the device in Okinotorishima of severe maritime conditions during 7 days.

MOLECULAR PHYLOGENETIC STUDY OF MUSHROOM CORALS (SCLERACTINIA: FUNGIIDAE) IN THE RYUKYU ARCHIPELAGO, JAPAN (Abstract ID: 28323 | Poster ID: 76)

The family Fungiidae is a member of the reef corals and lives in the tropical and subtropical Indo-Pacific regions. The taxonomy of the family has been recently revised using morpho-molecularly analysis (Gittenberger et al. 2011, Benzoni et al. 2012); the family currently consists of 15 genera and 53 species. The phylogenetic positions of some fungiid species, however, remain unanalyzed. For example, although 36 fungiid species have been reported from Japanese waters (Nishihira and Veron 1995), no phylogenetic

studies have been conducted yet. The present study aims to clarify the phylogenetic relationships of fungiid species inhabiting around Ryukyu archipelago (84 specimens of 12 genera, 28 species), together with published DNA sequences (Gittenberger et al. 2011, Benzoni et al. 2012). Their species identification was performed based on the taxonomic reference (Hoeksema 1989). Material examined includes *Cycloseris hexagonalis* and attached-type of *Fungia fungites* that have never been analyzed molecularly yet. As a result of molecular phylogenetic analyses of two markers (mitochondrial cytochrome oxidase I and the nuclear ribosomal internal transcribed spacers), it is revealed that *C. hexagonalis* formed an independent clade, which is clearly distant from the clades with all other congers as well as other fungiid genera. Moreover, attached and free-living types of *F. fungites* were genetically distinct and placed in two different clades. The systematic positions of these species need to be reviewed with detailed morphological analyses.

HISTORICAL ANALYSIS OF OCEANOGRAPHIC CONNECTIVITY IN THE PULLEY RIDGE (Abstract ID: 29482)

Pulley Ridge is a mesophotic 60-m-deep reef system located 66-km west of the Dry Tortugas. Far from the coast and surface, it is not affected by coastal pollution and/or bleaching from water temperature fluctuations. Many of the species living at Pulley Ridge are also found in shallower water, and they may be connected. Studying the oceanographic conditions in the region can help determine the extent to which the corals, sponges, and reef fishes living at Pulley Ridge are related to the shallower coral reef ecosystems of the Dry Tortugas and the Florida Keys, and other regions in the west Florida shelf. Here we consider historical surface drifting buoy trajectory data. More than 150 drifters are found to visit the Pulley Ridge area since 1996. A statistics of arrival times to potential settlement sites is constructed. This is compared with that of settlement times of regional species reported in the literature. Potential mean connecting pathways are deduced and the implications of their spatiotemporal variability are discussed.

QUANTIFYING THE CONSERVATION VALUE OF SEASCAPE CONNECTIVITY: A GLOBAL SYNTHESIS (Abstract ID: 28230)

Connectivity structures populations, communities and ecosystems in the sea. The extent of connectivity is, therefore, predicted to also influence the outcomes of conservation initiatives, such as marine reserves. We reviewed the published evidence of how important seascape connectivity (i.e. landscape connectivity in the sea) is for marine conservation outcomes. In the majority of cases, greater seascape connectivity inside reserves translated into better conservation outcomes (i.e. enhanced productivity and diversity). Research on reserve performance is, however, most often conducted separately from research on connectivity, resulting in few studies (< 5% of all studies of seascape connectivity) that have quantified how connectivity modifies reserve effects on populations, assemblages, or ecosystem functioning in seascapes. Nevertheless, evidence for positive effects of connectivity on reserve performance is geographically widespread, encompassing studies in the Caribbean Sea, Florida Keys and western Pacific Ocean. Given that research rarely connects the effects of connectivity and reserves, our thesis is that stronger linkages between landscape ecology and marine spatial planning are likely to improve conservation outcomes in the sea. The key science challenge is to identify the full range of ecological functions that are modulated by connectivity and the spatial scale over which these functions enhance conservation outcomes.

ADAPTIVELY MANAGING MARINE PROTECTED AREAS FOR RESILIENCE THROUGH COLLABORATIVE LEARNING AND RESEARCH PARTNERSHIPS (Abstract ID: 27855)

Marine protected areas (MPAs) are an important marine management tool for conserving ecosystems and ecosystem benefits. However, globally, many MPAs are not managed using science-driven approaches, and can be at risk due to local and global threats. By addressing local threats, managers can make ecosystems more resilient to global threats such as climate change. To promote managers ability to recognize and address threats, we developed a pilot program in adaptive management for Kenyan national marine protected areas. Adaptive resource management is an iterative decision making approach where management strategies are continually reviewed and adjusted in response to the best available information. At program inception, we found little management understanding of MPA status or progress toward ecological or social goals. This limited knowledge inhibiting staff ability to determine appropriate management actions. We discuss steps taken to engage MPA staff in adaptive management including establishment of measurable objectives, developing a data collection and evaluation system, and the use of decision-making support tools. We show how the approach transformed thinking at numerous operational levels within an agency – from stakeholders and entry-level MPA staff to the national agency executive committee. Finally, we demonstrate how the stakeholder-manager-researcher partnership resulted in new and creative pathways toward sustainability, including better ongoing planning to achieve both ecological and socio-economic goals.

CAN SELF-ARMOURING ISLANDS RESIST CLIMATE CHANGE? (Abstract ID: 28045 | Poster ID: 396)

Reef islands (RI) are low lying landforms that are constructed from unconsolidated carbonate sands and gravels that sit atop reef platforms, and have a limited areal extent. Because of the above-mentioned attributes it is often presumed that RI's are sensitive to rising sea levels and/or increased cyclone intensity and frequency. However, there are a number of geomorphic/geochemical processes, including (1) cementation of beach sand to indurated beach rock, and (2) the formation of elevated boulder beaches through the fracturing and transport of beach rock during cyclonic events, that when combined could provide enduring protection (i.e., armouring) against future climate change impacts. Examples of this armouring process are observed on the ~145 RI's that stretch along Australia's NW Pilbara coast, a region that experiences the greatest cyclone intensity/frequency in Australia. Almost all Pilbara RI's are constructed from carbonate sand and have a median island area of ~7 hectares. But unlike Pacific and Indian Ocean RI's that typically have land elevations of < 3 m, Pilbara RI's have elevations that range from 8 to 15 m above mean sea level (MSL). Beachrock is a ubiquitous feature on most islands, but equally common are imbricated boulder beach deposits, which rise to elevations of 4.5 m above MSL level. These boulder beaches are both formed by and provide protection from high-energy cyclonic events, and along with beachrock create a natural seawall that could provide long-term geomorphic stability and increase the resilience of these islands to climate change.

PREDICTIVE MODELS AND TRADE-OFF ANALYSIS FOR GUIDING COST-EFFECTIVE LAND-BASED MANAGEMENT ACTIONS FOR CONSERVING CORAL REEFS (Abstract ID: 28872)

Land-based source pollutants (LBSP) actively threaten coral reef ecosystems in west Maui and around the world. Managers recognize that changes in land use directly affect the export of sediments and nutrients to reefs, and are targeting management actions towards mitigating LBSP. To be successful and cost-effective in their efforts, managers require appropriate tools to estimate how alternative land use, land cover change, and management practices may drive sediment and nutrient runoff into coastal waters. Additionally, because watersheds often cover multiple landowners, understanding the costs of cooperative versus independent management actions relative to their effectiveness in reducing LBSP is important for guiding cost-effective landscape-scale decision-making. To meet these demands and advance effective and efficient land-based ocean conservation practices, we developed a spatially explicit predictive model that quantifies change in LBSP from dirt road repair management actions (water bars and/or gravelling the roads to divert and/or trap rainfall and sediment) across the landscape in west Maui. We then employed the tool to investigate changes in LBSP arising from alternative spatial configurations of roads repaired across the study domain and among multiple watersheds, and by landowners acting independently or in cooperation. Finally, we integrated our model with a trade-off analysis to identify effective and efficient land-based management strategies that enable managers to maximize the value (and/or minimize the cost) of mitigation efforts while minimizing LBSP.

DEVELOPING A MULTI-STRESSOR GRADIENT FOR CORAL REEFS (Abstract ID: 29455)

Coral reefs are often found near coastal waters where multiple anthropogenic stressors co-occur at areas of human disturbance. Developing coral reef biocriteria under the U.S. Clean Water Act requires relationships between anthropogenic stressors and coral reef condition to be established. Developing stressor gradients presents challenges including: stressors which co-occur but operate at different or unknown spatial and temporal scales, inconsistent data availability measuring stressor levels, and unknown effects on exposed reef biota. We are developing a generalized stressor model using Puerto Rico as case study location, to represent the cumulative spatial/temporal co-occurrence of multiple anthropogenic stressors. Our approach builds on multi-stressor research in streams and rivers, and focuses on three high-priority stressors identified by coral reef experts: land-based sources of pollution (LBSP), global climate change (GCC) related temperature anomalies, and fishing pressure. Landscape development intensity index, based on land use/land cover data, estimates human impact in watersheds adjacent to coral reefs and is proxy for LBSP. NOAA's retrospective daily thermal anomaly data is used to determine GCC thermal anomalies. Fishing pressure is modeled using gear-specific and fishery landings data. Stressor data was adjusted to a common scale or weighted for relative importance, buffered to account for diminished impact further from source, and compared with coral condition data to provide a conceptual framework relating stressor gradients to effects on coral condition.

OBSERVING PROCESS IN THE CARBONATE SYSTEM OF PACIFIC REEFS: NATIONAL CORAL REEF MONITORING PROGRAM IN THE PACIFIC (Abstract ID: 29562)

Over the past decade, NOAA's Coral Reef Ecosystem Program has been observing chemical and ecological impacts of changing carbonate systems of Pacific coral reefs at hundreds of sites around 35 islands spread across 45 degrees of latitude and 95 degrees of longitude. I will present an overview of the design of our observation system, with specific reference to the challenges of observing in the face of both temporal and spatial variability. In particular, I will discuss our observations of reef seawater chemistry, including offshore reference sample to provide estimates of Net Ecosystem Calcification (NEC) and Net Ecosystem Production (NEP) at both inter-annual and diurnal time scales. I will further discuss our efforts to develop a time and cost effective measure of net calcification output, and will focus on the results of our Calcification Accretion Units (CAUs). In both cases I will discuss the results of large-scale correlative models to highlight potential environmental and ecological drivers of calcification in these systems, and how these results may inform management and policy.

COMMUNITY-BASED CORAL AQUACULTURE AND REEF REHABILITATION PROGRAM: THIRTEEN YEARS OF LESSONS LEARNED OF CORAL REEF MANAGEMENT IN PUERTO RICO (Abstract ID: 28417 | Poster ID: 612)

Community-based engagement in coral reef management has become a fundamental tool for supporting institutional activities. It can also foster significant hands-on and behavior-modifying education of community stakeholders through direct participation in conservation projects. However, there is still scarce information regarding lessons learned from such experiences. We discuss the case study of non-governmental organization Sociedad Ambiente Marino (SAM) from Puerto Rico (PR) and its Community-Based Coral Aquaculture and Reef Rehabilitation Program established in 2003. SAM use low-tech coral farming to rehabilitate formerly bombarded coral reefs in PR, in collaboration with the University of Puerto Rico (UPR). This has allowed the academic-NGO integration in multiple marine applied research projects, significantly increasing SAM's technical training for leading conservation oriented research. It also empowered SAM to write their own grants, obtain and administer external funds, and implement multiple projects. In a time of unprecedented socio-economic constriction and declining governance capacity, SAM has become an alternative to provide community-based support to government institutions and the academia conducting conservation-oriented research. This fostered major educational transformation and technical empowerment in SAM to plan and implement priority projects. Outcomes of this include sustained community volunteers engagement, educational and outreach activities, and an increased number of peer-reviewed publications. Lessons learned in the process will be discussed.

DEVELOPMENT OF ACTIVE RESTORATION METHODOLOGY OF CORAL REEFS IN OKINAWA, JAPAN, USING ASEXUAL REPRODUCTION (Abstract ID: 28233)

Some people are still reluctant for active coral restoration, as they consider that, besides collateral damage to donor reefs, area that can be restored by means of transplantation is very limited to compare large scale degradation of coral reefs. However, as nursery for donor colonies can supply large numbers of transplantable seedling corals and spawning of the out-planted corals brings effective larval dispersion tool for natural recruitment enhancement, the active restoration processes need to be considered. The Coral Reef Preservation and Rehabilitation Project by Okinawa Prefectural Government, Japan, attempts to verify possibility of large-scale reef restoration since 2011. Three hectares of degraded reefs are being restored with more than 100,000 nursery-farmed coral fragments. The restored reefs will become larval dispersion hub after few years. The novel methodology consists of 1) finding of suitable species and location for out-planting, 2) farming of donor corals in nursery, 3) genomic DNA analysis of donor colonies, 4) farming of seedling fragments in nursery, 5) out-planting design for a single species without clonal colony, 6) combination of various species in wide area, and 7) long term monitoring.

EVIDENCE FOR CLIMATE-DRIVEN SYNCHRONY OF MARINE AND TERRESTRIAL ECOSYSTEMS IN NORTHWEST AUSTRALIA (Abstract ID: 28477)

The effects of climate change are difficult to predict for many marine species because little is known of their response to climate variations in the past. However, long-term chronologies of growth, a variable that integrates multiple physical and biological factors, are now available for several marine taxa. These allow us to search for climate-driven synchrony in growth across multiple taxa and ecosystems, identifying the key processes driving biological responses at large spatial scales. We hypothesized that in northwest Australia, a region predicted to be strongly influenced by climate change, the El Niño Southern Oscillation (ENSO) phenomenon would influence the growth patterns of organisms across ecosystems. To test this idea, we analysed the growth chronologies of two marine fish *Lutjanus argentimaculatus* and *Lethrinus nebulosus*, the coral *Porites* spp. and the tree *Callitris columellaris*. Principal components analysis and linear model selection showed evidence of ENSO-driven synchrony in growth among all four taxa at inter-annual time scales, the first such result for the Southern Hemisphere. Rainfall, sea surface temperature and sea surface salinity, which are linked to the ENSO system, influenced the annual growth of fishes, trees and corals. All four taxa had negative relationships with ENSO, where positive growth patterns occurred during strong La Niña years. This finding implies that future changes in the strength and frequency of ENSO events are likely to have major consequences for both marine and terrestrial taxa.

CRUSTOSE CORALLINE ALGAE, DOLOMITE, AND THE HISTORY OF MG/CA WITHIN THE CENOZOIC OCEAN (Abstract ID: 29849)

It has been recognized by several scientists over the past 30 years that dolomite precipitation, or lack of it, drives the Mg/Ca of sea water on time scales of millions of years.

The problem has been that no one had been able to put their finger on a mechanism for the deposition of abundant dolomite in marine and in particular coral reef ecosystems. With the discovery that crustose coralline algae (CCA) is the source of dolomite, we now have a specific sedimentary depositional environment we can call on for its origins. The CCA dominated algal rims and flats, most pronounced on mature and senile reefs, have the highest concentrations of dolomite, and are largely located in the intertidal zone. What we observe is that CCA abundance becomes more pronounced if the reef flat spends longer within that intertidal zone, hence sea level stability is key to concentrating significant thicknesses of the dolomite rich CCA. I will present a model that illustrates how sea level instability has lead to the decline in the abundance of this stable shallow water environment ever since Antarctica was glaciated 33.9 million years ago. This has lead to a corresponding decline in dolomite deposition and an increase in the Mg/Ca of sea water through the late Cenozoic.

SPATIAL AND TEMPORAL PATTERNS OF RECRUITMENT AND REPRODUCTION, AND STOCK-RECRUITMENT RELATIONSHIP OF CRUSTOSE CORALLINE ALGAE ON HERON ISLAND- GBR (Abstract ID: 28042)

Crustose coralline algae (CCA) are key organisms for coral reef ecosystems as they play important roles in reef building and reef resilience. While the number of studies looking at the impacts of anthropogenic activities on CCA has recently increased, very little is still known about their basic biological and ecological processes. This study aims to understand the spatial and temporal patterns of reproduction, recruitment, and the relationship between early stages and adult abundance of CCA around Heron Island, southern Great Barrier Reef, Australia. Three reef habitats were studied across four climatic seasons. CCA recruitment patterns were assessed using settlement plates and surveys were carried out to study the community of CCA adults. To determine the nature of the relationship between reproduction and recruitment, the reproductive structures of *Porolithon. c. f. onkodes* sp. were analysed at each habitat and season. The recruitment of CCA in Heron island reef varied significantly throughout the year and among reef habitats. Community structure of both the recruits and adults varied among seasons and habitats. Further, a positive relationship between reproductive output and recruitment, and adult stock and recruitment abundance was found, suggesting that CCA populations are, predominantly, "closed" populations. Overall, this information is fundamental for a better understanding of the patterns and causes of algal distributions in reefs, and the possible impacts of global environmental change on this important group of reef builders.

ACTIONS TO ENHANCE ENFORCEMENT IN THE U.S. VIRGIN ISLANDS THROUGH CAPACITY BUILDING TOWARD CORAL REEF ECOSYSTEM PROTECTION (Abstract ID: 28160)

The USVI priority setting and capacity assessment processes identified the need for improved enforcement as a key priority in order to improve the condition and sustainability of coral reef ecosystem resources. Historically, people living and working in USVI have identified the need for improved enforcement as a Territorial priority as reflected in the USVI economic assessment and in the 2005 "United Stated Virgin Islands Marine Resources and Fisheries Strategic and Comprehensive Conservation Plan" created by the Department of Planning and Natural Resources (DPNR) Division of Fish and Wildlife in part by interviewing commercial and recreational fishers and researchers in USVI. All groups suggested the need for additional officers, increased patrols, and increased site inspections supported through increased funding. The 2012 USVI Capacity Assessment made similar recommendations. NOAA's Coral Reef Conservation Program provided multi-year funds through FY13 to build capacity through officer training, a policy gap analysis and targeted solutions, and the analysis of enforcement data to identify focal areas for a long-term training plan. DPNR is now also working toward the creation and implementation of a strategic plan for enforcement to enhance consistency of enforcement procedures and increase capacity for protection of coral reef ecosystems in the USVI.

CHARACTERIZATION OF METABOLITES IN CORALS UNDER CONDITIONS OF HIGH SALINITY (Abstract ID: 28615 | Poster ID: 105)

Corals are frequently exposed to changes in salinity. Previously, it was thought that they could not respond to these changes; however, recent literature suggests them to be osmoconformers, i.e. able to maintain an internal environment that is isosmotic to their external environment. To further understand the effects of increased salinity on corals, we conducted a long-term *in situ* experiment with *Fungia granulosa* exposed to highly increased salinity levels. Contrary to expectation, coral colonies appeared visually healthy and photosynthesis efficiency was unaffected indicating unimpaired coral host and algal symbiont functioning. In comparison, the associated microbiome displayed drastic changes that could be associated with putative changes in metabolite production associated with salinity tolerance. We are currently applying Gas Chromatography Mass Spectrometry (GC/MS) to quantify the concentration of metabolites and subsequent identification by comparison to a reference compound library. We expect to find different metabolite concentrations in the coral holobiont under different salinity levels, and we will discuss possible osmoregulatory functions of these metabolites.

THE EFFECT OF WAVE EXPOSURE AND COMPETITION FOR SPACE ON THE COMMUNITY COMPOSITION OF CORAL REEFS (Abstract ID: 28936)

The effect of wave energy on the survivorship of corals is highly dependent on the coral growth form. Corals with higher skeletal density and lower resistance against water motion are less likely to be affected by wave energy. Here we use high resolution wave modelling to assess the effect of wave exposure on the relative abundance of corals grouped in three growth forms (massive, branching and tabular) around Heron Island Reef (Eastern Australia). We then incorporate the empirical relationships observed in an existing coral reef ecosystem model to be able to explore the effect of future disturbance scenarios at different levels of wave exposure. Our results suggest that 52% of the variability in coral community composition can be explained using a combination of 4 wave exposure metrics and the slope of the reef. We also identify that at low levels of wave exposure dominant populations are highly resistant to competitive displacement due to the low natural mortality in these conditions. These results suggests that although wave exposure can be used to predict the relative abundance of different growth forms, at least at low levels of wave exposure, ecological interactions and unusual recruitment events may be stronger drivers of community composition.

CONSUMER'S RESPONSIBLE SEAFOOD CONSUMPTION IS VITAL FOR CORAL REEF HEALTH (Abstract ID: 28155 | Poster ID: 262)

The Caribbean Fishery Management Council Outreach and Education initiative is targeting seafood consumers: fishers, fishmongers, fish markets restaurant owners and general public, to promote public understanding of coral reef dynamics, and thus understand the importance and significance of management measures applied to the fisheries. The main goal of this initiative is to establish the basis for a fisheries literacy among the consumer public to support a sustainable reef fishery, beginning with responsible fishers and a consumer's chain that will purchase species not prohibited and with healthy populations. Coral reefs are complex ecosystems in which the physical structure, the species dynamics of corals and other species, physico-chemical and biotic processes and connections among them, including human activities define the health of the ecosystem. Fish and invertebrate species that form the fisheries in the Caribbean Region are all part of this complex ecosystem, and understanding the dynamics of their populations by the consumers is essential. The management measures that need to be applied to these species (closed seasons and/or closed areas to protect reproduction aggregations or areas where the juvenile grow) have socioeconomic impact on their communities. This information very rarely is delivered to the consumers in understandable format and language. Through outreach and education strategies consumers understand why they should not consume these species during their closed seasons, and the need for these management measures, that on the long term, guarantee that the populations of these species will be healthy and that the fisheries will be sustainable.

SPATIAL PATTERNS OF SYMBIONTS AND CORALS ARISING FROM PROPAGULE REDIRECTION (Abstract ID: 27987)

The density of organisms typically varies among habitat patches (e.g., coral colonies), often due to inherent properties of a patch (e.g. the species of coral that comprises the patch or the density of other symbionts that occupy the patch). However, the density of coral symbionts, such as fish, also can be influenced by the density and proximity of adjacent coral colonies. Here, we summarize past work on "propagule redirection" (or settlement shadows: i.e., depletion of larval settlers by adjacent habitat) and explore its long-term consequences on spatial patterns in fishes (or other coral symbionts). Using spatially explicit simulations and analytic models, we determine the situations in which variation in the density of symbionts can be achieved even when patches are identical in their inherent quality. Heterogeneous patterns of settlement result from propagule redirection when corals patches are distributed non-uniformly in space. This heterogeneity in settlement persists in the long-term (e.g., at the adult stage) when there is a low supply of settlers, weak post-settlement density-dependent survival, and longer times between settlement events. Variation in settlement arising from the spatial patterning of habitat can therefore be an important process shaping long-term spatial patterns of organisms occupying patchy habitats. Furthermore, because the density of symbionts can affect coral growth and survival, propagule redirection may be responsible for pattern formation in corals, as well as in the organisms that occupy these corals.

REEFOLUTION – A NEW CORAL REEF DEVELOPMENT PROGRAM IN KENYA (Abstract ID: 29335)

A reef development program named REEFolution was recently launched in Southeast Kenya, aiming at improving coral reef environments in order to enhance fish stocks, increase possibilities for dive tourism and conserve nature. Pilot activities started in September 2015 with the positioning of three types of coral nurseries in the Wasini Channel, a shallow, dynamic coastal area with a high tidal amplitude, moderate coral cover and a relatively high turbidity. Nursery types tested were 1) rope nurseries positioned on the seafloor (variable distance to the sea surface); 2) rope nurseries on floating frames (fixed distance to the sea surface) and 3) tree-type nurseries. Four species of coral were cultured on each nursery type: three scleractinian corals (*Porites cylindrica*, *Acropora muricata*, *Pocillopora meandrina*) and one fire coral (*Millepora* sp). Whereas *Acropora*, *Pocillopora*and *Millepora* performed well, with high survival rates and good growth during the first three months, culture of *Porites* was less successful. The three nursery types performed similarly; the tree-type nurseries were least sensitive to fouling and were the most convenient option regarding costs for construction and maintenance. Current activities of the program include upscaling of the nurseries, outplacement of cultured corals on damaged areas of natural reefs (reef restoration) and the installation of artificial structures for outplacement of cultured corals (reef building). Future plans include the establishment of an offshore, floating reef that may act as a refuge for corals under the threats of climate change.

REORGANIZATION OF THE CORAL MICROBIOME ACROSS LATITUDINAL GRADIENTS OF THERMAL HISTORY IN THE RED SEA (Abstract ID: 29538)

Corals in the Red Sea where seasonal sea surface temperatures can be extreme, provide unique capacity to gauge the physiological and molecular adjustments required for reef resistance to climate change. Whilst the coral host can physiologically adapt to persist and thrive in more marginal environments, the role of associated microbiome and Symbiodinium spp. reorganization ("holobiont adaptation") remains unresolved. We therefore examined how symbiont identity (ITS2, psbA) and the bacterial community structure (16S meta-genomic next generation sequencing) differs along thermal gradient of the Red Sea. Corals were sampled from six key coral species persisting across five sites across Red Sea (29˚ to 20˚ N) that experience different thermal regimes. Symbiodinium spp. ITS2 identity associated with each coral species generally remained highly conserved throughout the sites sampled; however, psbA diverged with latitude, particularly within Porites sp. suggesting population-level differences. In contrast, and consistent with recent studies, we report for the first time in the Red Sea, the variability in microbial communities within and between species across sites. Corals from two sites (Hurghada and Jeddah) were exposed to a thermal stress experiment which demonstrated that corals were more heat resistant at Hurghada (annual SST mean is 3.3 ˚C less than Jeddah); however Symbiodinium clade types (ITS2) were identical at both sites. The functional role of the microbiome in the thermal tolerance of the holobiont across different thermal regimes is currently being explored.

THE FISHMARK TOOL FOR BENCHMARKING FISHERIES MANAGEMENT IN MUNICIPAL WATERS (Abstract ID: 29439)

Fisheries laws in the Philippines provide an enabling environment for local fisheries management programs in municipal waters. These programs generally comprise of adoption of a fisheries management plan, enforcement, institutional development and partnership, legislation and regulation, and monitoring and evaluation. After over two decades of local fisheries governance and considerable efforts done in coastal resources management, fisheries management remains a lesser priority of local governments. One of the prevailing issues is the limited capacity to assess the effectiveness of their programs on fisheries management. The Fisheries Management Assessment and Rating Toolkit (FishMARK)aims to objectively monitor and evaluate programs relative to fisheries management with focus on capture and marine-related fisheries. It serves as a tool to gather critical lessons on adaptive management and sustainability. Nested in five governance areas, the FishMARK consists of 27 indicators and 108 verifiable sub-indicators. The FishMARK is a means to improve management of fisheries by LGUs by reviewing actions (inputs) and assessing results (outcomes). A FISHMARK evaluation was conducted in 12 focal sites across the Philippines. Preliminary results show that more than half of the sites fall under very similar conditions either at Pre-level or Level 1. Ultimately, the results would show that a standardized tool is critical. Lessons were identified to help redirect efforts toward adaptive management.

IMPACT OF SNORKELERS ON SHALLOW CORAL REEF COMMUNITIES IN PALAU (Abstract ID: 29036)

The Republic of Palau has always been a popular destination for tourists, especially those who seek to snorkel and/or dive Palau's World Heritage reefs. Over the past couple of years, concerns on the state of marine ecosystems have risen due to the rapid increase of visitors at snorkeling sites. In 2008, Palau had a total of 83,180 visitors. In 2015, that number had almost doubled to over 161,000 visitors. This study investigated the impacts of snorkelers on the shallow coral reef communities, their behaviors in the water, and the tour guide practices. Surveys on coral fragmentation, benthic cover, fish density, snorkelers and tour guide behaviors were conducted in July 2015 and January 2016 at 5 popular snorkeling sites and 5 non-popular sites within the World Heritage Site. Results showed a higher coral fragmentation and percentage cover of rubble at most of the popular sites than at the non-popular sites. Most of the visitors came from neighboring Asian countries such as China, Japan, Taiwan and Korea. A majority of these groups that visited the studied sites lacked confident swimming abilities and relied heavily on floatation devices. Observations showed lack of proper in-water guidance and supervision of snorkelers. Any correlation between reef assessment and snorkelers and/or tour guides' behaviors will also be explored and presented. Findings will be adapted into management recommendations and communicated to government agencies to improve the present conservation management practices.

FILL AN OLD NICHE OR FIND A NEW ONE? COMPARING HABITAT USE FOR INVASIVE REEF FISHES IN NATIVE AND INVADED CORAL REEF HABITATS WITH SPECIES DISTRIBUTION MODELS (Abstract ID: 29988)

Two snappers (Lutjanus kasmira and L. fulvus) and one grouper (Cephalopholis argus) were introduced to the Main Hawaiian Islands in the 1950s to boost local coral reef fisheries. These introduced species have native home ranges in other archipelagos in the Western Central Pacific Ocean. Their success as prominent fisheries have been lack-

luster for various reasons despite successful establishment in the Hawaiian Archipelago. The establishing success of an introduced species in a new area is related to how well it interacts with its new environment. Habitat use is a common way to understand the niche partitioning of introduced organisms in new environments. Herein, we employ current species distribution modelling approaches to link pertinent benthic habitat and environmental covariates with the distributions of these three species from standard reef fish diver surveys in the Main Hawaiian Islands, Mariana Archipelago, and American Samoa. Subsequently, for each species the models were cross-evaluated among regions to quantify the extent to which benthic habitat and environmental covariates could predict species density by juvenile and adult life stages in the different regions. This type of work provides insight into the niche structure of these species in their native and invaded habitats, as well as the generality of habitat-based species distribution modelling on broad geographic scales.

USING SCIENCE TO INFORM TRADITIONAL MARINE RESOURCE MANAGEMENT (SASI) IN THE BIRD'S HEAD SEASCAPE MPA NETWORK, RAJA AMPAT, INDONESIA (Abstract ID: 28300 | Poster ID: 613)

Sasi is a traditional marine resource management system in the Raja Ampat Archipelago, Indonesia that has been in place for multiple generations. Sasi is managed by a clan (within an Indonesian social clan system) and/or by a religious governing body (e.g. Church), typically consisting of periodic closures for key species. Bridging traditional wisdom and modern fisheries science, we conducted a study to inform best sasi practices to optimize catch of key fisheries species. Specifically, we conducted a study within Kawe MPA to investigate changes in catch of key fisheries species across different periodic closures. Length and weight was recorded from sasi target species caught by local fishers, including sea cucumbers (Holothuria), lobster (Panulirus), and top-shell (Trochus) during the sasi opening event in 2009 (following a one year closure) and again in 2012 (following a three year closure) .As expected, results showed that catch amount, size, and length from a sasi location that was closed for three years was significantly higher than catch following a one year closure. However, the three year closure restricted access to key fisheries species for a much longer duration. Using this information, we developed recommendations for individual sasi species based on their life-history to maximize catch which fell between the one and three year closures. This study will provide recommendations for management guidelines across the Bird's Head Seascape MPA network to optimize catch of sasi species supporting the continuation of sustainable fisheries practices.

IMPACTS & DYNAMICS OF AN OUTBREAK SPECIES OF CORAL ON A REMOTE ATOLL BEFORE AND AFTER A SUPER-TYPHOON (Abstract ID: 28030)

Despite relatively low human population sizes in Ulithi Atoll, Micronesia, concern is mounting over declining coral reef health. Upon invitation, we began conducting annual ecological surveys there in 2012. We documented an "outbreak" coral - an undescribed species of Montipora. Its presence is strongly correlated with human activities, peaking in abundance at boat landings, heavily fished areas, and moderately exposed sites. This coral appears to be causing declines in reef function due to its ability to quickly overgrow other corals, limiting coral diversity, reducing structural complexity, and depressing fish diversity and abundance. Its presence and abundance on reefs was a major driver in site clustering based on benthic structure, and dendrograms of fish diversity showed remarkably similar patterns, indicative of ecological relationships between corals and fish communities. Clustering of reef sites remained stable for 3 years; however, in 2015, Typhoon Maysak hit Ulithi Atoll directly, causing severe damage. We surveyed reefs on and adjacent to the Atoll 2 months post-typhoon and found that while coral community structure was relatively stable among sites, the outbreak Montipora sp. was strongly impacted, with live cover reduced to fine rubble due to wave action and heavy scouring at many sites. Our 2016 surveys will help reveal whether the storm and the reef management actions of the islanders will affect the dynamics of this outbreak, allowing formerly Montipora-dominated reefs to regain species diversity, or whether the disturbance will facilitate its spread.

GULF OF MANNAR MARINE NATIONAL PARK: MEASURES NEEDED FOR STRENGTHENING EFFECTIVE CONSERVATION (Abstract ID: 28626 | Poster ID: 674)

The Gulf of Mannar (GoM) biosphere reserve (10500 sq. km., with 21 fringing reefs) is the second reef region to be afforded total protection by the Government of India since 1986. In conjunction with the declaration of all reef building corals as fully protected in 2001, this was expected to improve the health of the reefs in GoM. This has not happened to the expected extent and this paper identifies the reasons why. By comparing the conservation initiatives of the GoM with those of the Great Barrier Reef (GBR), this paper discusses what measures could add strength to the conservation of reefs of the third world and how sustainable management of reef resources could be built into the conservation initiatives. Some such measures needed are scientific studies such as coral reproduction, recruitment rate, community dynamics and post-bleaching structure of the ecosystem that could help in identifying the priority areas for attention and improve the health, function and resilience of the reef ecosystem. This also needs to be supplemented with policies on rational and sustainable use of renewable organic reef resources such as commercial and recreational fisheries, pharmaceutical and bio-active compounds. The value of this discussion lies in its applicability to reefs beyond the GoM, to those in several other regions where scientific approaches are not as well developed as in the GBR case.

MORPHOLOGICAL VARIATION IN THE COLONIES OF THE HARD CORAL ACROPORA HYACINTHUS IN SHELTERED AND EXPOSED CONDITIONS (Abstract ID: 29420 | Poster ID: 42)

Aspects of colony morphology and population genetic structure were measured for several colonies of the hard coral Acropora hyacinthus in exposed and protected reefs in the Philippines to investigate the effect of wave exposure on the structure of colonies. Measurements were made on underwater photographs of live colonies to limit time spent in the field. A size and color reference card was included in each photograph. No significant differences in colony morphology were found between colonies in exposed and sheltered areas for colony size, branch density and branch thickness; though there was a significant difference in the diameter of the axial corallites (those in the exposed colonies were slightly smaller). There was a significant difference in the depth where these colonies were found, with those in the exposed area being found deeper and on the reef slope while those in the sheltered area found shallower and on the reef flat.

ENVIRONMENTAL EFFECTS ON SEXUAL REPRODUCTION OF REEF BUILDING CORALS FROM HAWAII. (Abstract ID: 29978)

Using field observations and laboratory analyses we explored the reproductive biology of two of the most broadly distributed and important reef builders in the main Hawaiian Islands, *Montipora capitata* and *Porites compressa*. Specifically, this study examined (1) the relationship between environment, size, morphology and reproductive capacity in *Montipora capitata* (2) the role of parental effects in dictating the phenotypic range of traits in coral offspring and (3) how thermal stress (bleaching) affects the reproductive biology of both *M. capitata* and *P. compressa* located in areas with different sedimentation regimes. Our results indicate that spawning in M. capitata varies among years, months and lunar days, and that the proportion of colonies spawning and synchrony of spawning do not reflect coral colony morphology or colony size. Furthermore, we found large biochemical differences between adults and eggs, with the latter containing higher concentration of lipids, ubiquitinated proteins and antioxidants. Despite the broad phenotypic plasticity displayed by adults, parental investment in the context of provisioning of energy reserves and antioxidant defense was the same in eggs from the different sites. Current analyses are focused on comparing reproductive characteristics in colonies (from both species) exposed to different sedimentation regimes and that were affected during the 2014 bleaching event.

CUES FROM SPACE WAR OF MARINE SPONGES AND THE RELATIONSHIP WITH HUMAN TUMOR CELL PROLIFERATION INHIBITORY ACTIVITY (Abstract ID: 29377 | Poster ID: 101)

Twenty five species of marine sponges were selectively sampled from coral reefs of Palk Bay and Gulf of Mannar, India. The selection was based on sponges growing in sheltered environment, least diverse area (<3-8 individuals/$M^2$), and absence of conspicuous surface macrofoulers. Extracts of selected sponges were subjected to cytotoxicity (100µg $ml^{-1}$) with brine shrimp (*Artemia salina*) and anticancer activity (25µg $ml^{-1}$) against human breast, stomach (AGS), lung, central nervous system (CNS) and colon tumor cell lines. About 88% of the sponge extracts tested showed cytotoxicity to*Artemia salina* and the mortality varied between 16 and 100%. Nine species showed more than 90% mortality. With regard to anticancer activity, extracts of 56% of sponges

were active. Among the various cell lines screened against sponge metabolites, colon cancer cell line was more susceptible (52%) followed by breast (20%), lung (32%), CNS (32%), and AGS (28%). The breast cell line was least susceptible. The extracts of *Axinella tenuidigitata*, *Axinella carteri*, *Clathria procera*, *Petrosia nigricans* and*Oceanapia fistulosa*, were active against almost all cancer cell lines tested. The highest cytotoxicity among the cell lines varied between 43.67 ± 2.42 and 80.03 ± 8.89%. Significant correlation was found between cytotoxic activity and the observed surface fouling and reduction in sponge habitat diversity.

MICROFRAGMENTING FOR THE SUCCESSFUL PROPAGATION AND RESTORATION OF SLOW GROWING BOULDER CORALS (Abstract ID: 28710)

Slow growing, massive stony corals have often been overlooked in reef-restoration activities, despite their significant contribution to reef framework. Techniques to effectively propagate and successfully outplant these species have proven challenging, however, advancement in methodology may increase rates of success. In 2013, Orbicella faveolata and Montastrea cavernosa fragments were outplanted on reefs within the lower Florida Keys, to determine whether "microfragmenting" corals increased the rate of survival and substrate coverage (a proxy for growth) after outplanting. Microfragmenting was defined as a method of cutting parent colonies into several 1 x 1 cm fragments (i.e., microfragments).Arrays of eight microfragments, each from the same parent colony and totaling about 50 cm2, were planted near one large fragment of similar size. Eight replicate pairs were randomly planted within the study site, which was approximately 100m2. Fragments were monitored for substrate coverage and survival over 31 months, spanning two bleaching events. Initial predation occurred to varying degrees on microfragments, but was absent in large fragments. Survival and growth did not differ overall between large fragments and microfragment arrays. However, excluding plots with >40% predation showed that O.faveolata microfragment arrays covered 14 times more substrate than the traditionally used large fragment. Results from this study suggest that if predation events are reduced, massive corals can be successfully grown and outplanted for restoration purposes.

DIFFERENTIAL MODIFICATIONS OF SEAWATER CARBONATE CHEMISTRY BY MAJOR CORAL REEF BENTHIC COMMUNITIES (Abstract ID: 28171)

Ocean acidification (OA) may threaten coral reefs through reduction of calcification and increased calcium carbonate bioerosion and dissolution. In addition to anthropogenic OA, reef seawater carbonate chemistry is strongly influenced by benthic net metabolism. Therefore, predicting future reef seawater carbonate chemistry requires an understanding of how benthic communities modify their chemical environment and the potential metabolic responses of these communities to future environmental change. The relationship between five benthic reef communities (sand, crustose coralline algae, coral, fleshy algae, and mixed community) and seawater carbonate chemistry was studied in flow-through mesocosm experiments during two seasons under ambient and acidified conditions. Graphic analysis of total alkalinity (TA) and dissolved inorganic carbon (DIC) vectors was used to assess the relative balance between net community calcification and net community organic production, and whether TA-DIC relationships can be used as a tool to characterize benthic reef metabolism and composition. Fleshy algae, which had the lowest TA-DIC slopes, elevated seawater pH the most during the day while calcifying communities had the highest TA-DIC slopes but very small influence on seawater pH. The mixed community fell between fleshy algae and calcifying communities with intermediate slopes and modest elevation of daytime seawater pH. Significantly higher nighttime dissolution rates resulted in increased TA-DIC slopes and partially buffered against nighttime acidification owing to net respiration.

PRESENCE AND IMPACTS OF LAND-BASED SOURCES OF POLLUTION IN THE ST. THOMAS EAST END RESERVES, ST. THOMAS, USVI (Abstract ID: 29586)

The St. Thomas East End Reserves, or STEER is a collection of Marine Reserves and Wildlife Sanctuaries located on the southeastern end of the island of St. Thomas, U.S. Virgin Islands. NOAA's National Centers for Coastal Ocean Science conducted a project to develop an integrated assessment of chemical contaminants, bioeffects and a biological survey of the STEER. The information generated from this assessment is being used to establish a baseline of conditions, so that managers can understand not only the status, but also specific challenges that exist to improve the ecological functioning of the STEER. One hundred and eighty-five chemical contaminants, including a number of organic (e.g., hydrocarbons and pesticides) and inorganic (e.g., metals) compounds were quantified in the STEER. Nutrients and sedimentation were also monitored as part of the project. Higher levels of chemical contaminants were found in Mangrove Lagoon and Benner Bay in the western portion of the study area. Copper at one site in Benner Bay was above a NOAA guideline (ERM) indicating that effects on benthic organisms were likely. The concentration of tributyltin (TBT) in sediment cores was nearly an order of magnitude higher than any found in NOAA's National Status and Trends (NS&T) Program data base. Results of multiple bioassays indicated significant sediment toxicity in Mangrove Lagoon and Benner Bay. The benthic infaunal communities in Mangrove Lagoon and Benner Bay were also severely diminished. Nutrients and sedimentation were elevated in the STEER as well; some concentrations were above proposed thresholds, which could indicate impacts to the reefs in the STEER

MARINE PROTECTED AREAS AND POVERTY ALLEVIATION: SHORT TERM INSIGHTS FROM PAPUA, INDONESIA (Abstract ID: 29657)

Marine protected areas (MPAs) are an integral component of local, national, and international strategies for biodiversity conservation, but their impacts on human well-being remain contested. Advocates tout MPAs as win-win strategies for conservation and poverty alleviation, while opponents argue that MPAs place the welfare of fish above the well-being of impoverished fishing communities. To inform this debate, we are monitoring the social impacts of six MPAs in the Bird's Head Seascape (BHS). Using a quasi-experimental design, we examine social well-being across five social domains: economic well-being, health, political empowerment, education, and culture. Preliminary impact data from six MPAs and matched controls provides insights into the short-term impacts of MPA establishment on household well-being. We find that the social impacts of MPAs are far from uniform, with the magnitude and direction of impacts varying within and among social groups, across social domains, and between sites, resulting in complex arrays of impacts. In addition to providing insights for site-level adaptive management, the variable social impacts of MPA establishment in the BHS highlights the need for a more nuanced approach to evaluating the social impacts of conservation interventions as the foundation for analyzing protected area –poverty linkages.

EFFECT OF BALANCED AND IMBALANCED NUTRIENT ENRICHMENT ON THE BLEACHING RESPONSE OF TWO CARIBBEAN CORALS DURING HEAT STRESS (Abstract ID: 29993)

Interacting global and local stressors usually act together in driving the decline of coral reefs, with local impacts such as declining water quality often exacerbating global impacts such as coral bleaching, and vice versa. Recently, it has been suggested that poor water quality can decrease coral thermotolerance, either due to proliferation of the coral's algal symbionts under high nutrients and/or to exposure to imbalanced nutrient supply. We investigated the effect of balanced and imbalanced nutrient addition on the abundance of different *Symbiodinium* hosted by the Caribbean corals*Siderastrea siderea* and *Montastraea cavernosa* and their subsequent response to heat stress. Replicate cores (N=60, from 6 colonies of each species) were exposed to elevated nitrogen (N), nitrogen+phosphorus (NP), nitrogen+phosphorous+feeding (NPF), or iron (Fe), and compared to controls over a 180-day period. Thermotolerance was then measured by exposing corals to 32°C for 2 weeks. Throughout the experiment we used quantitative PCR to identify and quantify different symbionts, and chlorophyll fluorometry to assess their photochemical efficiency (Fv/Fm). This study allowed us to test the degree to which improving water quality might enhance future coral reef resilience to continued global warming.

MULTIPLE PREDATOR EFFECTS ON JUVENILE PREY MORTALITY (Abstract ID: 28594)

Loss of marine top-predators often leads to mesopredator release. Understanding the net effect that mesopredator release may have on low trophic-level fish is a key issue, but can be challenging to predict and measure in situ. Each mesopredator can impact prey

differentially and generally their combined effects cannot be predicted from their independent contributions. Using small mesopredator fishes with either active (*Pseudochromis fuscus* (F)) or ambush hunting mode (*Cephalopholis boenak* (B) and *Epinephelus maculatus* (M)), we conducted a mesocosm experiment to examine their predation rate on six damselfish juveniles (*Pomacentrus* spp). Treatments included each predator on its own (F, B, M) and all possible paired interactions (FF, BB, MM, FB, FM, BM). Prey mortality from predator pairs with different hunting mode either matched (FB) or exceeded (FM) the mortality expected from their individual effects. Interestingly, although pairs of active predators (FF) caused the expected mortality, the combination of ambush predators did generate risk-enhancing effects, but only within intraspecific pairs (BB, MM). For the interspecific combination of ambush predators (BM), prey mortality was lower than predicted (risk-reducing effect). Our study suggests multiple predator effects may be influenced by the hunting mode of predators, but also by the specific taxon of the species interacting. Further, it highlights the complexity of intraguild behavioural interactions and their importance for accurately predicting the consequences of mesopredator release.

THRIVING IN THE FACE OF NATURAL EXTREMES: WHAT HAVE WE LEARNED AT OFU ISLAND, AMERICAN SAMOA, ABOUT THE FUTURE ADAPTABILITY OF CORALS? (Abstract ID: 28221)

Healthy, growing corals in the back reef lagoons of Ofu Island experience large periodic swings in temperature, pH, oxygen, and other environmental factors that conventional wisdom suggests should limit their survival. An eight-year research program has used genomics, reciprocal transplants, common gardens and standardized stress tests to show that that these corals adapt and acclimate to environmental extremes across short temporal and spatial scales. Transcriptome and genome-wide variants help pinpoint the physiological traits most central to adaptation and acclimation, and highlight the genetic machinery associated with effective adaptation. The genetic architecture of adaptation appears to involve hundreds of genes, yet each individual coral also shows the ability to adjust its physiological tolerances through rapid acclimation. In addition, symbiont type varies with location and bleaching history. A general evolutionary model suggests that a high variability in fitness traits in the face of environmental variation is expected when environmental change occurs over spatial scales that are shorter than dispersal distances. This short scale of variation is common for reef species that live across fore and back reef environments. As a result, genetic variation for environmental resilience may be a common feature of large reef populations. Using this variation to enhance future reef survival might be advanced by protection of adaptation hotspots, restoration using the most resilient colonies, and maintenance of large populations with high variability.

IMPROVING SCIENTIFIC INPUT INTO CORAL REEF MANAGEMENT AND POLICY (Abstract ID: 28906)

Recent consensus on the new Anthropocene geological epoch marks widespread recognition of the permanent influence of Homo sapiens on planet Earth. Coral reefs are often cited as one of the most vulnerable ecosystems impacted by humans. The direct conduit from science to management is one of the most important tools we have for conserving coral reefs. Here I will discuss a number of ways in which the effectiveness of this nexus can be strengthened: 1) prioritizing research questions, ensuring that we are asking the right questions, or at least, not ignoring important ones; 2) getting the message right by incorporating nuance into public and policy debates; 3) expanding temporal perspectives to avoid misguided policies subject to shifted ecological baselines; 4) embracing and reporting uncertainty – anticipate not only what will happen when negative scientific predictions turn out to be true but also if they turn out to be false; 5) providing insight on potential biases; and 6) acknowledging the simultaneous effects of multiple stressors and the geographical variation in response to stressors. Recent studies of both Caribbean and Indo-Pacific reefs have shown one size doesn't fit all reefs for response to human activities and climate change. Incorporating these key concepts will allow coral reef scientists to serve the management and conservation community while maintaining scientific integrity, allowing the research community to continue to provide effective leadership in advising reef managers and environmental policymakers.

THE STATUS OF REEF BENTHOS IN MARINE PROTECTED AREAS IN THE PHILIPPINES (Abstract ID: 28608 | Poster ID: 672)

Marine Protected Areas (MPAs) are popular tools to help rehabilitate marine habitats and conserve biodiversity. While MPAs primarily impact fish communities, the response of reef benthic components are less straightforward. MPAs benefit the reef benthos by lessening damage due to human activities. Also, MPAs help maintain healthy herbivore populations which control algae from dominating the reefs. Here we present the condition of the benthic communities from 27 municipalities in the Philippines. Benthic cover was derived using the line intercept transect methods in more than 260 50-m transects inside and outside 28 MPAs. Most of the MPAs were in the fair condition, with an average hard coral cover of 42.3%. While it is assumed that protection will lead to better coral condition, hard coral cover did not significantly differ among transects inside and outside the MPAs. Likewise, covers of other benthic components such dead coral, algae, etc. did not vary with respect to protection. Condition, mortality, development, and succession indices were also explored. Differences in reef benthos were detected across municipalities and biogeographic regions. This implies that factors driving variation in reef benthos operate at larger scales.

CENTRAL PLACE REFUGING IN MARINE PREDATORS THAT NEVER SLEEP: EATING AT HOME AND AWAY (Abstract ID: 27998)

Central place refuging (CRF) is seen in a wide range of animals, including insects, fish and humans. In most cases the function of CRF is clear; the animal moves to/from a shelter or den site. CRF behavior is also seen in reef sharks, which swim continuously but would not seem to require a 'core' area to which they return. We used a combination of acoustic telemetry, biologging, and statistical modelling to understand potential drivers of CRF in reef sharks (blacktip and grey reef sharks) at an uninhabited atoll. Acceleration sensors and hidden Markov modelling identified crepuscular or nocturnal peaks in activity, but there was only a small increase in the probability of animals being active during peak periods. Animal-borne video cameras revealed that sharks would forage during the day on the reef, when they should be less active. We used acoustic telemetry with Brownian bridge models to generate 3D time-utilization distributions, which incorporated probability of activity, for individuals tracked over several years. Reef sharks showed strong residency to certain areas and displayed habitat shifts (diel) that did not necessarily match patterns of activity (e.g. crepuscular). Reef sharks essentially display CRF behavior that is counter to predictions as they forage both in their core area and likely their excursion habitats. The use of a core area may improve navigation especially if the animal uses reduced brain activity during the daytime as a replacement for 'sleep'. Future studies will investigate the implications of these behaviors to ecosystem predation effects and degrees of inter and intra-specific competition.

GENETIC TYPING OF TRIDACNIDS AND THEIR ALGAL SYMBIONTS ON THE CENTRAL SAUDI COAST OF THE RED SEA (Abstract ID: 30144 | Poster ID: 57)

The Red Sea hosts a diverse community of coral reef organisms despite relatively extreme environmental conditions (high temperature and salinity). Due to these conditions, the Red Sea may offer insight to the capacity of reef fauna elsewhere to adapt to climate change. Tridacnids, a family of giant clams, are found throughout the Indo-Pacific, including within the Red Sea. This study examines the species diversity of giant clams and their algal symbionts from the central Saudi coast of the Red Sea using a combined morphological and molecular approach. Samples were collected at nine different reefs from both the sheltered and exposed sides of depths between 5 and 10 m. Results will be presented on whether or not reef side and type correlated with species diversity. A total of three potential species of tridacnids were found, but the majority were T. squamosa and T. maxima. Interestingly, we identified a group of genetically diverse tridacnids that could potentially be specific to the Red Sea. When examining the diversity of Symbiodinium, all samples were found to belong to clade A, which is common in Red Sea corals. Giant clams did not appear to be affected during a thermal bleaching event that took place

during this study, potentially due to the tolerance of the Symbiodinium. Further research on the role of Symbiodinium biodiversity and their interaction with giant clam hosts is necessary to understand the capacity of these and other photosymbiotic organisms to adapt in the face of climate change in the Red Sea.

RECRUITMENT PULSES OF A BROODER DAMSELFISH, ACANTHOCHROMIS POLYACANTHUS IN PUJADA BAY, PHILIPPINES (Abstract ID: 29999 | Poster ID: 195)

The damsel brooder, Acanthochromis polyacanthus is one of the only two reef fishes with no pelagic larval duration. It has a narrow distribution ranging from GBR to Indonesia and all the way up to the southwestern portion of the Philippines. The recruitment pulses of A. polyacanthus was investigated to give light on how this particular species was able to disperse and attain its present distribution. Two stations in Pujada Bay (Tamisan and Catmunan Reefs) were surveyed monthly from January to November at 2 to 6 transects each. Tamisan Reef is exposed during the southwest monsoon (June to September) while Catmunan Reef is exposed during the northeast monsoon (November to March). A total of 1,792 recruits of A. polyacanthus was recorded for Catmunan Reef, whereas, only less than 50 individuals was observed in Tamisan Reef. However, the latter data was excluded in the analysis. Results showed significant difference across months with peak of recruitment from November to April covering two seasons in the Philippines, namely: northeast monsoon and the first month of weak easterlies (April-May). The pattern observed did not coincide with the known recruitment pulse in the Philippines which fall during the southwest monsoon and the second inter-monsoonal period (October). This suggests that the dispersal of A. polyacanthus most probably take place during the southwest monsoon, a non-breeding season for the species, through a stepping stone processes. More importantly, its distribution was confined within the net seawater mass movement during that period.

BENEFITS AFFORDED TO REEF FISHES: GEAR RESTRICTIONS VERSUS REMOTENESS (Abstract ID: 28689)

It is well accepted that no take fishery closures provide refugia for fish and boost their overall abundance and biomass. In developing countries where people rely heavily on coastal resources for their daily subsistence, there is little evidence that no take areas are fully complied with or are different to gear restricted areas. Over the past 15 years, we monitored coral reef fish biomass from west to east Indonesia in response to management, including full fishing closures, fishing gear restrictions and in areas with no management. We also applied Indonesia national guidelines to rank the management effectiveness of Marine Protected Areas (MPAs). Across 466 sites representing 19 MPAs, and 3 unmanaged remote areas, we found a gradient in fish biomass ranging from 40 kg ha-1 in East Flores to 31,650 kg ha-1 in the remote area of Southwest Maluku. Across the gradient of sites from lowest to highest biomass we detected distinct changes in the trophic composition due to the relative percentage of planktivores and omnivores increasing. We also found full fishery closures had higher biomass than areas with gear restrictions, which in turn were generally higher than areas open to fishing. We examined the relationship between the management effectiveness rankings and fish biomass to see how well they correlated. Although we found the highest reef fish biomass in remote areas, and in some recently established MPAs, our study suggests that in areas close to human populations management efforts are contributing to improvements in Indonesian fish stocks.

FINDING POTENTIALLY USEFUL REMOTE SENSING VARIABLES FOR A. PALMATA COVER PREDICTION (Abstract ID: 30082 | Poster ID: 540)

Acropora palmata is a key species conforming the structure of the Mesoamerican Coral Reef (MCR), sadly, a combination of factors have put it on the edge of extinction. That's why a periodic assessment of A. Palmata cover is a crucial part of an adequate monitoring of the MCR. To date, the only reliable method to estimate coral cover involves extensive fieldwork, which proves to be very expensive. It is then useful to test if other sources of information, like satellital images, could be used to lessen the cost of such assessments. We studied the distribution of various satellite derived variables (bottom reflectance, bathymetry and geomorphological zonation) conditional to percentage cover of A. Palmata, as a first attemp to identify remote sensing variables that can be important indicators of A. Palmata cover percentage. The study area is the national park "Arrecife de Puerto Morelos", which stands out for the highly conserved of some of its A. Palmata populations. We proceded by segmenting the area using the reflectance bands from a corrected WV2 image. After that, we used the information from an extensive fieldwork assessing Acropora cover to assign a level to each segment. Finally, we obtained the conditional distribution of the satellital variables per segment for each cover level. Results showed that spectral information per se is uncorrelated to A.palmata coverage. But complementary data like bathymetry and geomorphological features is not. We believe this is an important first step in the use of more powerful statistical techniques.

REVERSING THE DECLINE: MODELING TARGETED CONNECTIVITY IN BAHAMIAN ACROPORIDS (Abstract ID: 29865)

Knowledge of the physical pathways among coral reefs created by the movement of water masses is usually considered essential for a causal explanation of the patterns of larval dispersal, retention, recruitment, and connectivity. Consequently, understanding physical pathways has implications not only for the design and the establishment of networks of coral reef marine reserves, but also for the selection of locations for facilitating the recovery of critically threatened broadcast spawners, such as elkhorn and staghorn corals. For this purpose, we set up a new HYCOM configuration for The Bahamas regional circulation with a 2km horizontal resolution and adapt the open-source Connectivity Modeling System to acroporid larval transport. Detailed habitat maps from satellite imagery collected at different spatial scales from 1-2m per pixel in some areas to 10-30m per pixel for the whole country are used to create a realistic coral reef landscape for the coupled biophysical model. Climate scenarios during years of contrasted hurricane occurrence serve to introduce maximum range of variability in connections. Sensitivity analyses on the role of specific larval traits and behaviors, such as swimming, increasing sinking rates with ontogeny, and temperature-related mortality rates, are performed to explore the detailed biophysical interactions that lead to source and sink variability, dispersal barriers, and temporally stable settlement nodes. We explore emerging temporal and spatial connectivity patterns and discuss results in the view of coral rehabilitation in a changing climate.

RESILIENCE-BASED MANAGEMENT OF CORAL REEF ECOSYSTEMS: PAST, PRESENT AND FUTURE (Abstract ID: 28797)

The concept of resilience has been acknowledged as important to coral reef conservation for nearly three decades. However, we have struggled to demonstrate how resilience theory can be implemented to inform coral reef planning and management. Recent innovations in resilience-based management provide an approach to ecosystem-based management that is forward-looking, holistic and adaptive in nature, and address both current and future pressures including climate and non-climate threats. The NOAA Coral Reef Conservation Program is working with many partners including The Nature Conservancy, the Great Barrier Reef Marine Park Authority, the United Nations Environment Programme, academics and local managers around the world to advance the application of resilience-based management. These activities include science and research to better understand resilience, the development of data products and guidance to support the identification of resilience indicators, resilience assessments, and incorporation of resilience into planning and management decisions. Supporting resilience-based management is the priority of our climate-related work. This presentation will outline NOAA and partner contributions to this body of work, and will highlight priority next steps and progress made to integrate social and ecological resilience into coral reef management.

FINE-SCALE TRANSCRIPTIONAL RESPONSES TO CLIMATE CHANGE IN THE ENDANGERED CARIBBEAN STAGHORN CORAL *ACROPORA CERVICORNIS* (Abstract ID: 27937)

Individuals adjust gene expression to acclimate to different stressors, while expression variation among individuals represents raw material available for adaptation via natural selection. Climate change will create more frequent sea surface temperature anomalies, especially in marginal regions such as the Florida Keys, but it is unclear to what extent hot and cold stressors will drive synergistic or antagonistic responses in individual coral colonies, and whether the adaptive capacity of coral populations will be enhanced or restricted due to periodic exposure to opposing temperature extremes. Taking advantage of three coral restoration nurseries that serve as long-term artificial common garden experiments, we exposed ten genetically distinct*Acropora cervicornis* colonies at each nursery to ambient, hot, and cold temperatures seasonally and measured typical gene expression responses using RNA-seq on pooled individuals. Targeting 21 genes of interest, including those with synergistic or antagonistic responses to hot and cold, we designed a high-throughput qPCR array to quantify expression in all 30 individuals under each treatment: a total of 360 samples. This study represents one of the most comprehensive investigations into fine-scale transcriptional differences within a coral species to date, and reveals extensive genetically- and environmentally-driven variation in acclimatory/adaptive capacity for a population endangered by climate change.

COLONIZATION AND SUCCESSION OF HAWAIIAN GOLD CORAL (KULAMANA-MANA HAUMEAAE). (Abstract ID: 28750)

The Hawaiian gold coral is a parasitic zoanthid that colonizes other soft corals and secretes a protein skeleton that over millennia can more than double the mean height of the host colony. Visual surveys at 6 known coral beds in the Hawaiian Archipelago found mature gold coral to be a dominate taxa at all but the geologically youngest site. Less than 5% of the gold coral colonies seen were in the process of colonizing a host, described here as the "midas" phase. Bamboo coral (e.g. Acanella, Keratoisis) comprised 85% of the hosts of midas colonies with two thirds found at the younger site where the mean height of bamboo coral was significantly greater than at other sites. Marked midas colonies revisited after 5 and then 8 years showed the gold coral tissue spreading across the host at a rate of roughly 2 cm per year. Despite the rapid change much of the host skeleton is lost in the process of being subsumed. Cross-sections of mature gold colonies indicated the host comprises an average of 9.8 cm of the core of the gold coral stem. Midas colonies were notably absent from a bamboo coral assemblage growing on a 76-yr-old wreck adjacent (~1 km) to a patch of mature gold colonies indicating settlement was infrequent. This time lag between the bamboo coral host and the gold coral successor is essential because otherwise the speed of the midas phase would subsume the host population faster than it could replenish.

A CASE STUDY IN GOOD GOVERNMENT: ORDNANCE REEF CORAL ASSESSMENT AND MITIGATION PROJECT (Abstract ID: 29660 | Poster ID: 686)

Discarded military munitions (DMM) represent a risk to human health and safety as well as the environment. Addressing these threats requires that a host of Federal entities (both military and civilian), State and Local agencies, and community stakeholders work together in a manner that maximizes efficiency and minimizes environmental impacts. Overcoming community distrust and skepticism to fully empower stakeholders to participate in public input sessions is crucial to ensuring effective community input and to achieving positive resource outcomes. The Department of Defense (DoD) is responsible for addressing the legacy of contamination associated with these munitions, including unexploded ordnance (UXO) present from current and former testing and training ranges and disposal of discarded military munitions (DMM). In an effort to evaluate remote means to recover munitions, the U.S. Army completed a demonstration of the Remotely Operated Underwater Munitions Recovery System (ROUMRS) in July 2011 to recover DMM present off the coast of Wai'anae, Oahu, HI. Working in collaboration with the DoD, the National Oceanic and Atmospheric Administration (NOAA) and the State of Hawaii surveyed corals and munitions present in the area prior to initiation of the recovery effort. This allowed for the demonstration project to be planned and executed in manner that minimized injury to corals present. Post-recovery surveys documented injury to corals that did occur and will allow for the design of a coral mitigation project appropriate for the injury that was identified. Details regarding the pre- and post- recovery surveys and coral assessment and mitigation process will be presented

PATTERNS IN SOUNDSCAPES AROUND AUSTRALIA (Abstract ID: 29340)

Underwater soundscapes provide a wealth of information for resident, transient and settling fauna often using these cues for a number of independent or associated functions (e.g. mate selection, migration, recruitment). To researchers the sounds help assess presence, abundance, and distribution of vocal species, anthropogenic activity and resulting marine fauna responses. More recently, various acoustic components of a soundscape are being investigated as an index of habitat condition. However, restricted by technology, many previous studies relied on short-term sampling regimes, collecting only brief acoustic snapshots, increasing the likelihood of drawing uncertain conclusions on temporal patterns and soundscape composition. Over the last two decades, CMST has collected over 500, near-continuous (typically 5 of 15 minutes) long-term recordings at nearshore, offshore, reef and estuarine sites around Australia, collectively providing over a decade of coverage at some sites. This presentation will discuss several examples of soundscape spatial and temporal patterns in various biological contributions to soundscapes on a range of scales, some displaying significant day-to-day variations (up to shifts of hours between days). Many of these correlate with environmental drivers, such as temperature, salinity, tide, light or dissolved oxygen etc. Possible implications for short-term or snapshot datasets are discussed.

RECONSTRUCTION OF THE HISTORY OF A ST. CROIX, USVI REEF LAGOON SYSTEM FROM THE SEDIMENTARY RECORD (Abstract ID: 29383)

Studies of ecosystem fidelity have shown that time-averaged molluscan death assemblages in surface sediments are representative of the living community on decadal scales. The assumption becomes that the death assemblage is preservable once buried beneath the surface, and can be used to reconstruct the history of the reef/lagoon system. Vibrocores through the entire sediment package (2-5m deep) revealed that the modern seagrass community is poorly represented in the subsurface. The lagoon is strongly bioturbated by callianassid shrimp that have reworked the sediment package such that it is nearly devoid of molluscs. Instead, there is a thick shelly lag deposit atop the Pleistocene substrate at the bottom of each core. Taxonomic analyses of the shells in the lag do not match the surface seagrass death assemblage. Instead, they are strongly skewed toward small infaunal bivalves matching open sandy environments in St. Croix lagoons. These results suggest one of two scenarios: 1) The typical seagrass community (epifaunal gastropods and larger, shallow infaunal bivalves) is not easily moved into the subsurface by callianassids, but remains at the sediment-water interface and degrades; or 2) the seagrass ecosystem is a relatively recent environmental change following a 7,000yr history of primarily open bioturbated sand. Applying taphonomic analyses to the mollusk assemblages avoids problems with taxonomic change over time. Taphonomy of the surface mollusks versus lag deposits supports the hypothesis that the lagoon has been dominated by open sand, not seagrass, throughout its history and therefore the lagoon has undergone a recent change from open sandy bottom to seagrass.

DIVERSITY AND FUNCTION OF VIRUSES IN CORAL REEF SPONGES (Abstract ID: 28990)

Viruses are ubiquitous biological entities that regulate diverse biological processes. However, despite their abundance, we have limited knowledge about how viruses interact with marine invertebrate hosts, particularly with sponges, which are ecologically important components of coral reef environments. As marine holobionts, sponges harbour dense communities of microorganisms and this high symbiont complexity makes them an ideal model for studying host-virus interactions. Morphological and molecular approaches were used to describe the diversity and function of viruses in some of the most representative coral reef sponge species from the Great Barrier Reef and the Red Sea. Sponge viruses were isolated from their hosts, viral metagenomes were sequenced and taxonomic composition and function were assessed using a customized bioinformatic pipeline designed specifically for analysis of holobiont metaviromes. In addition, Transmission Electron Microscopy (TEM) was used to morphologically characterize the viral particles and resolve their spatial location within the holobiont. Initial molecular analyses indicate that sponges host a wide diversity of bacterial and eukaryotic viruses, including abundant Caudovirales and representatives of Mimiviridae, Phycodnaviridae and Iridoviridae. TEM analysis of different sponge species further revealed that distinct icosahedral virus-like particles were associated with both sponge and bacterial cells. This study highlights viruses as an important component of the sponge holobiont.

MORPHOLOGICAL CHARACTERIZATION OF SPONGE-VIRUS ASSOCIATIONS USING TRANSMISSION ELECTRON MICROSCOPY (Abstract ID: 29234 | Poster ID: 498)

Viruses are among the most abundant organisms in marine ecosystems and play important roles in several biological processes. In this context, sponges are likely to be an important reservoir for viruses as they host a diverse array of macro and micro symbionts. Recent efforts have been made to improve and standardize methods for describing and quantifying viruses associated with other marine hosts such as corals. However, substantial technical challenges - e.g. the preparation of high quality transmission electron microscopy (TEM) images – have limited our understanding of sponge-associated viral communities. Here we assessed the efficacy of three different methods for TEM imaging of sponge-associated viruses: i) Viral purification from host tissue by cell lysis followed by ultracentrifugation in cesium chloride gradients to separate viruses based on density; ii) Ultracentrifugation of homogenized host tissue in liquid media directly onto Formvar-coated electron microscopy grids and iii) Preparation of ultrathin sections from the host tissue. To date, co-precipitates during ultracentrifugation have limited effective visualization of viruses although virus-like particles have been successfully observed in ultrathin sections of sponge tissue. Furthermore we successfully imaged viral-host interactions including the observation of inter- and intracellular viruses within the sponge holobiont.

ISLAND EROSION AND MIGRATION IN HATOHOBEI STATE, PALAU (Abstract ID: 28261 | Poster ID: 392)

For small island nations, global warming and climate change has prompted predictions of disappearing islands swallowed by sea level rise. However, recent studies have shown dynamic reef island conditions over time, indicating that the situation is not so simple. Here, we assess the coastal changes on two remote and near-equatorial southwest islands of Palau using satellite imagery, historical aerial/coastal photographs, and GPS-based land surveys. Hatohobei (or Tobi) is an oceanic island surrounded by fringing reef and has experienced areas of both erosion and accretion of its coastal beach and land in past decades. Helen Reef is a medium-sized protected coral atoll with a single small sand spit island, an important turtle and bird nesting site. In the past 25 years Helen Reef Island has changed slightly in size and shape, but more critically has migrated sufficiently that only 10% of the island that was land in 1992 is still part of the present island. The island has literally "left behind" most of its larger vegetation so that in the last 25 years its general appearance has greatly changed. We examine changes of both islands relative to natural conditions and human influences and have attempted to obtain precise data that will allow detailed determination of changes in the future.

LESSONS LEARNED FROM A QUARTER CENTURY OF A SUCCESSFUL MARINE CITIZEN SCIENCE PROGRAM (Abstract ID: 30027 | Poster ID: 721)

Since 1993, Reef Environmental Education Foundation (REEF) has coordinated the Volunteer Fish Survey Project, a citizen science program that engages divers and snorkelers to collect data. REEF surveyors record all positively identifiable fish species, along with categorical estimates of log-scale abundance. To date, approximately 16,000 volunteers have submitted over 200,000 surveys. Collectively, the surveys include over 8.5 million sightings records on over 3,400 species from 12,038 sites worldwide. All REEF data are made available to the public through summary reports via the REEF website. REEF also provides raw data files upon request. Scientists from government agencies and academic institutions use the REEF database to address management and conservation issues, including fisheries assessments, evaluation of species trends, understanding ecological patterns, tracking non-native species, and identification of new species. Over forty scientific publications have included REEF data. To ensure a high level of accuracy, REEF staff have incorporated layers of quality assurance, including experience levels, automated error checking during submission, and extensive post-processing. Several recently published papers have developed analyses that capitalize on the power of the data collected while addressing uncertainty. Based on experiences in the development, cultivation, and expansion of the REEF program, I will discuss characteristics that foster long-term participation and generation of data that have proven useful for marine conservation and discovery.

CO-MANAGEMENT TO ADDRESS LIVELIHOOD LINKED THREATS TO CORAL REEFS – CASE STUDY FROM GULF OF MANNAR, SOUTHEASTERN INDIA (Abstract ID: 29116)

The fishers live along the coast of Gulf of Mannar depend mainly on the fishery resources for their livelihood. Though reefs in Gulf of Mannar are protected, there is good accessibility for coastal communities. The steady increase of population (34% in 15 years), crafts and competition forced them to diversify into shore seine fisheries, trap fishing and poaching of ornamental fishes in reef areas. The 2004 Indian Ocean Tsunami made the community significantly more aware of the importance of reefs. The increase of additional livelihood options through eco development activities under various national and international programmes like CORDIO, GCRMN, GEF-UNDP also helped the fishers to reduce their dependence on the sea. However, nowadays the cultivation of exotic seaweed, Kappaphycus alvarezii and seaweed collection in reef areas have inflicted considerable damage to reefs. Due to invasion of exotic seaweed, about 1.2 Km2 reef areas have been affected and seaweed collection makes regular disturbances to reefs.. These activities are not permitted as per Wildlife Protection Act of India and respective Government Orders, however the activities are linked to livelihood of over 600 fisher families and there was always conflicts between community and reef managers on this issues. The Government through a GEF-UNDP project with 252 grass root level organizations - Village Marine Conservation (VMC) and Eco Development Committees (EDC) have been formed and loans are provided as revolving fund to enhance their livelihood activities and to reduce pressure on reefs.

A NEW SPATIO-TEMPORAL RECORD OF BIOEROSION IN DEGLACIAL FOSSIL REEF SEQUENCES FROM IODP EXPEDITION 325 CORES, GREAT BARRIER REEF, AUSTRALIA (Abstract ID: 29133)

Bioerosion traces preserved in coral reef systems provide insight into past environmental conditions and reef health, however few studies have explored this in fossil reefs. The International Ocean Drilling Program (IODP) Expedition 325 sampled fossil Last Glacial Maximum (LGM) to deglacial (~10-30 ka) reef sequences off the northwest continental shelf of the Great Barrier Reef. Presence of bioerosion traces (*ichnogenera*: *Entobia*(Sponges), *Gastrochaenolites* (Bivalves) and *Maeandropolydora*/*Trypanites*(Worms)) was quantified based on detailed core observations and high-resolution 3D CT data from 14 drill holes from 3 cross-shelf transects within two regions, Hydrographers Passage and Noggin Pass. A new high-resolution temporal record of bioerosion activity was defined from the cores using a comprehensive chronologic database. This new record, along with paleo-environmental interpretations derived from coralgal assemblage data, were used to study multi-scale spatio-temporal patterns of bioerosion across-shelf, along-shelf and within individual sites. Pooled bioerosion data show temporal differences in relative abundance and intensity, which is consistent with

position of major reef sequence boundaries, including shallow reef death events. Bioerosion intensities vary between both regions possibly inferring distinct post-depositional environmental settings. Finally, we discuss the influence of bioerosion on reef systems during periods of rapid environmental change (last deglaciation) when environmental conditions were very different from now.

ELECTRICAL NETWORK MODELING OF PERFORATE AND IMPERFORATE CORAL PHYSIOLOGICAL PERFORMANCE UNDER ENVIRONMENTAL STRESS (Abstract ID: 29066 | Poster ID: 355)

Scleractinian coral body plan potentially affects resource sharing and response to stress that can lead to bleaching. We use electrical network models, where resistance, capacitance, voltage, and current have identifiable correlates with organism structures and the environment. Perforate taxa share a common gastrovascular system connecting all polyps. In imperforate taxa, a colony's polyps are connected only to nearest neighbors (in a hexagonal array) and only when the colony is expanded. We present microelectrode data for dissolved oxygen inside and around imperforate (Montastraea cavernosa) and perforate (Acropora cervicornis) colonies in no flow and flow conditions (colony Reynolds number = 4,000 and 10,000), and morphological data, used to estimate parameters for a resistance-capacitance network model of mass transfer between colonies and the environment. SPICE network simulations of the performance of perforate and imperforate models of colonies of varying size exhibit strikingly different dynamic behaviors to environmental perturbations. Perforate coral colonies exhibit larger time constants, on the order of many minutes, for response to environmental perturbation compared to imperforate species, which have faster system dynamics but uncouple neighboring polyps from each other. A key parameter requiring further characterization is the mixing time constant of the polyp coelenteron. Ecophysiological network models of resource sharing are useful in predicting response to changing environmental conditions.

EFFECTS OF TEMPERATURE AND SALINITY ON CORAL BLEACHING UNDER LABORATORY CONDITIONS. (Abstract ID: 29526 | Poster ID: 415)

Coral bleaching occurs when cell densities or/and cellular content of photosynthetic pigments in zooxanthellae are decreased which may due to some environment stresses espeacially under conditions of elevated temperature and low water salinity or a combination of these factors. To clarify the important role of temperature and salinity on coral bleaching, this study has been conducted in the cauliflower coral, *Pocilloporadamicornis* collected from Samaesan Island, Chonburi, Thailand. The same size of cauliflower coral's colonies were collected and placed in wide mouthed glass jar at temperature of 28, 31 and 34 C. For each temperature level, there were 3 levels of salinity experiments 10, 20 and 33 psu. The percentage of bleaching in cauliflower coral's colonies were observed in conjunction with the cell densities of zooxanthellae in seawater of the glass jar. Sampling cells were enumerated every 3 hours for 33 hours. High cell density of zooxanthellae was found the glass jar seawater and coral bleaching (50% of coral colony) were observed only in the low salinity (10 psu) at 28 and 31 C. On the other hand all coral colonies were bleached at 34 C in all salinity levels. These results suggested that high temperature and low salinity play an important role on coral bleaching.

DECIPHERING CHEMICAL SIGNALING IN BLACK BAND DISEASE (Abstract ID: 29919)

Black Band Disease (BBD) is the first reported coral disease and the most widely distributed polymicrobial disease of corals. In BBD, a polymicrobial disease consortium dominated by the filamentous cyanobacterium*Roseofilum reptotaenium* displaces members of the epibiotic microbiome. We investigated the natural products chemistry and chemical ecology of BBD and nonaxenic cultures of *R. reptotaenium*. Within the BBD consortium, we identified lyngbic acid, a cyanobacterial secondary metabolite. It strongly inhibited quorum sensing (QS) in the *Vibrio harveyi*QS reporters, which depend on the presence of the CAI-1 receptor CqsS. Lyngbic acid inhibited luminescence in native coral *Vibrio* spp. that also possess CAI-1-mediated QS. *R. reptotaenium* also produces a novel malyngamide. Since malyngamides from other cyanobacteria are known to inhibit QS activity we also examined the functions of this new compound. The effects of these naturally occurring QS inhibitors on bacterial regulatory networks potentially contribute to the structuring of interactions within BBD consortia.

WHAT IS THE BEST SCIENTIFIC JUSTIFICATION FOR MPAS ON CARIBBEAN REEFS? (Abstract ID: 27853 | Poster ID: 653)

Marine protected areas (MPAs) are a common policy tool used for the conservation of coral reefs worldwide. The scientific justification for MPAs is based on community-level indirect effects of overfishing on the competitive interactions between seaweeds and reef-building corals: more fishing, more seaweeds, less coral. Some have questioned this justification for MPAs in the Caribbean, which has reefs that are distinct from those found elsewhere in the tropics. We found an explicit indirect effect of overfishing on competition between sponges and reef-building corals from surveys of 69 sites across the Caribbean. Removal of sponge-eating angelfishes and parrotfishes resulted in > 3 fold increase in overgrowth of corals by sponges, with coral-sponge contact increasing from 11.0% to 25.6%, and these sponges were mostly species palatable to sponge predators. Palatable sponge species have faster rates of growth or reproduction than defended species, which instead make metabolically expensive chemical defenses. Surprisingly, overfished sites had lower seaweed cover, contrary to prevailing assumptions about seaweed control by herbivorous fishes. Coral-sponge competition provides an unambiguous justification for MPAs in the Caribbean, while seaweed cover does not.

HYBRIDISATION AMONG GROUPERS (GENUS CEPHALOPHOLIS) AT THE EASTERN INDIAN OCEAN SUTURE ZONE: TAXONOMIC AND EVOLUTIONARY IMPLICATIONS (Abstract ID: 28560)

A suture zone in the eastern Indian Ocean is home to numerous hybridising species, providing an opportunity to determine how hybridisation affects speciation and biodiversity in coral reef fishes. At this location, hybridisation between two grouper: Cephalopholis urodeta (Pacific Ocean) and C. nigripinnis (Indian Ocean) was investigated to determine the genetic basis of hybridisation, and to compare the ecology and life history of hybrids and their parent species. This approach aimed to provide insights into the taxonomic and evolutionary consequences of hybridisation. Despite clear phenotypic differences, hybrids and their parent species were genetically homogenous within and (thousands of kilometres) outside of the hybrid zone. Hybrids were at least as fit as their parent species (in terms of growth, reproduction and abundance) and were observed in a broad range of phenotypes. The two species appear to be interbreeding due to inherent biological and ecological similarities and the lack of genetic structure may be explained by three potential scenarios: 1) hybridisation and introgression; 2) discordance between colouration and genetics; and 3) incomplete lineage sorting. Further genetic analyses may be necessary to distinguish these scenarios. Regardless, the two species are unlikely to evolve in reproductive isolation as they cohabit at Christmas Island and will source congeneric mates at Cocos (Keeling) Islands. Our results suggest that hybridisation among coral reef fishes is a dynamic evolutionary factor.

RESPONSES OF COMPLEX VS ROBUST CLADE CORALS FROM HIGH LATITUDE SOUTH AFRICAN REEFS TO WARMING AND ACIDIFICATION. (Abstract ID: 28634)

The high latitude reefs of South Africa's Maputaland coast are considered marginal as they are at the extremes of coral distribution. They are, however, extremely vibrant and biodiverse ecosystems with a high biodiversity including >90 hard and >40 soft coral species. These corals occur at the lower ranges of their thermal tolerances and are subject to significant seasonal variation, suggesting that they might have greater capacity for thermal acclimation than tropical conspecifics. Indeed, the Maputaland reefs were

not affected by the global coral bleaching events in 1998 and 2010 that significantly affected many other reefs in the Western Indian Ocean. The basis for this may lie in the abilities of the corals to acclimate or could be due to local physical and oceanographic features that reduce exposure to thermal stress. In order to investigate the potential for acclimation to current and future stresses, representative local corals from the complex (*Acropora austera*) and robust clade (*Hydnophora exesa*) were exposed to preindustrial, current and future temperatures and pH in a multifactorial design. Physiological changes were observed with changing temperature but not pH. Tag-based RNA-Seq was used to determine differential transcriptional responses to temperature and pH. This entailed assembling the full transcriptomes of the target species, which are the first corals from the highly diverse WIO and one of the few species from the robust clade to be sequenced. As such they are also of great interest for evolutionary studies.

THE INFLUENCE OF HABITAT AND CONSPECIFIC ADULTS ON THE ABUNDANCE AND SPATIAL DISTRIBUTION OF JUVENILE CORALS (Abstract ID: 29941)

Despite an increased understanding of recruitment and population dynamics of stony corals, there is a lack of knowledge on how various mechanisms may influence or create spatial patterns within a population, mainly due to methodological limitations. We use photomosaic images created by stitching together thousands of individual images, giving us the opportunity to look at how processes operate on a broader spatial scale. At eight sites on the forereef of Palmyra Atoll, photomosaics (100 $m^2$ in size) were used to identify and digitize all juvenile (<5 cm diameter) and adult coral colonies. Using various metrics such as density, percent cover, and the position of each colony, we examined relationships between juveniles and adults in terms of abundance and spatial patterning. Our results show that juvenile density is more strongly related to adult density rather than adult percent cover (by genus). Additionally, we found that juveniles of some genera were associated with specific habitat characteristics (consolidated versus unconsolidated substrata). A look at the spatial relationship between juveniles and adults using mean nearest neighbor distances shows three genera in which juveniles were clumped around adults of the same genus, while all other genera were randomly distributed with respect to adults. Using spatial patterns, this study provides insight into the potential role adult reproduction and settlement preferences play on the early life stages of corals.

POPULATION STRUCTURE AND MIGRATION PATTERNS OF THE CORAL *MUSSISMILIA HISPIDA* ALONG THE SOUTHWESTERN ATLANTIC OCEAN (Abstract ID: 29389 | Poster ID: 185)

The Brazilian coast encompasses the only true coral reefs from the Southwestern Atlantic Ocean, with a unique coral fauna characterized by low diversity and a high percentage of endemics. *Mussismilia hispida* is an endemic coral and one of the main reef builders, having one of the broadest distributions along the coast. Although important, there are no estimations of its population structure, even with reproductive asynchrony being observed among localities. This study aimed at estimating the population structure and patterns of migration for *M. hispida*, at 15 sites along its distributional range, using 13 microsatellites loci. Results show that *M. hispida* can be divided into five genetically structured populations: Northern region (NR), Oceanic islands (OI), Central region (CR), Southeastern region (SER) and Southern Limit (SL). Reproductive asynchrony does not seem to explain the observed patterns of gene flow. The CR and OI were the most genetically diverse populations, while SL had the lowest diversity. The migration model that best explained gene flow among populations was the one where OI exports migrants to NR and CR, CR exports migrants to the OI and SER and the latter exports migrants to SL. This pattern is mostly consistent with the main oceanic currents in the area. This is the first study to assess population structure and gene flow of a coral species along the Southwestern Atlantic coast using a highly variable marker. Results are useful for Brazilian coral reef conservation management strategies.

SOCMON CARIBBEAN AND COMPREHENSIVE INTEGRATED MONITORING (Abstract ID: 27955)

The Caribbean node of the Global Socio-economic Monitoring Initiative for Coastal Management (SocMon) has been developing regional capacity in socio-economic monitoring since 2003. Site assessments are tailored to site needs with study goals and objectives aligned to relevant management plans and/or management questions. Assessment data are often compared to socio-economic and ecological secondary data in order to better understand socio-economic impacts and explain trends in socio-economic characteristics. However, SocMon has never been deliberately incorporated into biophysical monitoring until recently. SocMon is one of the most widely recognised methodologies for human dimensions monitoring in the Caribbean region due in part to (1) its institutional base at the University of the West Indies, Barbados, and (2) the number of sites at which it has been implemented. Consequently, large conservation organisations and global monitoring initiatives recognise its value and have demonstrated interest in incorporating the methodology as needed to achieve relevant resource conservation and management goals. The Nature Conservancy's (TNC) Eastern Caribbean Marine Managed Areas Network (ECMMAN) Project and the Caribbean arm of the Global Coral Reef Monitoring Initiative (GCRMN-Caribbean) have both adopted SocMon as the socio-economic monitoring methodology of choice for integrated coastal and coral reef monitoring. This presentation demonstrates progress towards integrated comprehensive monitoring in the region through the ECMMAN Project and GCRMN-Caribbean.

MASSIVE BLEACHING IN THE CORAL TRIANGLE: THE OCCURRENCE OF SURFACE WARMING ANOMALIES AND POSSIBLE CONNECTION TO OTHER PHYSICAL PARAMETERS (Abstract ID: 28138)

There have been two major recorded bleaching events in the Coral Triangle, in 1998 and 2010. Both events coincided with a La Nina event. However, we noted that other La Nina events and anomalous warming have occurred between these two years with no corresponding massive bleaching reports. This prompted this study which investigates the patterns in the timing and extent of anomalies from 1997 to 2010 of some parameters thought to be associated with coral bleaching occurrences. These parameters include SST, wind speed, cloudiness and PAR. The ITCZ latitude position is also included since this parameter is said to be affected by ENSO and might provide additional insight to the process that favors coral bleaching occurrence. Time-latitude plot of SST anomaly shows a more extensive warming in the Coral Triangle in 1998 than 2010. Investigations show an intense decrease in cloudiness and an increase in PAR can also be observed prior to the intense increase in SST in those two years. A strong drop in the wind speed as the ITCZ mean latitude shifts southwards is also seen to coincide with the 1998 and 2010 SST anomaly. The long duration of intense negative anomaly in ITCZ latitude position likely hindered the monsoonal winds in the Coral Triangle in those times. We contend therefore, that conditions of low cloud, high PAR, high SST, and low wind, favored the occurrence of mass coral bleaching. The combination of conditions can likely occur in the Coral Triangle if a strong/moderate El Niño is followed by a strong/moderate La Niña.

CORAL REEFS AND PEOPLE IN A HIGH CO2 WORLD: WHERE CAN SCIENCE MAKE A DIFFERENCE TO PEOPLE? (Abstract ID: 27858)

Increasing levels of CO2 put shallow water coral reefs, and the people who depend upon them at risk from two key global stresses: elevated sea surface temperature, and ocean acidification. These global stresses cannot be avoided by local management, compound local stresses and hasten the loss of ecosystem services. Impacts to people will be most grave where human dependence on coral reefs is high, sea surface temperature reaches critical levels soonest, and ocean acidification levels are most severe. Where these elements align, swift action will be needed to protect people's lives and livelihoods. Designing policies to offset potential harm to coral reefs and people requires a better understanding of where CO2-related global stresses could cause the most severe impacts. To identify where people are at risk and where more science is needed, we integrate spatially-explicit indicators from biological, physical and social sciences to map human dependence on the coral reefs and the globally-driven threats to corals from a high-CO2 world. Western Mexico, Micronesia, Indonesia and parts of Australia have high human dependence and will likely face severe combined threats. As a region, Southeast Asia is particularly at risk. These areas require new data and interdisciplinary scientific research to help coral reef-dependent human communities better cope with, prepare for, and adapt to increasing atmospheric CO2. Many of the countries most dependent upon coral reefs are also the countries for which we have the least robust data on ocean acidification.

WHAT'S A CLEAN BEACH WORTH: RECREATIONALIST WILLINGNESS TO PAY FOR COASTAL WATER QUALITY AND ATTRIBUTES (Abstract ID: 29662)

Like many places across the world, corals in Hawaii are under threat from anthropogenic degradation, with significant economic costs to human welfare. To understand the economic implications of coral reef degradation in Hawaii's coastal waters, we undertook a non-market valuation. We used a discrete choice experiment to capture recreationalists' preferences for coastal water, coral, and fish attributes. Each attribute had three levels (low, medium, and high). We conducted in-person surveys with 263 beach users from June-November 2014 across a representative sample of Oahu's beaches staffed by lifeguards. For each beach visit, analysis of a mixed logit model suggests an individual is willing to pay approximately $17.17 to reduce days of bacterial exceedance from 11 to 5 per year, a further $19.76 to reduce it to no bacterial exceedances at all. WTP to move from 15 ft to 30 ft of underwater visibility was $29.99, a further $9.85 to increase from 30 ft to 60 ft. Respondents were willing to pay $13.97 to improve coral reef cover from 10% to 25%, a further $3.75 to improve to 45% cover. WTP for moving from 9 species in the environment to 18 species in terms of fish diversity was $11.79, a further $0.82 to increase that to 27 fish species. Our results provide critical information for resource managers and policy makers about the economic costs of water quality and coral decline. While dollar amounts may not fully represent the richness of natural resources and the diversity of ecosystems, valuation can help ensure environmental goods are considered alongside competing interests

MANAGING RECREATIONAL DIVING IN TEMPORARY CLOSURES FOLLOWING THE 2010 CORAL BLEACHING EVENT IN THE ANDAMAN SEA (Abstract ID: 29302 | Poster ID: 662)

The severe coral bleaching events have led to coral mortality in many dive sites of Thailand. This study focused on appropriate management strategies for degraded recreational dive sites following the 2010 coral bleaching event in a marine national park in the Andaman Sea. Management strategies for recreational dive sites that were proposed and implemented were prevention of coral damage from snorkeling in the shallow reefs through the use of life vests, reduction of sediment load from coastal development and wastewater discharges, temporary closure of selected dive sites, establishing new dive sites, conducting research and monitoring program for coral conservation and restoration and establishing effective networks of relevant agencies. Popular dive sites in marine national parks have been temporarily closed since 2010, in order to build resilience and to enhance coral recovery. The long-term coral reef monitoring program showed that live coral covers at both dive sites increased slightly over the last five years. However, coral recruitment rates were low. As numbers of recreational divers in the Andaman Sea are increasing, the Mu Ko Similan National Park management are considering establishing new dive sites in the park. However we recommend that active coral restoration in small controlled areas for recreational diving should be carried out instead of creating new dive sites. Raising public awareness is required intensely for coral reef conservation in Thailand in the period of increasing human and climate change impacts.

COLONY SIZE AND STRUCTURE AS DETERMINANTS OF HABITAT USE AND FITNESS OF CORAL-DWELLING FISHES (Abstract ID: 27951)

Competition for space affects patterns of habitat use and individual performance of coral-dwelling fishes; however, the physical attributes of corals that influence habitat preferences are uncertain. We investigated the influence of coral colony size and branching structure on habitat use and growth rate of two coral gobies, Gobiodon histrio and Gobiodon erythrospilus. First, we examined two key aspects of coral colony structure, interbranch depth and interbranch width that may influence habitat preferences. We then used laboratory and field-based experiments to test the effects of coral species, coral colony size and branching structure on habitat preference and growth rates of two gobies. The preferred coral species, A. nasuta had smaller interbranch width than A. spathulata. A laboratory experiment demonstrated that both gobies preferred colonies with smaller interbranch width, except when they had the opportunity to occupy A. nasuta over A. spathulata. A field experiment showed that both goby species grew faster on larger coral colonies and in colonies with smaller interbranch width. G. erythrospilus grew faster than G. histrio on A. spathulata, indicating that it suffers less of a fitness loss occupying this alternative habitat. Our results show that coral physical attributes are important factors driving habitat preference of coral-dwelling gobies; however, there must also be additional factors that influence their habitat use. Declining average coral size and reduced habitat complexity on coral reefs could have significant impacts on the performance of fishes.

CONDITION ASSESSMENT OF CORAL REEFS OF TWO MARINE PROTECTED AREAS UNDER DIFFERENT REGIMES OF USE IN THE NORTH-WESTERN CARIBBEAN (Abstract ID: 28359 | Poster ID: 631)

We assess the conditions of reefs of two MPAs in the Caribbean: Guanahacabibes National Park (GNP), Cuba and Costa Occidental Isla Mujeres-Punta Cancun-Punta Nizuc National Park (CNP), Mexico, in 2014. The reefs (two per MPA) undergo different diving intensities. The indicators analyzed for corals in transects of 10 m were cover, diameter of colonies and old and recent mortality. The abundance of coral recruits and black sea urchin were assessed in 1m2 quadrats and the cover of macroalgae in 25x25 cm quadrats. We detected different stages of the path that have been following the Caribbean reefs to a change in dominance of coral species and the deterioration of the 3-dimensional structure. Cuevones (closed to tourism for 15 years) in CNP seems to remain dominated by corals, with high cover (33.36%), but with a species dominance (headed by Porites astreoides), different from the observed in Caribbean reefs few decades ago. Reefs of GNP subjected to a low diving intensity appear to be experiencing the beginning of a shift phase to be dominated by macroalgae. However, the coral cover remains similar to previous reports (Yemaya 18.3%, Laberinto 12.1% ) and the density of recruits (Yemaya 5.02 recruits/m2, Laberinto 4.67 recruits/m2 ) was high, typical of healthy reefs, so there may still be hope of conservation for these sites. Manchones, CNP, showed the lowest coral cover (11.49%) and the lowest recruit density (0,6 recruits/m2), probably due to the joint action of natural pressures that Caribbean reefs are subjected and to the heavy influx of visitors the reefs receive.

VARIABILITY OF CORAL REEF PRIMARY PRODUCTION AND CALCIFICATION COMPLICATES SCALING UP RATES ON HERON ISLAND REEF FLAT IN SOUTHERN GREAT BARRIER REEF, AUSTRALIA (Abstract ID: 28419 | Poster ID: 109)

Measuring and monitoring primary production (P) and calcification (G) of coral reefs has become increasingly important to understand how and why coral reefs are changing due to natural and human factors. This study assessed three sites with different surface cover composition within the western reef flat around Heron Island, southern Great Barrier Reef to test flow respirometry methods to measure net primary production and calcification in July 2015. Differences in P and G were apparent between sites measured, which could be explained by differences in benthic community composition. Net P and G were highest for the live coral dominated areas to the north-west of the island with -137.24 mmol C m^2/hr and 38.04 mmol CaCO3 m^2/hr, respectively. East of the island, was second highest with –72.61 mmol C m^2/hr and 9.26 mmol CaCO3 m^2/hr, and was characterized by sandy area with patches of coral, macroalgae, and microphytobenthos. The lowest net P and G rates were directly south of the island with –11.45 mmol C m^2/hr and 0.45 mmol CaCO3 m^2/hr, which is a sandy area with sparse live coral, macroalgae, and microphytobenthos. Due to variability in reef metabolism and calcification which are dependent on benthic community type, care must be taken for scaling processes across entire reef systems that do not account for such variability within a geomorphic zone. This presentation will further discuss alternative approaches to linearly upscaling field measurements through application of a model to estimate variable rates of primary productivity and calcification.

MORPHOMETRIC ANALYSIS OF OTOLITH SHAPE VARIATION IN SIGANUS FUSCESCENS (HOUTTUYN, 1782) FROM THE WEST AND NORTHERN PHILIPPINE SEA (Abstract ID: 29033 | Poster ID: 250)

Otolith shape is affected by several factors including fish growth, genetic variations, and diverse environmental conditions. As such, otolith shape analyses have proven to be a promising tool for stock identification. The capacity to isolate stocks of commercially important species is vital for the development of site-specific fisheries management and conservation schemes. However, separating fish stocks using otolith shape have yet to be explored for Philippine basins. This study aims to address this data gap by analyzing the effect of environmental conditions and fish growth on otolith shape by comparing the otolith shapes of Siganus fuscescens specimens from the West and Northern Philippine Sea. In the study, otolith shape was analyzed in two ways: (a) traditional morphometrics, where linear distances traversing the otolith are associated with head measurements, and (b) geometric morphometrics, where landmarks and semi-landmarks are used to outline and quantify the boundary of the otolith. Variations in otolith shape was analyzed using thin-plate spline transformations. At present, the initial batch of otolith specimens analyzed through geometric morphometrics showed noticeable differences in otolith shape between populations from the West and Northern Philippine Sea. In contrast, only slight variation in otolith shape between populations within the West Philippine Sea biogeographic region was observed. This is in agreement with the stock-specific variations in body shape of S. fuscesens in these basins. Furthermore, validation of these results via genetic analysis could establish otolith shape as a cost effective alternative in separating S. fuscescens stocks.

THE STODDART SOCIETY: LONG-TERM RESEARCH ON THE ECOLOGY AND CONSERVATION BIOLOGY OF LIGHTHOUSE REEF ATOLL, BELIZE (Abstract ID: 29825)

In the early 1960s, David Stoddart conducted the first surveys detailing the flora, fauna, and geology of the three Caribbean atolls, including Lighthouse Reef (LHR), about 45 miles off the coast of Belize. Stoddard's descriptions of the ecological distributions of the marine, intertidal, and terrestrial organisms created a baseline for future scientists to compare how oceanographic, atmospheric, and anthropogenic stresses have come to shape the current community structures at LHR through time. Revisiting some of Stoddard's transects more than 50 years later, we have begun to understand which species have shifted their habitats, some expanding and some decreasing their distributions. Three years ago, The Stoddart Society, as our Ecology and Conservation Biology of Coral Reefs course at Wake Forest University has become informally known, began visiting LHR each March to conduct annual surveys documenting the current diversity and abundance of the flora and fauna. Using methods established by Coral Watch and REEF, we have increased the number of field sites to survey the coral health and fish populations across the atoll. By taking undergraduate students to the reef and teaching them various techniques to study the flora and fauna at LHR, along with increasing our efforts to include local NGOs and students from the University of Belize, we will continue to promote the conservation and appropriate management necessary to sustain this coral reef ecosystem and its services.

SIZING UP METABOLIC HETEROGENEITY AT SINGLE CELL LEVEL: TOWARDS A FUNCTIONAL UNDERSTANDING OF OPTICAL MICRONICHES IN CORAL SYMBIOSIS (Abstract ID: 28904 | Poster ID: 94)

Tropical marine ecosystems based on reef-building corals are among the most productive marine ecosystems on Earth. At the heart of the success of corals as ecosystem is their mutualistic symbiosis with dinoflagellate algae from the genus Symbiodinium – which provides enormous amounts of energy to the anthozoan host. Previous studies have revealed the presence of steep light gradients in tissues of corals. Yet, it is unknown whether such resource stratification allows for physiological differences of Symbiodinium across optical microniches within coral tissues. In this talk, we emphasize the potential of combining single cell metabolomics with stable isotope labelling and microsensors measurement to study the metabolic activity of individual Symbiodinium cells along microscale gradients of light within coral tissue. Our results demonstrate the functional diversity of Symbiodinium along microscale gradients in the coral tissue, where carbon fixation varied about six-fold depending on the local light levels. Further, our data suggest substantial differences in light utilisation efficiency along the coral tissue light microgradient. These results could have important consequences for coral responses to environmental stress as they suggest the presence of physiologically distinct populations of Symbiodinium, that could act as a reservoir of variation, providing selective advantage to corals exposed to or recovering from environmental stress.

CHANGING DYNAMICS OF CORAL REEF CARBONATE PRODUCTION AND IMPLICATIONS FOR FUTURE REEF GROWTH POTENTIAL (Abstract ID: 27816)

Coral cover is rapidly declining globally, and coral species assemblages changing. Although poorly quantified these changes are projected to lead to lower carbonate production rates and thus reduced reef growth potential. Using data from sites in the Caribbean and Indian Ocean which have undergone different post-disturbance ecological trajectories over the last 20-30 years, the differential impacts of disturbance on carbonate production regimes and on resultant reef growth potential can be explored. In the Caribbean, a region which has undergone major ecological change, average carbonate production rates are now less than 50% of pre-disturbance rates. In contrast, the budgets of many reefs across the Chagos archipelago (central Indian Ocean), which is geographically remote and largely isolated from direct human disturbances, have recovered rapidly from the 1998 coral bleaching event. The carbonate budgets on these reefs average +3.7 G (G = kg CaCO3 m-2 yr-1) and are especially high on Acropora-dominated reefs (average +8.4 G). These budget data provide a basis for estimating vertical reef growth potential (mm yr-1). Although addition data are urgently needed to parameterise reef growth rate estimates, current best-estimates point to marked inter-site variability. Across the Caribbean the growth potential of most reefs is probably insufficient to track future sea-level rise. In contrast, rates measured across the more geographically remote Indian Ocean reefs suggest a more positive prognosis – albeit one that is dependent on the maintenance of high Acropora coral cover.

THE MYTH OF THE "HEALTHY" CORAL: THE NEED FOR PHENOTYPIC ANCHORING BEFORE AND DURING THE AGE OF 'OMICS (Abstract ID: 28164)

A fundamental problem in the study of corals and other reef organisms is the difficulty in determining their health, which may lead to incorrect conclusions about the results of observations and experiments. Studying cells and tissues using microscopy helps us understand how the structures formed by molecules function and allows us to detect changes in structure that are related to functional impairment (disease). The use of histopathological examinations and clinical diagnostic assays continues to be overlooked in studies on these organisms. Corals that meet visual criteria as healthy may actually contain microscopic lesions, parasites, or pathogenic microorganisms that affect their metabolism and the interpretation of molecular analyses. The tissue loss diseases in Caribbean acroporids first seen in the 1970s are now known to be influenced by chronic infection of polyp mucocytes with a rickettsia-like organism. Coral bleaching and hyperpigmentation can be subtle and have multiple causes, but the use of spectral imaging paired with microscopy may provide non-invasive health screening techniques.

Interactions of coral polyps with endolithic fungi deep in the skeleton can be limited and benign, but in other cases environmental stimulation of fungal hyphae leads to basal body wall necrosis and loss of gonads. Clinical and diagnostic methodologies support evidence-based human and veterinary medicine; microscopic tissue examinations can also contribute descriptive and mechanistic data to identify causes of organism decline and focus management efforts to conserve coral reefs.

ASSISTED RECOVERY OF DEGRADED REEFS: CORAL RESTORATION WITHOUT THE NEED FOR TRANSPLANTATION (Abstract ID: 28312)

Current reef rehabilitation practices involving coral transplantation are labor and cost intensive since each individual must be reared to a suitable size and transplanted manually. These constraints have limited the scale of most restoration efforts to less than a hectare, while reef degradation occurs on scales of 10's to 1000's of km2. We introduce a new concept to seed larger areas of reef with sexually reared coral juveniles bypassing the need for transplantation. Following the concept of a farmer bedding out seedlings on a field, sexual coral propagules settled on engineered substrates (=SExual COral REproduction Seeding Unit, SECORE SU) and reared in a nursery for a short time period are introduced to the reef by wedging them in reef crevices without the use of any adhesives. This concept was initially tested in Curacao with the brooding coral Favia fragum using tetrapod-like shaped cement substrates. Three weeks after larval settlement and after an intermediate ex-situ hatching period, SUs were introduced to reef areas of varying structural complexity. Substrate stabilization, recruit survival and SU performance were monitored for 1 year. After 1 year, 70-81% of the tetrapods were recovered across all reef complexity levels, of which 71-94% stabilized on the reef. In total 55-57% of the tetrapods that were originally seeded to the reef still harbored ≥1 recruit (SU performance). The results of this initial study indicate seeding SUs without the need for transplantation offers great potential to increase the scale of reef restoration efforts. Case studies carried out in Mexico, Guam and Singapore further highlight possibilities and limitations of this new concept.

FRESHWATER LENS DYNAMICS UNDER THE MAIN ISLAND OF AILUK ATOLL, NORTHERN MARSHALL ISLANDS (Abstract ID: 28100 | Poster ID: 395)

Rising sea levels and drought threaten atoll settlements, as cisterns dry and wells become brackish, and in our study location, Ailuk Atoll in the northern Marshall Islands, such an event necessitated the emergency deployment of aid reverse osmosis (RO) treatment units. Drought events are likely to continue; records on nearby Kwajalein Atoll indicate an annual decline of 2.5 mm pa since 1954. Whilst the synergies between precipitation, groundwater lenses and saltwater inundation have been modelled, measurements are lacking. Here we provide a summary of groundwater lens dynamics on remote Ailuk Atoll in the northern Marshall Islands, combining ground water levels, sea water influences, precipitation, and coral reef status in a groundwater dynamic model. We used wells in different locations around the main island to monitor tidal fluctuations and the quality of groundwater. We surveyed the ground elevation, coastline, wave attenuation on different exposures, and reviewed historical records. The lens recharges 0.7 ML/mm rain - less seaward losses and evapotranspiration. Most household wells were too brackish to serve potable needs. Tidal efficiency of wells and taro pits was found range from 8% to 16%. The strongest correlation was found at the Dispensary set among a grove of luxuriant breadfruit trees, which coincidentally also had the least lag from the lagoon and among the least brackish. Modelling accounts for the lens as a leaky reservoir so that it can be managed to support a sustainable island ecosystem - perhaps with a sand dredge to maintain shore elevation.

NO-FISHING RESERVES PROTECT CORAL ASSEMBLAGES (Abstract ID: 27811 | Poster ID: 638)

Nature reserves are used globally as a management tool for protecting biodiversity both on land and in the sea. In 1976, Australia established the Great Barrier Reef (GBR) Marine Park, then by far the largest marine protected area in the world. In 2004, 33% of the Park was designated as no-fishing reserves, creating a globally significant network of highly protected reserves that stretches along the 2000 km length of the Reef. As expected, the number and sizes of targeted fishes are consistently higher inside well-protected no-fishing reserves. However, a recent meta-analysis of coral cover throughout the tropics found that coral abundance was stable over a one-year period within marine parks, whereas cover on unprotected reefs declined slightly by 0.3% in the Caribbean and 0.4% in the Indo-Pacific. Therefore, it remains unclear if marine reserves also afford protection to corals, the principal architects of tropical reefs. We quantified coral cover and composition at different life history stages along the length of the GBR. We found that corals are substantially more abundant inside no-fishing reserves. Furthermore, the species composition of coral assemblages also changes as cover increases, indicating that fishing can generate important functional differences between reefs located within reserves and those where fishing is present. The abundances of newly settled and juvenile corals do not differ between reserves and fished reefs, suggesting that protection by no-fishing reserves can be beneficial to adult corals.

ANNOTATING AND ANALYZING LANDSCAPE-SCALE 3D MAPS OF BENTHIC HABITATS IN CORAL-REEF ECOSYSTEMS (Abstract ID: 30124)

Systematic underwater photography can be used to assemble a detailed digital record of a benthic landscape's visual appearance, topography and geometric structure. Photogrammetric and computer vision techniques enable the reconstruction of massive 3D pointclouds---on the order of 500 million to 1 billion points for a 100 m^2 region---offering a dense digital representation of the landscape under study. We describe the development of an efficient visual workflow for interactively inspecting and annotating such massive datasets, with the aim of increasing their utility for performing ecological analyses. In particular, we describe a scriptable software framework allowing taxonomic annotation to be performed by virtually 'painting' the desired classifications onto the visualized pointclouds, differentiating individual colonies. As an aid to classification, the system can drape the most appropriate raw photograph locally onto the pointcloud (or display it separately)---making the entirety of the collected data efficiently accessible. Further quantitative and qualitative analyses can be done both programmatically---by writing and executing a script traversing the annotated dataset---and interactively, with the use of custom script-defined measurement tools and 'brushes.' For example, the spatial distribution of colonies of a given morphology can be assessed, or the points constituting one or more colonies can be exported (and optionally meshed and filtered) for further study. We evaluate the results of these experiments and discuss our planned next steps.

CAPACITY BUILDING IN THE CORAL TRIANGLE REGION: G2G EFFORTS (Abstract ID: 27907)

Since 2009, The Coral Triangle Initiative has proved a unique opportunity to provide government to government support for capacity building around ocean and coastal resource management - from Marine Protected Area Management, Ecosystem Approach to Fisheries Management, and Illegal, Unreported, and Unregulated Fisheries. This initiative has included the governments of the six CTI countries (Indonesia, Malaysia, Philippines, Papau New Guinea, Solomon Islands, and Timor-Leste), several USAID missions, NOAA, and several international and local NGOs. The main goal of this initiative was to build capacity and partnership towards better ocean governance. We will provide an overview of our project with USAID-Philippines and the government of Philippines with short presentations from the Bureau of Fisheries and Aquatic Resources and the Biodiversity Management Bureau.

OUR PROJECT IN HAWAI'I'S INTERTIDAL (OPIHI): CITIZEN SCIENCE IN AN ACCESSIBLE MARINE ENVIRONMENT (Abstract ID: 30086)

Our Project In Hawai'i's Intertidal (OPIHI) is a citizen science program for middle- and high-school teachers and students to survey rocky intertidal areas in Hawai'i—a place-based, problem-based approach to learning through inquiry. The intertidal is vulnerable to threats such as overharvesting, species invasions, and climate change effects. Howev-

er, long-term monitoring is difficult to implement as seasonal wave activity, a small low tide window, and limited tidal range mean the Hawaiian intertidal is often underwater or inaccessible. Fortunately, the accessibility that makes the intertidal susceptible to human impacts also makes it ideal for citizen-science research. The intertidal provides a safe environment to engage students in marine science, an environment that might otherwise be overlooked by educators due to student swimming restrictions. Teachers are prepared to lead their students to collect rigorous monitoring data through the OPIHI professional development program. OPIHI has both scientific and educational goals: (a) to improve the content and scientific process knowledge of teachers and students, and (b) investigate if and how the Hawaiian intertidal community has changed since the last OPIHI systematic surveys were conducted 10 years ago. This paper will share preliminary educational and scientific results from our statewide spring 2017 OPIHI teachers and their students. We will also share best practices and lessons learned on conducting citizen science research with students in species-rich environments—including data validation and training techniques.

LINKING PLOT TO REEF SCALES – HOW REEF SCIENCE AND MANAGEMENT BENEFITS FROM OPEN DATA, MODELS AND KNOWLEDGE (Abstract ID: 28106 | Poster ID: 544)

Significant changes in how we conduct coral reef science and management over the past five years have altered how we collect and share data, as well as how we build, evaluate and share methods and knowledge. This paper examines how changes in data collection, analysis, modelling and publication are affecting coral reef science and management. A critical assessment is provided of both the use of science in management and the increasing role of public involvement through community engagement and citizen science. A fundamental conceptual model linking different scales of coral reef structures and processes, from polyps to reef scales, is initially presented to define the scope of data and knowledge required for addressing current coral reef science and management objectives. Within this framework, open data publication and data re-use represent a key factor for a more open, reproducible and transparent set of scientific activities. Additionally, open collaboration provides the basis for developing regional to global scale models and assessments, as well as creating code repositories for the implementation, validation, and modification of methods in other study areas. Specific examples are shown from different large-scale, long-term, regional and global data sets, which demonstrate the advantages that open data and open collaboration provide for achieving expanded science capabilities. This collaborative, multi- and inter-disciplinary approach is essential for addressing the many regional and global challenges faced by the coral reef science community.

FROM JAPAN TO THE NORTHERN TIP OF THE RED SEA: A LONG, NON-STOP JOURNEY FOR THE MESOPHOTIC SCLERACTINIAN SPECIES*LEPTOSERIS AMITORIENSIS* ? (Abstract ID: 28564)

*Leptoseris amitoriensis* Veron, 1990 was described from Amitori Bay, Iriomote, in the Ryukyu Archipelago, Japan. In Amitori Bay, it is a rather abundant, typically mesophotic species, found around and below 50 m depth, co-occurring with other *Leptoseris* species with a wider depth range, such as *L. gardineri*, *L. papyracea* and possibly other *Leptoseris* species. More recently the species was collected, also at mesophotic depths in several stations at Eilat and Aqaba, the northernmost tip of the Red Sea, where it can be equally abundant, forming large thickets of typically foliose colonies. Specific identity of the specimens from both locations has been confirmed by examination of colony gross morphology, both live *in situ* and from skeletal material, detailed stereomicroscopic examinations, Scanning Electron Microscopy imaging and genetic analyses. Comparisons of skeletal morphologies indicate that specimens from both localities are conspecific. This conclusion is also supported by the genetic data despite the complex situation of molecular evolution in *Leptoseris* and corals in general. The presence of the species in such widely separated areas in the Indo-Pacific, is indeed a remarkable case of complete dissociation of geographic distribution likely to be unique in the scleractinian world. We propose that such a distribution in the mesophotic environment may indicate either the presence of relict populations or a more widespread distribution in the hitherto little explored or unexplored deeper reef communities.

THE APPLICATION OF SOCIOECONOMIC MONITORING (SOCMON) METHODOLOGY IN ASSESSING BETWEEN TWO TIME PERIODS BINDUYAN MARINE PROTECTED AREA IN PALAWAN, PHILIPPINES (Abstract ID: 29489)

Integration of Socioeconomic Monitoring (SocMon) at conservation sites can serve to involve local communities in resource management, provide adaptive management strategies to reflect the local needs, and facilitate understanding of the importance of marine and coastal resources. In 2007, the SocMon methodology was used to assess the status of Binduyan Marine Protected Area (MPA) in Puerto Princesa City, Palawan Province, Philippines. The same methodology was used in 2016 (nine years later) to assess the status of the same MPA. In addition to using the same set of selected SocMon indicators/variables, this study also involved other features that included an enrichment of data gathering methods including the following: (1) additional data on coastal and marine goods/activities using focused group discussion (FGD) method; (2) household level climate change variables, including vulnerability, using household interview (HHI); and (3) community-level climate change indicators/variables using FGD. The SocMon methodology was found useful in coming up with a comparative perspective between two time periods. This project has become an avenue to propagate the use of SocMon among academics, researchers, policy makers and coastal managers thereby enhancing coral reef conservation and coastal resources management. SocMon has likewise become a capacity building tool by convening and training new researchers, managers and key stakeholders in generating relevant socioeconomic information.

EFFECTS OF CORAL DISEASE ON EXOSYMBIOTIC INVERTEBRATE ASSEMBLAGE (Abstract ID: 30160 | Poster ID: 614)

Coral diseases have persisted in our global oceans altering coral reef ecology. As environmental conditions continue to alter ocean processes, coral colonies will be left vulnerable to disease occurrences (Bruno 2007, Galloway 2009, Abey et al. 2010). Common coral diseases such as coral bleaching, algal over growth, Trematodiasis, and growth anomalies cause a variety of afflictions that increases coral mortality (Bruno 2007, Work 2008, Becker 2013). Scleractinian coral species are primary reef builders that play major roles within coral reef systems. Predominant corals impacted by disease are species from the montiporid, pocilloporid, and poritid coral families (Domart-Coulon 2006, Work 2008, Burns 2011). Because of different morphological features and physiological processes these coral species are host to many invertebrate exosymbionts that will either seek refuge within or on the coral or feed on the coral itself (Bailey-Brock 1976, Ritson-Williams 2003, Apprill 2007, Shima 2010). These relationships can be either specific or general depending on the coral host and the exosymbiont (Ritson-Williams 2003, LaJeunesse, 2004). The impact to these relationships from coral disease has been understudied with little understanding of the effect of disease on exosymbiont assemblage. This study aims to examine the invertebrate exosymbiont assemblage on diseased and healthy Porites colonies and create a field definition for growth anomalies (GA) on Porites species that will contribute to understanding the impact coral disease has at the community level to coral reef systems.

MESOPHOTIC CORAL REEF FISH COMMUNITIES IN THE CENTER OF MARINE BIODIVERSITY (Abstract ID: 28858)

Philippines coral reefs are known for their extremely high biodiversity. However, most of the information available for the area comes exclusively from shallow reefs, with very few data published on Philippines' mesophotic coral ecosystems (MCEs, 30-150m depth). Here we describe the MCE fish community of three sites of the Verde Island Passage, Philippines, the center of the center of global marine biodiversity. Sampling was done using trimix (a breathing mix containing helium, nitrogen, and oxygen) closed-circuit rebreather diving. Data was obtained from 20 underwater visual censuses at depths between 45 and 105 meters. A total of 22 families and 87 species were recorded, with an average (SE) of 9.9 (0.9) species and 47 .7 (11.7) individuals per 40 m2. The richest families were Labridae (16 species), Serranidae (12), Pomacentridae (11), Pomacanthidae (8) and Chaetodontidae (6). Both richness and density of fishes decreased significantly with depth. Community composition also changed with depth: the most abundant fishes of the upper MCE zone (45-70m) were Chromis analis, Pseudanthias luzonensis, Pterocaesio pisang and Naso minor. Dominant fishes of the lower MCE zone (70-105m) were Paracaesio sordidus, Genicanthus melanospilus, Pseudanthias engelhardi and Genicanthus lamarck. Although some commercial species and sharks were recorded, signs of overfishing and habitat degradation were also observed, and in some sites the

bottom was covered in abandoned broken fishing lines. Since most people don't know these diverse ecosystems exist and they sit outside marine protected areas, research and an education campaign are necessary to better understand and protected them.

ORIGIN AND MAINTENANCE OF REEF FISH BIODIVERSITY IN SEAMOUNTS AND OCEANIC ISLANDS OF THE SOUTH ATLANTIC (Abstract ID: 28714)

In the Southwestern Atlantic, twelve species are considered endemic to the seamounts and islands of the Vitória-Trindade Chain (VTC). Endemic species exclusive to the islands are suggested to have undergone allopatric speciation after sea level made the seamounts connecting continental and insular populations uninhabitable by shallow water species. These island endemic species are small and have limited dispersal ability. Most of them are genetically and morphologically very similar to their mainland sister species, suggesting recent divergence. Others endemics are wide spread along deeper (mesophotic) ecosystems of VTC seamounts and islands, and also show evidence of recent divergence. However, simple isolation cannot explain the origins of these species. In addition, two species endemic to the shallow waters of the islands and two from mesophotic habitats along the chain are much older than most species (i.e.: paleo-endemics or relict species). We hypothesize that VTC seamounts became a refugia for coral reef fauna during Pleistocene climatic variations, preserving these relict lineages, probably due to environmental stability. Therefore, VTC islands and seamounts seem to be acting as both cradle and museums for reef fish biodiversity.

EQUIVALENCE OF MARINE DISPERSAL SCALES OVER EVOLUTIONARY AND ECOLOGICAL TIME (Abstract ID: 29005)

The scales over which offspring disperse is critical for understanding ecology and evolution in the ocean. At the moment, most estimates suggesting short-distance dispersal are based on direct ecological observations of dispersing individuals, while evolutionary estimates often suggest greater homogeneity among populations. Reconciling these two approaches and their seemingly competing perspectives on dispersal has been a major challenge. Here we show that evolutionary and ecological measurements of dispersal can agree, if carefully calculated and compared. In populations of the orange clownfish (*Amphiprion percula*), we found that evolutionary isolation by distance methods almost exactly matched an exhaustive set of direct larval dispersal observations in two separate time periods. Our results also suggest that carefully constructed evolutionary estimates may be more broadly relevant for understanding ecological dynamics than previously recognized.

BACKGROUND RATES OF MORTALITY AND INJURY FOR COMMON CORAL TAXA ON AUSTRALIA'S GREAT BARRIER REEF (Abstract ID: 28685)

Studies on the population and community dynamics of scleractinian corals typically focus on catastrophic mortality associated with acute disturbances (e.g., coral bleaching and outbreaks of crown-of-thorn starfish), though corals are subject to high levels of background mortality and injuries caused by routine and chronic processes. This study quantified prevalence (proportion of colonies with injuries) and severity (areal extent of injuries on individual colonies) of background mortality and injuries for four common coral taxa (massive Porites, encrusting Montipora, Acropora hyacinthus and branching Pocillopora) on the Great Barrier Reef, Australia. Sampling was conducted over three consecutive years during which there were no major acute disturbances. A total of 2,276 adult colonies were surveyed across 27 sites, within nine reefs and three distinct latitudinal sectors. The prevalence of injuries was very high (>83%) across all four taxa, but highest for Porites (91%) and Montipora (85%). For these taxa (Montipora and Pocillopora) there was also significant temporal and spatial variation in prevalence of partial mortality. The severity of injuries ranged from 3% to more than 80% and varied among coral taxa, but was fairly constant spatially and temporally. Establishing background levels of injury and regeneration are important for understanding energy investment and life-history consequences for reef-building corals as well as for predicting susceptibility to, and capacity to recover from, acute disturbances.

A DECISION SUPPORT FRAMEWORK TO PRIORITIZE CORAL REEFS FOR CONSERVATION IN THE U.S. VIRGIN ISLANDS (Abstract ID: 29402)

The coral reef ecosystems of the U.S. Virgin Islands are some of the most intensively surveyed and threatened tropical ecosystems on earth. These coral reefs vary widely in terms of biophysical structure, seascape context, socio-economic value and exposure to threats presenting a complex challenge for resilience-based management. How should managers prioritize actions to maximize conservation outcomes? To meet multiple conservation objectives, a novel map-based decision support tool was designed to synthesize large amounts of data to help managers identify and rank coral reefs according to quality and threats. The framework integrates local expert knowledge from SCUBA divers, scientific field data and spatial models on biophysical features, ecosystem services, stressors and resilience to characterize and rank priority coral reefs. The framework will support risk assessments of coastal development, management of protected areas, optimization of monitoring designs and broader marine spatial planning.

SIMPLE, FAST AND REPEATABLE SURVEYS FOR UNDERWATER VISUAL 3D BENTHIC MAPPING (Abstract ID: 29102)

State of the art visual 3D reconstruction techniques provide rich structural information from underwater imagery. However, systematically covering areas much larger than the footprint of a single image is challenging underwater. Properly instrumented robots perform this task by precisely navigating a desired survey path. Unfortunately, access to suitable robotic systems is limited and requires specialised operators, which curtails the use and impact of these techniques. While humans can carry a similarly instrumented imaging package, they cannot navigate so as to consistently maintain image overlap over large extents. We present a simple method to quickly generate repeatable, high resolution and large extent (~100m2) surveys with one swimmer and one support person (~15 min). The amount of image overlap is a design parameter, yielding surveys that can be used in an automated processing pipeline to generate georeferenced 3D reconstructions, orthographic 2D mosaics and structural complexity indices. Individual images or mosaics can also be labeled for benthic cover estimates. We describe the method and present results from surveys conducted at reefs around Lizard Island in the Great Barrier Reef, as part of an ongoing cyclone recovery monitoring project. As of 2016, 21 sites have been visited 4 times, every ~6 months. We characterise the quality of data products and repeatability of the technique. Its speed and reliability make it suitable for large-scale benthic monitoring and research programs that aim to capture structural complexity and benthic community dynamics.

CHARACTERIZING AN IMPROBABLE REEF AT VARADERO, CARTAGENA BAY, COLOMBIA (Abstract ID: 29888 | Poster ID: 300)

In 2013, Colombian scientists discovered Varadero reef in the least expected place. The reef is located off one of the entrances of Cartagena Bay (Colombia), a highly polluted Bay that receives industrial and sewage waste, as well as high sediment and freshwater loads from an outlet of Magdalena River. The latter is the main cause of the loss of all reefs within the Bay and the high reef degradation at nearby Rosario Archipelago.

Varadero reef was overlooked as the high turbidity of its overlying waters led to the assumption that no corals would develop. After a quick initial characterization, Varadero reef was shown as one of the healthiest reefs in Colombian Caribbean waters (up to 80% live coral cover). To understand how and why a highly developed reef is thriving under such unusual conditions, in 2015 data were collected to have a more complete description of the reef in terms of extension, community composition and diversity, coral health and water quality. Varadero reef extends over 1740 m and continues towards Baru island. Although reef structure starts at 30 m, high coral cover is between 2 and 12 m depth. A total of 38 coral species occur there, with Orbicella spp. as the dominant genus. Average live coral cover was 47% and disease prevalence was less than 0,4%. Varadero reef seems to be healthier than nearby reefs, despite the poor quality of its overlying waters. Future research includes studies on the coral holobiont and its responses to environmental drivers and physiological observations to assess algal performance and coral calcification rates.

CORAL REEF ASSOCIATED CRYTPOFAUNA DIVERSITY PATTERNS ALONG A NATURAL PH GRADIENT (Abstract ID: 28856)

Naturally occurring high CO2 zones on coral reefs provide us with the opportunity to study whole community patterns of biodiversity influenced by both the direct and indirect effects of low pH. We investigated the cryptofauna diversity at two localities in the Milne Bay Province, Papua New Guinea, where CO2 vents provide naturally low pH conditions. We deployed standardized 3-dimensional samplers (ARMS) on the reef at 3 m depth at three pH regimes (regular 8.0, medium 7.8-7.9 and low 7.6-7.8). After 2 years, we retrieved the structures and extracted all living organisms. The larger motile invertebrates (>2mm) were individually barcoded using the standard cytochrome oxidase subunit I fragment (COI). The smaller motile organisms (500 - 2000 µm) and the sessile organisms were bulk collected and metabarcoded using high-throughput sequencing of a shorter COI fragment. Diversity patterns were most different for the >2mm invertebrate fraction with a reduction of 56% in diversity and 60% in abundance at the lowest pH. Rarefaction curves showed that ACE diversity estimator reached a plateau at low pH, whereas curves continued to rise in control pH. The differences were not as pronounced for the bulk fractions with reductions in diversity of 24% and 21% for the motile and sessile fractions. The ARMS community composition at higher taxonomic levels was similar in all pH conditions. The resulting data allow us to determine how future changes in pH could affect coral reef diversity while providing critical data for a region and fauna that are both highly diverse and poorly known.

CONNECTING SCIENCE AND PEOPLE TO IMPROVE LOCAL FISHERIES MANAGEMENT WITH GLENN (Abstract ID: 29627)

Understanding the complex life cycle of coral reef fish is of critical importance if we are to succeed in improving fisheries management. But science alone cannot solve management problems. In the Pacific, local communities have been managing their marine resources for millennia, but with today's changing world and dwindling resources, these communities are facing overfishing. To ensure the persistence of these island communities and cultures through time, science and local community management must come together to find solutions. Glenn's research was motivated by this concept, and his global proposal for the CNRS build a research program designed to improve marine conservation planning and biodiversity protection by synthesizing and incorporating connectivity data. Glenn himself was in fact a connector, as he used to say, with a goal of connecting the best colleagues to (1) increase understanding of ecological connectivity among coral reefs; (2) evaluate MPA theory and guidelines based on analyses of new connectivity data; and (3) revise or develop new tools to implement recommendations stemming from current projects. Glenn was a scientist and someone who cared deeply for people and nature and was driven to make important research outcomes relevant and accessible for decision to local communities, governments and NGO partners. This was his passion… and now his legacy.

NON-RANDOM VARIABILITY IN FUNCTIONAL COMPOSITION OF CORAL REEF FISH COMMUNITIES ALONG AN ENVIRONMENTAL GRADIENT (Abstract ID: 28047 | Poster ID: 504)

Changes in the coral reef complex can affect predator-prey relationships, resource availability and niche utilisation in the associated fish community, which may be reflected in decreased stability of the functional traits present in a community. This is because particular traits may be favoured by a changing environment while other traits can be selected against where degradation can relax the association between fishes and benthic habitat. We characterised six important ecological traits for fish species occurring at seven sites across a coral reef archipelago in Indonesia, where reefs have been exposed to eutrophication for decades. Two functional diversity indices were related to important environmental factors (live coral cover, rugosity and distance from shore) examining both the change in mean, as well as temporal and spatial variability, to assess whether fish-habitat association became relaxed along with habitat degradation. Increases in live coral cover and rugosity were associated with decreases in the variability of functional diversity and with community-level changes in the abundance of several traits. A decrease in coral increased variability of RaoQ while rugosity and distance both inversely affected variability of FRic; however averages of these indices did not reveal patterns. These results suggest that increased degradation of coral reefs is associated with increased variability in fish community functional composition resulting from impacts on specific traits, thereby affecting the functional response of these communities to increasing perturbations.

RESPONSES OF THE CORAL HOLOBIONT TO LABILE DISSOLVED ORGANIC CARBON SHED LIGHT ON THE ROLE OF DINITROGEN FIXATION IN BLEACHING (Abstract ID: 27922)

The temperature-induced disruption of the coral-algae symbiosis (coral bleaching) has caused a global coral reef decline. Still, the understanding of mechanisms underlying bleaching remains incomplete. Both elevated temperatures and labile dissolved organic carbon (DOC) not only induce bleaching, but also stimulate coral-associated dinitrogen (N2) fixation actvity. Thus, increased N2 fixation may mediate symbiotic breakdown by shifting Symbiodinium from nitrogen (N) limitation to phosphorus (P) starvation. To test this assertion, we selectively stimulated coral N2 fixation activity ex situ via daily doses of labile DOC over 28 days and measured individual responses of the main holobiont compartments of Pocillopora verrucosa. Corals exposed to high DOC conditions rapidly exhibited significantly increased N2 fixation rates and abundance of N2 fixing bacteria, and a depletion in Symbiodinium stable N. Together with an increase in the N:P ratio in algae and coral tissue, this confirms the rapid uptake of fixed N by algal symbionts. Concomitantly, we observed symbiotic breakdown resulting in bleaching, reflected in loss of symbiotic algae, and drop in photosynthetic yield and rates. Our data suggest the breakdown was caused by shifting algae to P starvation due to elevated fixed N availability. This mechanism appears independent of thermal stress. In conclusion, increased N2 fixation may mediate coral bleaching by alleviating Symbiodinium from N limitation. Our findings imply that improved water quality may mitigate the effects of anthropogenically-driven environmental change.

EVIDENCE OF ADAPTATION IN A CORAL-ALGAL SYMBIOSIS AT MESOPHOTIC DEPTHS IN THE NORTHWEST GULF OF MEXICO (Abstract ID: 28846 | Poster ID: 331)

Many coral species common in shallow habitats also live in the mesophotic zone (30-150 m). Similar to shallow corals, many mesophotic corals maintain important symbioses with photosynthetic microalgae in the genus *Symbiodinium*. Despite the importance of the coral-algal symbiosis in corals' ability to thrive in multiple dynamic environments, few studies have focused on symbionts associated with mesophotic corals. This study compares the algal symbiont assemblages in *Montastraea cavernosa* found at shallow (20-25 m) and mesophotic (45-50 m) sites at the East and West banks of Flower Garden Banks (FGB) National Marine Sanctuary. Symbiont densities per unit area of coral tissue are significantly higher in mesophotic corals at FGB. Additionally, while chlorophyll concentrations are similar between depths, the overall chlorophyll concentrations per unit area of coral tissue are significantly higher in mesophotic corals. These results suggest that increased symbiont densities may be a method of adaptation for zooxanthellate corals in mesophotic reef environments. Symbiont densities and chlorophyll concentrations did not differ between the East and West banks. Next generation sequencing of the ITS2 gene provides a comprehensive assessment of symbiont community structure, including uniformly stable assemblages in *M. cavernosa* at the shallow sites. This study and ad-

ditional comparisons between shallow and mesophotic reefs are designed to help inform management strategies for FGB and similar coral reef communities.

SHIPWRECKS, PHASE SHIFTS AND REEF RESTORATION: SCIENCE AND MANAGEMENT OF THE PALMYRA UNIT OF THE PACIFIC REMOTE ISLANDS MARINE NATIONAL MONUMENT (Abstract ID: 29616 | Poster ID: 626)

Management of remote coral reefs is a challenge, and the removal of a shipwreck 1600 km away from civilization is a daunting task. Palmyra Atoll is a unit of the Pacific Remote Islands Marine National Monument. The atoll is managed by the US Fish and Wildlife Service (FWS) and The Nature Conservancy, who administer a research station for the Palmyra Atoll Research Consortium (PARC). The grounding of a fishing vessel at Palmyra subsequently caused a phase shift from a healthy coral reef, to a monotypic stand of an invasive species. Systematic surveys and monitoring of Palmyra's reefs by PARC researchers' discovered corallimorph smothering the reef around the wreck, revealing the phase shift to be associated with the degrading wreck. Continued monitoring documented the spread of the corallimorph over 3 km of pristine coral reef. In the fall of 2013 the FWS, with the help of marine salvors, removed the wreck. Data collected by researchers were used to document both the spread of the corallimorph, indicating an immediate problem, and helped guide the removal process, leading to best management practices for removal and restoration without further damaging the reef ecosystem. Novel approaches were used to accomplish and monitor this difficult task. The wreck removal was the first step in a larger coral reef restoration project. Managers and partner scientists continue to monitor the corallimorph, efficacy of wreck removal, and explore options for larger-scale corallimorph treatment and habitat restoration. Information learned aids in the management of the Monument, and informs coral reef management throughout the Pacific.

THE CORAL MICROBIOME ACROSS SPECIES, SPACE AND TIME (Abstract ID: 29365)

Coral-associated bacteria are increasingly recognized as indispensable contributors to coral physiology and health, yet we know very little about their basic ecology. Here, we employ high-throughput 16S rRNA gene sequencing to examine host, environmental and temporal influences on the microbiome of 35 coral taxa from three locations across Australia (Lizard Island, Northern Great Barrier Reef; Lord Howe Island, the world's most southern coral reef; and Ningaloo Reef, Indian Ocean). We also explore patterns in microbiome structure between seasons, through repeated sampling at Lizard Island, and across anatomic locations, by partitioning coral sample into mucus, tissue and skeleton compartments. This study characterizes the bacterial composition of 687 unique coral samples and 59 environmental samples (i.e. seawater and sediment) to assess: 1) the 'core' microbiome within and among coral taxa, 2) microbiome partitioning across micro-scale habitats within the coral host and 3) the influence of local environmental conditions on bacterial community structure. Establishing patterns in coral-associated microbiomes and determining the environmental factors underlying them is vital to understanding coral symbiont community assembly, and ultimately, the role of coral-associated microbes in host physiology and health.

TOWED-DIVER SURVEYS OF THE 2015 CORAL BLEACHING EVENT IN HAWAII: AN EFFICIENT METHOD FOR BROADSCALE ASSESSMENT OF BLEACHING IMPACTS (Abstract ID: 28991)

The 2015 global coral bleaching event brought widespread impacts to Hawaii. Our team deployed on a 2-week research cruise in November 2015 to observe the spatial extent and severity of bleaching impacts in the main Hawaiian Islands using towed-diver survey methods. Survey tracks for the entire mission covered approximately 80 km of 15 m wide transects in coastal Maui, Lanai, Hawaii, and Oahu Islands at depths ranging from 2 to 10 m. A team of two towed divers collected visual estimates of percentage of live coral that was pale and bleached. Photographic data were collected using a downward-facing DSLR camera with strobes that captured a benthic image every 15 seconds. Conductivity, temperature, depth, chlorophyll-a, turbidity, and dissolved oxygen were collected continuously along each survey track using a suite of sensors mounted to the towboards. Preliminary analyses of field observations show significant bleaching affects at all islands. The most severe impacts were seen at Hawaii Island, where observers estimated 49% of live coral was affected by the event. We will present a correlative analysis of observer data with 1) total local degree heating weeks, 2) terrigenous input (sedimentation, development history, land use), and 3) the observed oceanographic parameters. Towed-diver surveys offer reef managers an efficient option for broad-scale characterization of extent, intensity, differential taxonomic response, and oceanographic correlates of coral bleaching.

MOVINGTOWARDSANECOSYSTEMAPPROACHTO FISHERIES MANAGEMENTIN THE CORALTRIANGLEREGION (Abstract ID: 27924)

Applying an EAFM is considered the preferred option and best practice under the CTI-CFF for the long- term sustainability of fisheries and the ecosystem services provided to society (e.g., food security, livelihoods, economic security, coastal protection, human health and well-being). This paper presents progress of the six CTI countries toward implementation of an EAFM. The results of a country analysis of the existing institutional, policy and legal frameworks in terms of the ability of each country to align with EAFM principles is presented. Challenges to effective implementation of an EAFM in the Coral Triangle region are discussed and recommendations to overcome some of the key challenges are provided.

MAPPING EFFECTS OF 3D HABITAT STRUCTURAL COMPLEXITY AND ORIGIN ON FISH ASSEMBLAGES (Abstract ID: 28098 | Poster ID: 237)

Habitat structural complexity is a key driver of local biotic assemblages. Modifications to marine habitat (both intentional and coincidental) present an opportunity to explore how elements of 3D complexity influence fish and sessile assemblages. To capture complexity at fish-relevant spatial extents and resolutions, a novel mapping tool using affordable and widely accessible off-the-shelf tools was developed and trialled. Target spatial extents of 500 – 1000 m2 were achieved with cm resolution and only 4% coefficient of variation. Paired with Underwater Visual Census data these maps allow exploration of the relationship between local assemblages and complexity at 100, 250 and 600 m2 spatial extents. Abundance and diversity increased with 3D complexity of habitat. Additionally, fish assemblages were significantly different at anthropogenic habitats (break walls) than at natural reefs. Interestingly, this trend was driven largely by pelagic species such as T. Novaezealandiae and highly habitat-attached species such as Pempheridiidae. These findings suggest that modifying structural complexity of anthropogenic structures could significantly influence local fish biodiversity.

SPECIES DIVERSITY TRENDS OF STONY CORALS IN THE FLORIDA KEYS NATIONAL MARINE SANCTUARY, 1996-2010 (Abstract ID: 28709)

Coral biodiversity is critical to maintaining reef survival and function. We assessed the changes in coral community diversity to determine spatial and taxonomic patterns of change. Annual species counts were conducted at 34 fixed sites throughout the FKNMS over a 15-year period from 1996 - 2010. Keys-wide, average species richness declined at rate of -0.21 species per year. Species richness at deep sites along the offshore reef tract decreased most severely between 1996 and 2006, at a rate of -0.51 species per year, but leveled off after 2007. Shallow sites on the offshore reef tract had variable richness in the early years of the survey, but decreased at an average rate of -0.15 species per year since 1999. Mid-channel patch reef stations lost an average of -0.16 species per year throughout the survey period. Species lost from the highest number of sites included *Mycetophyllia ferox* (-35%), *Acropora cervicornis* (-32%), *Mycetophyllia lamarckiana* (-29%), and *Favia fragum* (-21%). Our data show a uniform, almost monotonic, decline in species. Multiple regression models reveal that spatial factors (such as shallow-offshore, deep-offshore, and patch reefs) and nutrient concentrations (both N and P) were the

most important parameters influencing species decline rates. These data argue against the influence of climatic extremes, such as hurricanes and bleaching events, and for the importance of chronic stressors, such as water quality, as major controllers of species number. Current (2016) El Nino conditions will test this hypothesis.

LONG-TERM DYNAMICS OF A HIGH-LATITUDE CORAL COMMUNITY AT SODWANA BAY, SOUTH AFRICA (Abstract ID: 29347)

Dynamics in percentage cover, mortality and recruitment success of a high-latitude coral assemblage in South Africa were studied over 20 years with the rationale of detecting the effects of climate change. Coral communities at this locality are the southernmost on the African continent, non-accretive, attain high biodiversity and are dominated by soft corals. Long-term monitoring within fixed transects on representative reef was initiated in 1993, and has entailed annual photo-quadrat surveys and hourly temperature logging. Although sea temperatures rose by 0.15°C p.a. at the site up to 2000, they have subsequently been decreasing, and the overall trend based on monthly means since monitoring commenced has been a significant decrease of 0.03°C p.a. ($p = 0.0013$). Minor bleaching was encountered during the 1998 El Niño Southern Oscillation event. A significant decreasing trend in soft coral cover has been evident throughout the monitoring period, attributable to decreases in Sinularia and Lobophytum spp. cover ($p < 0.005$). Contrastingly, hard coral cover gradually and significantly increased ($p = 0.0048$) up to 2005, this being largely attributable to increases in cover by Acropora spp. ($p = 0.0089$). Recruitment success and mortality for both soft and hard corals has displayed high inter-annual variability with increasing but non-significant trends in the last five years. The reduction in soft coral cover has been more consistent and greater than that of hard corals but it is difficult at this stage to attribute this to changes in acidification-linked accretion or temperature.

INCORPORATING CATASTROPHES AND PROBABILITY OF SUCCESS IN SPATIAL PLANNING OF MARINE CONSERVATION ACTIONS (Abstract ID: 28434)

Coral reef spatial planning focuses on representing a range of conservation features, usually habitats and species, and creating well-connected management area networks, while minimising impacts on human socio-economic systems. One area of conservation planning that is often ignored, or considered in a confused fashion, is risk and uncertainty. There is always uncertainty about data, there are different risks to different sites, plus there are risks conservation actions will fail (via catastrophes or poor implementation) . In this talk we will discuss a range of situations where threats, uncertainty and catastrophes affect the coral reef system of interest. First we note there are three kinds of threat – those that are stopped by marine reserves, those that are partially mitigated and those that are not mitigated and may be catastrophic (e.g. tropical storms). In the first situation, high threats lead to high benefits of actions, while in the third situation, high threats usually mean that we will avoid those sites for conservation action. Second, uncertainty in the ecological effect of actions and their socio-economic feasibility is clearly pivotal to planning, and can be quantified with probabilities (all of which are uncertain). In the spatial planning software, Marxan, we use probability theory to determine priorities for coral reef conservation that integrate threat and feasibility with issues of cost, connectivity and representation.

EXTENSIVE LINEAGE DIVERSITY AND CRYPTIC SPECIES IN AGLAOPHENIIDAE (HYDROZOA) SPECIES REVEALED BY MOLECULAR SPECIES DELIMITATION METHODS AND POPULATION GENETICS (Abstract ID: 29309)

A comprehensive inventory of global biodiversity would be greatly improved by automating methods of species delimitation. The ABGD method, the PTP algorithm and the GMYC model, using single locus data, were proposed as means of increasing the rate of biodiversity description. We applied these methods to explore the cryptic diversity of Aglaopheniidae, a hydrozoan family widely distributed in the Indo-Pacific region. For two species of this family, Lytocarpia brevirostris and Macrorhynchia phoenicea, we compared the outputs to several clustering analyses based on microsatellite data and to nuclear genes phylogenies. Our analyses revealed widespread cryptic diversity in this family, various species presenting several independent evolutionary lineages, and supported hypothesized cases of synonymy. Comparisons of results between species delimitation methods and microsatellite data were congruent for Lytocarpia brevirostris, revealing the existence two cryptic species. For Macrorhynchia phoenicea, results were inconsistent but all analyses confirmed the divergence of two evolutionary lineages in the South-West Indian Ocean that could not be distinguished using standard morphological characters. Our study suggests that the diversity of Aglaopheniidae might be extremely high, likely due to low dispersal capacities. Sequence-based species delimitation methods seem highly valuable to reveal cryptic diversity in hydrozoans; their application in an integrative framework will be very useful in describing the phyletic diversity these organisms.

INVOLVING TRADITIONAL FISHERMEN IN MPA MANAGEMENT : TOWARDS A WIN-WIN SITUATION IN REUNION (Abstract ID: 29478 | Poster ID: 605)

The success of conservation initiatives is often linked to trade-offs between the stakeholders' personal interests, the protection of the natural ecosystem and the management initiatives. Coral reefs in Reunion are limited to the west coast and strongly exploited by a variety of users, that includes the traditional fishermen. These fishermen fish using traditional fishing gears but do not depend anymore on their catch for their livelihood thanks to the government aids. In January 2015, they started arguing with the management team about possible changes of the MPA regulation policy, especially regarding the move of their fishing zones and the increase in fishing duration. The MPA team took this opportunity to propose a "win-win" contract, which aimed in reinforcing the MPA acceptation within the fishermen. It agreed for some changes in the location of the fishing zones if the fishermen accepted to strictly follow the regulations and participate in the daily collection of fishery data using a logbook. Fisheries mediators were planned to be recruited to verify the fishermen engagement and maintain a strong link between the two stakeholders. Good progress was made and the new fishing zones were ready to be opened after one year. Nevertheless, the fishermen ended the discussion process at the last minute. This presentation will discuss on the success and limits of this challenging situation, which is a common problem in MPA management and can be used for further comparison.

MACROPLANKTON, MICRONESIA, AND MESOSCALE MOVEMENT MODELS: QUANTIFYING LARVAL TRANSPORT PATHWAYS AROUND THE MARIANA ARCHIPELAGO (Abstract ID: 29891)

Many coral reef organisms have a larval development phase in pelagic environments. These larvae may return to their natal islands or be dispersed downstream in ocean currents. Understanding the strength and geographic patterns of larval connectivity is an important part of managing marine ecosystems through ecosystem based fisheries management, marine protected area network design, recovery strategies for endangered species, and promoting resilient reefs. Sufficient sources of larvae must be maintained to sustain future generations. In recent years, there have been calls for a better understanding of larval connectivity in the Mariana Archipelago, an ~800 km span of islands and submerged banks that includes the Commonwealth of the Northern Mariana Islands and Guam. To evaluate ocean currents as a mechanism of larval transport in this region and to compare larval connectivity patterns for several taxa, computer simulations were used to track cohorts of virtual larvae transported according to an ocean circulation model. Virtual larvae were spawned from 2004-2012 at each of 116 locations. Larval production was scaled to each island's area of potential reef ecosystem. Simulations incorporated several larval life history parameters, including pelagic larval duration, precompetency, mortality, and sensory capability. Cumulative connectivity over the 9 year period was summarized for the entire region. The role of each island in the archipelago as a larval source or destination was evaluated. For Saipan and Guam seasonal and inter-annual variation in larval supply was examined.

EFFECTS OF TEMPERATURE AND PH ON GROWTH OF *OSTREOPSIS* CF.*SIAMENSIS* (Abstract ID: 29936 | Poster ID: 407)

The impact of global warming on high temperature and low pH of seawater lead to coral bleaching and benthic microalga bloom in coral reef area.*Ostreopsis* cf. *siamensis* is a benthic dinoflagellate that reported as one causative microalga for ciguatera fish toxin. In order to clarify the effects of temperature and pH on growth of *Ostreopsis* cf. *siamensis*, the experiments have been conducted on this species isolated from Chang Island. Three set of temperature at 27 (control), 30 and 33 C have been designed for the experiments. For each temperature level there were four experiments of pH 6, 7, 8 and 9. Sampling cells were enumerated every 2 days for 25 days. Cells cultured at 27 and 30 had the normal growth rate whereas the growth rate of cell at 33 C gradually decreased from the beginning and most cells died on day 15. At 27 and 30 C *Ostreopsis* cf. *siamensis* grew normally in all pH levels but very low growth rate with high mucus excretion and pale cell color have been found at pH 9. The highest specific growth rate of 0.56 was found in pH 6 at 27 C.

## A DIFFERENT KIND OF OCEAN ACIDIFICATION AND ANOTHER REFUGIUM FOR PH-TOLERANT ORGANISMS (Abstract ID: 30053)

Many modern reefs grow on submerged portions of older limestones deposited by previous reef systems. Sub-surface cavities, formed by karstic erosion during lower Pleistocene sea levels, now channel meteoric groundwater offshore, where it often emerges as submarine springs in or near living reefs. As rainwater percolates through karstic sediments and limestones, dissolved carbon dioxide reacts with calcium carbonate; modifies pH, alkalinity, and carbonate saturation states; and leads to other changes in water chemistry. Off the coast of the Yucatan Peninsula, this groundwater mixes with seawater before discharging at permanent springs or "ojos" with water that is close to oceanic salinity but has low pH, elevated alkalinity, and variable nutrient content. Many ojos are surrounded by often stable and persistent pH and alkalinity gradients that are occupied by long-lived calcifying organisms. We describe assemblages of coralline algae and scleractinian corals living in a system of low pH springs near Puerto Morales, Mexico and summarize physical and chemical correlates. We hypothesize that individuals able to survive for decades in these gradients have genotypes (i.e., adaptation) or plastic phenotypes (i.e., acclimatization) likely to confer tolerance of low pH. While each spring may be too small for recruitment of planktonic larvae to their parental sites, multiple springs within a defined region ensure that some tolerant individuals are always present within the region, and they are likely to increase in abundance and distribution with increasing acidification of the oceans.

## KEEP THE EYES ON THE REEF DURING HOT SEASON IN ARCHIPELAGIC NATION OF INDONESIA: A CASE OF CORAL BLEACHING NETWORK INDONESIA (Abstract ID: 29306)

To monitor bleaching event and how the reef is impacted, timing is really important. However, tracking bleaching development in vast-scattered reef nations such as Indonesia is really challenging. Reef Check Network Indonesia (RCNI) and partners worked together in creating a coral bleaching network to cope with 2009-2010 bleaching event. An alert, based on NOAA coral bleaching satellite data, was distributed regularly to the network during the hot season. This is followed by personal communication to certain members in bleaching alert areas. The network provided an in situ coral bleaching early warning. RCNI then distributed this information to its scientist members so they can determined whether or not a more thorough coral bleaching data was needed. By 2010, the network gathered the most comprehensive coral bleaching data in Indonesia despite that there was no resources dedicated to this effort. The success lays behind RCNI structured. Started in 1997, the network rapidly grows comprising ranges of reef stakeholders from individual to institution, from fisherman to scientists. By 2015 the network has covered all main islands in Indonesia, involving up to 2,500 volunteers. A headquarter coordinates the network and provides supports for both science capacity and organizational building. To minimize the costs, innovative coordination using various modes include social media. With the bleak prediction of future bleaching events, it is hoped that the RCNI can be strengthened and expanded by using a more high tech and simpler information sharing system, as well as a data base.

## EMPTY NICHES AFTER EXTINCTIONS INCREASE POPULATION SIZES OF MODERN CORALS (Abstract ID: 28334)

Estimates of population size as a function of time can show how history has shaped the evolution of current species, provide accurate models to interpret contemporary genetic data, and generate a framework to implement successful conservation strategies. This information is relevant when paleontological evidence is rich and provides direct ecological evidence on what triggers variations in population size. We studied how variation in abiotic and biotic environments since the late Pliocene shaped historical changes in the population sizes of corals of the genus Orbicella, the major current reef builders in the Caribbean. Our results suggest populations of all three Orbicella species share patterns of population decline around 1-2 million years ago (Ma) coincident with the extinction of 80 % of Caribbean coral species. The change in population size is consistent for the three species despite their ecological difference. More recently, the two shallower specialists, O. faveolata and O. annularis expanded their population sizes by at least two fold. The growth of these two species coincides with the recent disappearance of their sister competitor species Orbicella nancyi (organ-pipe). Our study suggests that populations of modern Orbicella species are capable of rebounding from reductions in population size under suitable conditions.

## OCEAN WARMING AND ACIDIFICATION SYNERGISTICALLY INCREASE CORAL MORTALITY (Abstract ID: 29374)

CO2-driven ocean warming (OW) and acidification (OA) has prompted urgent research to assess their potential effects on the marine environment, with strong emphasis on calcifying organisms. To correctly predict how these stressors will affect marine organisms, their synergistic effects must be assessed. Here we investigate the interactive effects of OW and OA on the mortality and growth of three Mediterranean coral species: the solitary zooxanthellate Balanophyllia europaea, the solitary non-zooxanthellate Leptopsammia pruvoti and the colonial non-zooxanthellate Astroides calycularis. Corals were transplanted, in different seasons, in proximity to a volcanic CO2 vent where water is naturally acidified to levels matching future IPCC scenarios. We show a strong synergistic adverse effect on mortality rates of the three species. Net calcification rates of the zooxanthellate species were not affected by reduced pH, while those of the two non-zooxanthellate species were negatively affected, indicating that different levels of resilience/resistance to OW and OA among species in symbiosis with photosynthetic algae or asymbiotic ones may be related to different modes of nutrition and/or biomineralization processes. Natural CO2-leaking marine sites can provide essential information on the combined effects of OA and OW on Mediterranean scleractinian corals, which may help understand to which extent different corals will be threatened by increasing atmospheric CO2 pollution.

ACCLIMATION OF ADULT AND JUVENILE MESOPHOTIC *SERIATOPORA HYSTRIX* TO SHALLOW REEF HABITATS (Abstract ID: 29381)

Mesophotic coral ecosystems (MCEs), have often been suggested as a source to recolonize shallow reefs. Shallow reef recovery could occur through natural (i.e. larval recruitment) or artificial recolonization (i.e. man-made transplantation). However, the success of the mesophotic coral's contribution to shallow reef recovery depends on their ability to acclimate to shallow reef conditions. Here we examined the physiological capacity of adults and juveniles of the coral *Seriatopora hystrix* from an upper MCE (ca. 40 m depth) to acclimate to shallow reef conditions for 6 months. Both adult fragments and coral juveniles were transplanted to 3, 20, and 40 m depth reef habitats and monitored monthly. Most of the adult fragments at 3 m depth were lost due to a typhoon and were discarded from the analysis. High survival of adults was observed at 20 m and 40 m depth. All coral juveniles died when transplanted at 3 m depth, while at 20 m and 40 m depth they died by an average of 20.5% and 21% every month, respectively. This study revealed the capacity of mesophotic *Seriatopora hystrix* to acclimate to shallower environmental conditions. The mid-depth reef habitats (i.e. 20 m depth) might act as a stepping-stone for shallow reef recovery, with mesophotic corals avoiding mortality due to extreme environmental conditions in the shallow reefs but adapting to shallower conditions. The photophysiological and symbiont characteristics of the transplants and their role in the adaptation process will be discussed.

VARIABLE REPRODUCTIVE TIMING AND FECUNDITY OF CROWN-OF-THORNS STARFISH (ACANTHASTER CF. PLANCI) IN THE NORTHERN GREAT BARRIER REEF, AUSTRALIA. (Abstract ID: 28479)

Understanding the initiation and spread of outbreaks of crown-of-thorns starfish (Acanthaster cf. planci) requires detailed knowledge of their reproductive behavior and output. While crown-of-thorns starfish are known to have exceptional reproductive potential, reported estimates of fecundity are based on limited sampling from just one location. We quantified fecundity for a wide range of individuals collected from the northern Great Barrier Reef, and showed that fecundity varies enormously with individual size and condition. This study also examined temporal changes in the reproductive condition of crown-of-thorns starfish collected from the same location every month for 2 years, revealing marked inter-annual differences in spawning behavior. In the first year of sampling, there was little evidence of any distinct spawning event and females had consistently large gonads throughout the summer period from November 2013 to April 2014. In 2014/15 however, there was a marked reduction in the size of gonads for females collected in late December versus early January, indicative of extensive spawning during this period. Variability in reproductive behaviour and output of crown-of-thorns starfish may account for spatial and temporal differences in the propensity for outbreaks to occur (e.g., in different geographic locations) and warrants much further investigation.

BOOSTING CORAL REEF CONSERVATION THROUGH REGIONAL COLLABORATION: A LESSON LEARNED FROM REGIONAL CTI-CFF PARTNERSHIP (Abstract ID: 27851)

Coral reefs in Asia-Pacific region, particularly in the Coral Triangle area, is one of the most ecological, biological rich and huge regions on earth, which urgently need a commitment from people to conserve and protect from increasing potential natural and anthropogenic threats. Relying upon individual commitment from each country's to conserve is challenging as the coral reef ecosystem shows interconnectivity that clearly region-wide borderless system. At this point, regional initiative becomes fundamental. CTI-CFF is one of the regional initiatives engaging region-wide marine conservation. The initiative was established by head of states in May 2009 in Manado, of six-coral-triangle- countries: Indonesia, Malaysia, Papua New Guinea, Philippines, Timor Leste, and the Solomon Islands, which systematically wrap up individual and nation-wide commitment to region-wide conservation through a Regional Plan of Action. Regional collaboration through CTI-CFF boosts CT-marine protected areas in the view that it is not only for the sake of conservation, but also the MPA should be developed in the frame of prosperity of the people, sovereignty of the country, and sustainability of the resource use. In this presentation, challenges of managing regional activities would be discussed.

THE EVOLUTIONARY CHALLENGE OF CLIMATE CHANGE: ADAPTIVE PROCESSES IN THE MEDITERRANEAN RED CORAL (Abstract ID: 27813 | Poster ID: 17)

The on-going climate change should have major impacts on the different components of biodiversity, from genes to ecosystems. Marine species, and especially corals, are already suffering from climate change, as shown by mortality events linked with thermal anomalies. These events highlighted a diversity of thermotolerance levels in the Mediterranean red coral (Corallium rubrum). The main objective of this work was to understand the origin of these differences and to search for local adaptation to thermal conditions in the red coral. This species is present in very contrasted ecological conditions which correspond to genetically differentiated populations. Moreover, colonies from different regions, but also from the same site at different depths , display thermotolerance differences. These differences can be linked to the individual history through acclimatization or to genetic adaptation at the population level. Two complementary approaches were developed to study these mechanisms: i. Transcriptomic (gene expression and polymorphism) basis of thermotolerance differences. ii. Genomic study of local adaptation. We looked for genetic-environment associations through the identification of outlier loci with particular patterns of genetic differentiation using RAD-sequencing (Restriction site Associated DNA sequencing). For this purpose we chose to compare populations from above the thermocline which deal with high thermal variations to populations from a more thermal stable zone below the thermocline. The obtained results are analyzed at the light of transcriptome polymorphism and plasticity.

GALL CRABS, CORALS, AND WHITE PLAGUE; HOW ARE THEY ALL CONNECTED? (Abstract ID: 28340)

Cryptochiridae gall crabs are small crabs that reside on scleractinian corals, altering their morphology, physiology, and likely their microbiota. Despite their relative abundance, gall crabs are commonly overlooked in most scleractinian coral studies, and entirely absent in microbial studies. This aquarium-based study identified the Cryptochiridae gall crab as a potential disease vector for white plague-like lesions on the scleractinian corals*Diploria labyrinthiformis* and *Pseudodiploria strigosa*. 16S rRNA gene profiling demonstrated that the microbiota of white plague-like lesions, lesions created by the crab, and the microbiota of the crab itself were highly similar, while the microbiota of apparently healthy *D. labyrinthiformis* was significantly different. Manipulative experiments revealed that the removal of the crab from corals with white plague-like lesions and placement onto apparently healthy *D. labyrinthiformis* corals resulted in the development of similar lesions. Microbial analysis suggested that a member of the*Roseobacter* clade may be a potential pathogen of the corals *D. labyrinthiformis* and *P. strigosa*, which may be transmitted by gall crabs of the Cryptochiridae family. This study is the first to examine the microbiota of the coral-dwelling gall crab, and has identified the gall crab as a potential disease vector for devastating diseases such as white plague.

LOCAL HABITAT INFLUENCES THE RESPONSES OF THE LARGE BENTHIC FORAMINIFERA AMPHISTEGINA LOBIFERA TO THE COMBINED EFFECT OF ELEVATED TEMPERATURE AND NITRATE (Abstract ID: 28282)

Large benthic foraminifera are crucial marine calcifiers in coral reefs, and sensitive to environmental changes. Yet, many species successfully colonise a wide range of habitats including marginal and highly fluctuating environments. This study aimed to identify populations of Amphistegina lobifera that could potentially acclimate to high environmental fluctuations. Specimens were collected from different reef sites on the Great Barrier Reef (GBR) across a shelf gradient of temperature and nutrients, and exposed to the combined effects of elevated temperature and nitrate in lab-controlled conditions for 30 days. We analysed survivorship and fecundity, and are sequencing 18S rDNA from A. lobifera diatom symbionts to investigate flexibility in symbiotic partnerships. Survivor-

ship and fecundity varied significantly among reef sites and experimental conditions. Survivorship was highest (>95%) among inshore reefs exposed to control conditions of temperature and nitrate, whereas outer-shelf populations showed substantially reduced survivorship (<25%) when exposed to the combination of elevated experimental conditions. Fecundity was significantly reduced by elevated temperature across the GBR shelf, and only inshore A. lobifera showed consistent reproduction in all treatments. Initial assessment of diatom composition showed spatial differences in symbiont community composition. These preliminary results showed that local habitat is an important factor shaping the response of A. lobifera to the combined effect of temperature and nitrate.

3D MAPPING OF CORAL REEFS: VISUALIZATION, CHARACTERIZATION, AND QUANTIFICATION WITH PERMANENT, EXTENSIVE, AND INFORMATION-RICH VIRTUAL DATA SETS (Abstract ID: 28780)

3D mapping of coral reefs provides a unique virtual record of the spatial relationships between reef complexity and its related biota. Imagery is collected using digital still photography and ultra-high definition (4K) videography. Camera arrays can be mounted on dive scooters, ROVs, or AUV platforms depending upon depth, site conditions and project needs. The camera array is "flown" at a height of 1-2 above the sea bottom in a series of overlapping swaths that cover the entire study site. Photographic sequences taken over the reef provide multiple perspectives of the sessile benthic organisms and reef topographic structure. The application of "structure from motion" computer algorithms use 100,000s of these photos, for each site to create a 3D point cloud that accurately records site topography and position and structure of organisms. Point clouds or derived polygonal mesh models can be analyzed as "virtual" models of reef site. These models can be used to determine dimensions of organisms and abiotic features. Incorporating 3D mapping in reef monitoring improves precision and accuracy of field surveys. This computer-based approach captures a permanent record with sufficient detail to perform statistically robust desk-top analysis of complex ecological data. This permanent, "virtual" record also allows the user to employ various ecological methods integrated on this permanent record to answer hypothesis-driven, project specific questions. Importantly, if the questions change in time – so can the resultant, subsequent analysis without the need to acquire additional data.

PLANNING AND MANAGING MARINE PROTECTED AREAS: FROM BELIEF SYSTEMS TO EVIDENCE (Abstract ID: 29115)

People involved in establishing and managing marine protected areas (MPAs) are motivated by wanting to make a positive difference to the eventual state of the marine environment. In parallel with medicine, education, and development aid, the difference we make in conservation is referred to as "impact". Impact can be evaluated retrospectively, to offer lessons to planners and managers, and estimated predictively, to guide decisions on priorities for conservation investments. But much of the decision-making around MPAs is based more on untested belief systems than on evidence. Effective MPAs require decision-makers to critically assess their assumptions and beliefs about approaches to planning and management. This presentation critiques five aspects of decision-making about MPAs, showing that none of them can be linked reliably to conservation impact: 1. Accumulating km2 2. Establishing large, remote MPAs 3. Management based on criteria for effectiveness 4. Setting criteria-based priorities (e.g. KBAs, EBSAs) 5. Systematic methods to represent species or marine bioregions. All five approaches fail to inform funders and decision-makers about conservation impact and risk being used to over-state progress in marine conservation. A consequence is avoidable degradation of marine ecosystems and loss of marine biodiversity. The barrier to moving to evidence-based decisions for MPAs is not lack of capacity, but lack of willingness to use and refine available tools to look critically at and improve approaches to decision-making about MPAs.

CORALLINE ALGAE HOST PHYSIOLOGY, MINERALOGY, AND FUNGAL INFECTION DYNAMICS RESPOND TO TEMPERATURE ANOMALIES AND NATURALLY VARYING SEAWATER PH (Abstract ID: 29971)

Recent advances in autonomous sensor technology have illuminated the spatio-temporal complexity of carbonate system dynamics on coral reefs. The consequences for reef organisms experiencing naturally occurring combinations of elevated temperatures and/or acidity are unclear. Ecologically important benthic seaweeds – the crustose coralline algae – which cement coral reefs and attract larvae of reef-building corals, may respond physiologically to dynamic inorganic carbon diel cycling and temperature anomalies. By co-locating autonomous pH/T sensors across 10 sites with long-term (>5 yrs) monitoring plots and transplanted specimens, we demonstrate that net calcification rates (linear extension and calcimass), mineralogy (mole fraction Mg) and relative abundances of coralline algae are positively correlated with the least variable and most benign physicochemical conditions. Further, coralline fungal disease (CFD) prevalence and lesion expansion rates (linear) on individual coralline algae hosts are related to temperature anomalies and can reach 6.5 mm per day. We demonstrate experimentally that ocean-warming events may increase the frequency of CFD outbreaks on coral reefs, but that OA-induced lowering of pH may ameliorate outbreaks by slowing progression within a host. Lowered pH may still impact overall host survivorship, however, by reducing calcification and facilitating fungal bio-erosion. Future research will explore the role of environmental conditions and host coralline mineralogy on disease transmission, severity and population susceptibility to CFD.

FISH SPAWNING AGGREGATIONS MODIFY MULTI-SPECIES AND -TROPHIC INTERACTIONS (Abstract ID: 28960)

The vast majority of fish spawning aggregation (FSA) research has focussed on the identification, characterisation and monitoring of the focal spawning species. This is understandable given their imperilled status. However, little attention has been paid to the effects FSAs have on resident fish and benthic assemblages, which may be particularly evident during large predatory fish aggregations. Here we use repeated underwater visual surveys and behavioural observations to assess how resident fish and benthic assemblages respond to the natural variation in predator biomass found at a multi-species grouper FSA site in Palau, Micronesia. We found strong risk effects of grouper presence resulting in changes in overall fish assemblage, and decreased excursion areas and bite rates in the ubiquitous surgeonfish, Ctenochaetus striatus. Concurrent increases in turf algal biomass suggest indirect behaviourally mediated effects occur across multiple trophic levels. Such species interactions can be a primary force in structuring communities and food webs, highlighting the wider importance of FSA sites at a time when FSAs worldwide are in decline.

COMPOUNDING EFFECTS OF CONTAMINATED GROUNDWATER ON CORAL REEF BIOEROSION AND HEALTH (Abstract ID: 28183)

Increased CO2 concentrations from greenhouse gases have been linked to a lowering of surface seawater pH by 0.1 and aragonite saturation state (Ω) by 15%. Global climate models predict an additional change of 0.3 pH units by 2100, triggering a decrease in Ω 5x greater than natural variability over the last millennium. Managing local stressors that exacerbate vulnerability of coral reefs to climate change is therefore of paramount importance. Land-based sources of pollution that alter coastal water nutrient and pH levels can magnify vulnerability to CO2-related impacts, with nutrients and pH acting together to accelerate bioerosion rates. We examine coral reef health, indicated by bioerosion, calcification, and growth rate, in response to multiple stressors from high-nutrient, low-pH submarine groundwater discharge in West Maui. Freshwater discharging directly from groundwater vents off of Kahekili Beach Park in West Maui contains elevated nutrient concentrations and lower pH values than surrounding waters. The range of conditions that corals living in the vicinity of the vents are exposed to is comparable to those arising from end-of-century pCO2 projections, however measured bioerosion rates at Kahekili are greater than those predicted from previous relationships between Ω and bioerosion. Elevated nearshore nitrate and coral tissue δ15N values distinctly reflect the down stream signature of nutrient loading from wastewater effluent injected into the coastal aquifer ~300 m upland of the reef. These results suggest nutrient loading from human

activity is driving a disproportionate escalation of bioerosion rates under low pH/ocean acidification conditions.

USE OF SEXUAL REPRODUCTION TO ACCLIMATIZE EARLY LIFE STAGES OF CORALS TO CLIMATE CHANGE: WHAT DOES NOT KILL ME, MAKES ME STRONGER? (Abstract ID: 29780)

Restoration in coral reefs involves the use of both reproduction patterns of corals (e.g. sexual and asexual). Nonetheless, sexual reproduction in corals is of paramount importance to ensure high genetic diversity. Transgenerational acclimatization was achieved in corals, but there is almost no information about whether intra-generational effects may also occur. In our work, we hypothesize that early life stages of corals may be preconditioned to thermal stress, meaning that a first exposure to short-term thermal stress may render them more resistant to a second exposure at a later stage. To achieve that, early life stages (gametes and larvae) of Acropora species were pre-exposed to short-term temperature stress (e.g. 30 min to 24h) before the main thermal stress experiment was performed. Our results show that 1h of preconditioning improves the successful fertilization rate of gametes, by a 57.6% increase in fertilization rate. Moreover, both age of the larvae and timing of preconditioning matter in order to acclimate larvae to sub-lethal temperatures. Indeed, non-swimming larvae (2 days old) showed a better capacity to acclimatize to thermal stress than 6 to 10 day old larvae. In conclusion, our results are promising, and revealed that intra-generational acclimatization may occur in Acropora. This has the potential to 1) enhance current restoration efforts of coral reefs by transplanting recruits or larvae with better resistance and 2) improve our knowledge of acclimatization and adaptation processes among key organisms, such as scleractinian corals.

SIGANUS VIRGATUS IS A KEY BROWSER IN CORAL REEFS OF THE GULF OF THAILAND (Abstract ID: 28481 | Poster ID: 582)

Browsing fish species are important functional players in coral reefs because of their ability to remove macroalgae. Their identification thus has important implications for future management strategies aimed at increasing the resilience of coral reefs. However, very few studies have been conducted outside of the Great Barrier Reef in Australia. This study aimed to identify important browsers at two study sites in the Gulf of Thailand: Mae Haad, a heavily touristic and fished bay dominated by algae and the Marine Park Ang Thong, dominated by hard corals and exhibiting very low algae cover. Findings revealed that more than 90 % of size-adjusted bites taken from macroalgae assays derived from only one species, Siganus virgatus, which dominated feeding in both reefs. Higher size-adjusted bite rate in Ang Thong (11.2 $\pm$ 18.4 msb h-1 vs. 0.7 $\pm$ 2.3 msb h-1 in Mae Haad) coincided with 2.4 times higher biomass of S. virgatus and 10 times higher biomass removal on overnight assays (53 $\pm$ 44 % removed compared to 4 $\pm$ 8 % in Mae Haad). No Acanthurids were observed in either reef. As reefs without Acanthurids often undergo phase shifts, the healthy state of Ang Thong is remarkable. The data suggest a key role of Siganus virgatus for macroalgal removal on coral reefs in the Gulf of Thailand. In the absence of the usual important Acanthurid browsing species such as Naso spp., Siganus virgatus assumed the role as dominant macroalgae remover and should thus be considered more extensively in management and conservation efforts.

SEASCAPE IDENTITIES; UNDERSTANDING VALUES AND CULTURAL PATTERNS (Abstract ID: 29278)

Seascapes symbolize both the physical dimensions of ocean and coastal areas, as well as the meanings humans ascribe to their observations, interactions, and relationships to the sea. Seascapes have value and contribute to building identities and understanding territories. More than beautiful scenery over the ocean, a seascape is a fluid cultural and geographic space, whose dynamics make it complex to define but should be at the center of analysis. In Pacific Island communities, seascapes are particularly important given that the ocean (1) contributes considerably to the well-being of coastal communities, (2) is an area of high overlap between tourists and residents, and (3) are threatened as our climate continues to change and human pressures are increasing. We will discuss various methods we use to understand seascapes including observation notebooks, interviews, surveys, focus groups, participatory mapping, discourse analysis, and integration of weather, oceanographic, and population data. Seascape maps and results will be presented for a small coastal community of Hilo, Hawaii as an example of these approaches. By interviewing respected ocean observers we are learning more about changes they have witnessed over time and the spatial scales and ocean conditions important to them. Managing complex seascapes requires the integration of both human and mechanical observations to ensure that multiple systems of knowledge are included and valued; strengthening our understanding of seascapes and their resiliency in this changing environment.

A ROBUST METHOD FOR PREDICTING WHERE TROPICAL CYCLONES DAMAGE REEFS (Abstract ID: 29174)

Tropical cyclones (TC) waves can severely damage coral reefs. Models that predict where such damage occurred (the 'damage zone') enable reef managers to: 1) target management responses after major TCs in near-real time to promote recovery at severely damaged sites; and 2) identify spatial patterns in historic TC exposure to help explain habitat condition trajectories. To provide these capabilities, damage models must be valid for a wide range of TCs, which vary in intensity, circulation size and duration. Here, we map damage zones for 46 TCs that crossed Australia's Great Barrier Reef from 1985-2015 using four models – three from the literature and one we develop to extend the capability of the others. We ground truth model performance with field data of damage from seven TCs of varying characteristics. The model we develop, 4MW, significantly out-performs the other models at accurately capturing damage. The next best performing model – AHF - under-predicted damage for the large and/or long-lived TCs which are most likely to cause widespread damage, and over-predicted damage for short-lived TCs. These two models produce strikingly different spatial and temporal patterns of damage frequency when examining historic patterns in TC damage exposure over the 30-year time series. We conclude that the 4MW model greatly enhances both of the main capabilities TC damage models provide to managers. The 4MW model can be used wherever both TCs and corals occur, such as in parts of SE Asia where reefs frequently experience the largest and most intense TCs in the world.

MULTI-FACTOR VARIATION IN ARTISANAL SEA CUCUMBER FISHERIES IN OCEANIA (Abstract ID: 30149)

Small-scale fisheries on coral reefs are important to livelihoods of millions of fishers, yet catches, gender participation and livelihood options are often poorly understood. We characterised fishing and fishers in multi-species sea cucumber fisheries using questionnaire-based surveys in multiple regions within each of four countries in Oceania. Many women were fishing sea cucumbers in Fiji, Tonga and New Caledonia, whereas women in Kiribati mostly participated in postharvest processing. Catch-per-unit-effort (CPUE) differed among countries depending on fishing modes and species targeted. Fishers tended to view stocks as declining or greatly over-exploited. In many cases, women received much lower prices than men for their catch. Sea cucumbers were often a primary source of income for fishers, and a majority of them rely on other coastal resources as fall-back income streams. This study shows that fishers and their catches in artisanal reef fisheries can be highly context-dependent. Understanding species composition and catch rates of fishers through sociological surveys will support better fishery management. Management measures and interventions to support fisher livelihoods must consider gender differences and location-specific fishing activities. Our study indicates that closure of certain reef fisheries will likely cause greater pressure on other fisheries unless livelihood diversification programs are developed.

REVERSING THE DECLINE OF SHARK POPULATIONS IN RAJA AMPAT, EASTERN INDONESIA (Abstract ID: 28500)

The high marine biodiversity and natural beauty of Raja Ampat, Indonesia attracts not only dive tourism but also outside fishers, who often engage in destructive and illegal fishing, including the targeting of sharks for their economically valuable fins. Since 2009, Raja Ampat local government made several efforts to improve shark conservation, including: media campaign; develop surveillance system that includes monitoring shark fishermen activities; and develop prohibit shark fishing regulation. The declaration of 4,6 million hectares marine areas as a Raja Ampat shark sanctuary in December 2012 was the first of its kind for Indonesia and for the Coral Triangle. Since the declaration of the shark sanctuary, the Indonesian government has been supporting the enforcement of the shark finning ban, with several illegal fishers being caught and prosecuted. Shark populations have been surveyed approximately annually from 2009 to 2015 as part of routine reef fish monitoring. Preliminary results indicate shark populations inside MPAs have increased five-fold after three years the sanctuary was implemented. Whereas outside MPAs, shark populations are increased two-fold. This is further reinforced by anecdotal evidence from local patrol team observations on the reappearance of juvenile shark populations in several areas. Amidst an overall trend of shark population decline in Indonesia, this shark sanctuary is showing a promising outlook for the recovery of shark populations in Raja Ampat, providing a model for other regions in the Coral Triangle and beyond.

A ROLE FOR INDUCIBLE DNA METHYLATION IN CORAL INTRA- AND CROSS-GENERATIONAL ACCLIMATIZATION TO FUTURE OCEAN CONDITIONS (Abstract ID: 28934)

As climate change intensifies and the pace of warming and ocean acidification increases, reef-building corals must acclimatize to persist. One mechanism of intra- and cross-generational acclimatization (IGA, CGA) is inducible DNA methylation and its associated phenotypic plasticity. In a series of experiments we have identified 1) CGA of Pocillopora damicornis larval metabolism to high temperature and low pH, 2) beneficial parental effects on juvenile survivorship and growth following adult preconditioning to low pH during brooding, and 3) IGA of adult P. damicornis associated with changes in host DNA methylation induced upon exposure to low pH, together supporting a role for acclimatization through DNA methylation. We then tested the hypothesis that inducible DNA methylation is heritable, associated with changes in gene expression and has performance consequences for P. damicornis adults and offspring after exposure to ambient (~27 °C) and future temperatures (~29 °C). Adults and offspring were collected prior to exposure and after larval release at 1, 2, and 3 months for comparison of DNA methylation and gene expression patterns. Thermal performance curves of larval respiration and survivorship across 5 temperatures (26-34 °C) suggest a shift to higher thermal tolerance in offspring whose parents were exposed to higher temperature. Together with ongoing RNAseq and reduced representation bisulfite sequencing data, these results indicate a strong role for dynamic DNA methylation in rapid CGA with implications for coral performance in a future of climate change.

MARINE CONSERVATION MANAGEMENT OF KRAKATAU ISLANDS, INDONESIA (Abstract ID: 27897 | Poster ID: 568)

The Krakatau Islands form a group of isolated, uninhabited, but accessible volcanic islands in the Sunda Strait between Sumatra and Java (Indonesia Archipelago). Their geological growth and development are well documented. Based on an Indonesian Government decision, the Krakatau complex was designated as a Natural Reserve, consisting of Marine Reserves and Nature (land) Reserve. The present report provide suggestions concerning their marine conservation management in relation to natural and anthropogenic disturbances. The result showed the ongoing impact of the anthropogenic disturbances (i.e. destructive recreational activities) on coral communities in the area will continue to lead to degradation in the future unless the utilization of the area will become more controlled.

LONG-TERM CHANGES AND RESTORATION MEASURES OF SOFT CORALS (*DENDRONEPHTHYA* SPP.) AT MU KO SIMILAN NATIONAL PARK, THE ANDAMAN SEA (Abstract ID: 28667 | Poster ID: 678)

Soft corals, *Dendronephthya* spp., are members of 19 genera (in four families) of soft corals found in Thai waters. In the Andaman Sea, *Dendronephthya*spp. is dominant at several coral reefs. Their beauty and color attract divers to these reefs making them popular diving destinations. In this study, we investigate the long-term changes of the soft corals, *Dendronephthya* spp., from 2009 – 2013 in three study sites of the Mu Ko Similan National Park, one of the most frequented diving destinations in the Andaman Sea. We found that the average percent covers of *Dendronephthya* spp. spp. were significantly different among the study sites. The highest coverage of*Dendronephthya* spp. was observed at West of Eden while the lowest one was recorded at Ao Faiwab. Significant temporal variation was also detected among years. Reduction in soft coral bottom cover as influenced by certain environmental factors and rapid growth of tourism. The number of tourists visiting Mu Ko Similan in 2013 was nearly doubled compared to that in 2011. Based on our analysis, controlling tourism impacts on soft corals could be possible by implementing the following measures: 1) setting appropriate management action plan with the implementation of effective enforcement and regulation of diving activities; 2) establishing zoning and their appropriate carrying capacity for tourists in certain areas and 3) enhancing research and techniques on soft coral restoration.

THE HABITAT PERSISTENCE HYPOTHESIS: A NEW PERSPECTIVE ON THE DISTRIBUTION OF CORAL-REEF ORGANISMS (Abstract ID: 29098)

We propose the "Habitat Persistence Hypothesis" (HPH) to explain patterns of diversity on tropical coral-reefs. We reviewed distributions of organisms inhabiting tropical coral reefs, and formulated the HPH to account for biogeographical patterns on both shallow (<30m) and deep (30–150m) coral-reef habitats. Species occurring on deep reefs appear to show higher rates of endemism and less eastward diversity attenuation than their counterparts on shallow reefs. The HPH stipulates that shallow-reef habitats persist across glacio-eustatic sea-level changes in regions with sloped bathymetry (e.g., continental regions and large islands), but are largely extirpated during low sea-level stands in regions with steep bathymetry (e.g., coral atolls); in contrast to deep-reef habitats, which persist in all regions. The HPH suggests that habitat persistence results in higher rates of endemism, and that patterns of attenuating diversity with distance from centers of species richness reflect recolonization from areas with shallow-habitat persistence. Whereas existing hypotheses that attempt to explain biogeographic patterns rely on observations limited to shallow (<30m) coral-reef habitat and invoke processes operating on speciation time-scales (~10^7 yr), the HPH also incorporates patterns on the remaining 80% of coral-reef habitat (30–150m), and invokes processes operating on time scales associated with sea-level changes (~10^5 yr). The HPH posits seven specific predictions that can be directly tested to distinguish its role from existing coral-reef biogeographic hypotheses.

CORALLINE ALGAE DISEASE REDUCES SURVIVAL AND SETTLEMENT SUCCESS OF CORAL PLANULAE IN LABORATORY EXPERIMENTS (Abstract ID: 28836)

Coral reef diseases have increased in frequency and severity, spread worldwide and threaten to worsen with changing environmental conditions. Disease outbreaks have been involved in the deterioration of coral reefs and have been particularly striking among crustose coralline algae (CCA). Although CCA represent important cues for coral settlement, the impact of CCA diseases on the survival and settlement of coral planulae is unknown. Exposing coral larvae to healthy, diseased, and recently dead crusts from three important CCA species, we show a negative effect of disease in the inductive CCA species *Hydrolithon boergesenii* on larval survivorship of*Orbicella faveolata* and settlement of *O. faveolata* and *Diploria labyrinthiformis* on the CCA surface. No effect was found with the less inductive CCA species *Neogoniolithon mamillare* and *Paragoniolithon accretum*. Additionally, a majority of planulae that settled on top of diseased*H. boergesenii* crusts were on healthy rather than diseased/dying tissue. Our experiments suggest that CCA diseases have the potential to reduce the survivorship and settlement of coral planulae on coral reefs. Exacerbated under climate change conditions, the impacts of diseases on CCA could potentially hamper the resilience of coral reefs. This study aids understanding of disease cascading effects on reef communities.

VARYING LEVELS OF HERBIVORY AND NUTRIENT CONDITION MEDIATE CORAL SETTLEMENT SUCCESS (Abstract ID: 29266)

Herbivores play an important functional role in regulating the proliferation of algae in coral reef ecosystems. A short-term caging experiment was designed to investigate the role of herbivorous fishes on coral settlement at three sites in Bacuit Bay, Philippines. Coral settlement tiles were subjected to the following herbivore exclusion treatments: caged, partially caged and no cage, set at 5 m intervals along 50-m transects. After six months, tiles were retrieved and brought to the laboratory for microscopic analyses. To correlate spat abundance and densities with potential reef fish herbivores, underwater fish visual census was undertaken along the same transect. Water samples were collected at 1 m depth and 1 m above the reef at 15 m intervals along transects to measure nutrients. Preliminary results reveal that mean coral settlement rate was highest at Tres Marias (4.3 ± 0.7) followed by Depeldet (3.2 ± 0.6) and South Miniloc (0.8 ± 0.3). Experimental treatments that were open to herbivore grazing resulted in higher rates of coral settlement at Tres Marias and Depeldet, because herbivores mediated coral-algal competition. However, at South Miniloc, the herbivore exclusion treatments resulted in the highest numbers of coral settlers, which seem to suggest that incidental predation by herbivores reduced coral settlement in the partial and open treatments. There was no significant difference in phosphate and nitrate concentrations across sites, however, ammonium concentration was two-fold higher in Depeldet compared to South Miniloc which could favor algal growth.

CATCH TRENDS IN MARINE TROPHIC GROUPS: AN EVALUATION OF SELECTED MARINE KEY BIODIVERSITY AREAS IN THE PHILIPPINES (Abstract ID: 29310 | Poster ID: 579)

Overfishing is a rampant ubiquitous phenomenon attributed to human-induced impacts. Fisheries are often selective towards high trophic groups (TG), progressing towards low TG as the former becomesdepleted (i.e. fishing down the food web). Determining the catch trends per TG in conservation hotspots or Marine Key Biodiversity Areas (MKBAs) is vital towards successful management and sustainability of the fisheries. This study investigates the catch trends per TG through time in 3 selected Marine Key Biodiversity Areas in the Philippines. Moreover, a snapshot comparison in fishing gears used in the past and present as well as overall catch per trip per gear was also determined. Quantitative estimates of catch trends and gear history were obtained using 1 on 1 interviews with the local communities. Fish catch were grouped into 8 TG by clustering similar trophic levels (TL) obtained from FishBase (www.fishbase.org). Catch per trip for all the sites in the past and present were composed of both high and low TG with the latter comprising the bulk. Catch per trip for all TG initially increased during the 1950s and 1960s. However, catch per trip has been on a gradual decline since the 1970s until the present. Gear composition per site were similar between past and present, however, catch per trip was higher in the past. The results indicate that fishing down the food web is experienced in the 3 MKBAs. Management interventions such as MPA establishment, catch quotas, close season and alternative livelihoods should be pursued to ensure fisheries sustainability.

COMPLIANCE MANAGEMENT IN THE GREAT BARRIER REEF WORLD HERITAGE AREA (Abstract ID: 29198)

Protecting the world-renowned beauty and biodiversity of the Great Barrier Reef World Heritage Area and providing a level playing field for all users are key aims of the compliance management undertaken by the Australian and Queensland State governments' joint Field Management Program. This compliance program is risk-based and involves assessing the impact of illegal activities and the likelihood of them occurring. This is used to focus the compliance programs core functions of intelligence, surveillance and investigations on those activities of the highest impact and risk. To ensure effective compliance with relevant legislation the program is coordinated by a central compliance unit that works with and coordinates the efforts of the multiple Australian and Queensland government agencies that participate in the compliance management of the Great Barrier Reef World Heritage Area. The approach to compliance management consists of education, aerial surveillance, vessel patrolling, remote surveillance and audits of activities that require a formal permission. The aim is to achieve high levels of voluntary compliance and use enforcement where warranted. Increasingly the program is incorporating technological enhancements and new administrative measures to tackle recidivist behaviour where traditional approaches may be limited. It is the combination of a strategic risk-based program and incorporating new tools that enables the compliance program to be flexible and tackle emerging issues to assist in protecting the values of the Great Barrier Reef World Heritage Area.

EFFECTS OF INORGANIC NUTRIENTS ON CORAL PRODUCTION OF FLUORESCENT DISSOLVED ORGANIC MATTER (Abstract ID: 29769 | Poster ID: 93)

Photosynthetic benthic organisms in tropical reefs all exude a portion of their primary production as dissolved organic matter. Understanding the composition and fate of this organic matter is central to a holistic characterization of coral reef ecosystem metabolism. We experimentally examined the effect of a gradient of nitrate and phosphate enrichment on the quantity and composition of exudates produced by corals during a multi-week chemostat incubation. We characterized temporal shifts in the spectral characteristics of fluorescent dissolved organic matter (fDOM) using scanning fluorescence spectroscopy and measured concentrations of dissolved organic carbon, nitrogen and phosphorus. While bulk measures of dissolved organics remained stable across a gradient of nutrient enrichment, fDOM exudates from corals were compositionally distinct from ambient pools and nutrient addition altered coral-derived fDOM in specific fluorescent regions that may indicate differential production and consumption of organic compounds by corals under shifting inorganic nutrient regimes. Our results are relevant to understanding coral organic exudation and the impacts of anthropogenic pollution on reef organic matter cycling.

RESILIENCE OF THE CORAL REEFS FISH POPULATIONS ON THE PADANG SHELF REEF SYSTEM, WEST SUMATRA, INDONESIA, AFTER THE 1997 MASSIVE CORAL DIE OFF (Abstract ID: 28173 | Poster ID: 211)

Quantitative surveys of six coral reefs of the coast West Sumatra began in the latter decade of the 20th century. Then, as many as 50% of the reefs were classified as degraded, primarily because of blast fishing. Some of the reefs surveyed were in an area that subsequently became the Marine Tourism Park Pieh Island. In 1997, reefs in the Padang Shelf Reef System experienced a massive die off associated with the Indian Ocean Dipole where an upwelling caused by unusually strong winds increased nutrient levels in the ocean and a drop in water temperature by >4oC. Together with aeolian Fe from wildfires in Sumatra, oceanic nutrient levels were elevated to a point where a massive red tide event occurred and persisted for six months. Live coral cover (LLC) declined to 0% to a depth of at least 10-15m and many of the obligate coral reef fish populations were extirpated. In 2014, nearly 17 years after the die off, the reefs were resurveyed. All the surveyed reefs experienced increased live coral cover with some sites up to 70%

LCC and a recovery of many of the fish populations with 28 families observed. Only four fish families were recorded at all eight sites: Chaetodontidae, Labridae, Lutjanidae and Pomacentridae. The most abundant family, the Pomacentridae, comprised 30.1% of the fish recorded. Species common in 1996, but not recorded in 2014 were Heniochus moncerus and C. oxycephalus. The most abundant Chaetodon in 1996, C. trifascialis, was ranked 10th in abundance in 2014. Three species with a ranking of >10 in 2014 were not recorded in 1996: Chaetodon kleinii – Rank 3, Heniochus singularius – Rank 4, Forcipiger longirostrus – Rank 6.

MONITORING LA REUNION AND MAYOTTE CORAL REEFS (WESTERN INDIAN OCEAN) DURING EXPECTED EL NIÑO EVENT (Abstract ID: 28706 | Poster ID: 342)

Scientists and volunteers of Reef Check France have been surveying La Reunion's and Mayotte's coral reefs for 15 years. Due to the occurrence of an El Niño phenomenon, a bleaching event took place during the austral summer 2015-2016 period in the Western Indian Ocean. Studies during previous events (1997-1998; 2001-2002) showed that there exist variability in extent and severity from site to site. Fortunately, the studies revealed areas with a good resilience. Since 2005, Reef Check France has monitored 18 reef stations in Reunion Island and 7 reef stations in Mayotte Island. To monitor the 2015-2016 bleaching event, Reef Check France and partners has selected some "sentinel stations" to implement surveys, from March to May 2016, during and right after the hottest critical period. Coral monitoring has been completed including a temperature record. Results will be compared with existing datasets to assess, if any, differences in hard coral cover, including bleached coral cover, dominant coral forms, macroalgae cover, and temperature relationships. Reef Check, operated by volunteers, use two world-wide basic protocols to survey coral bleaching, which so can't provide species or genera richness comparison. Even so, it is rapidly and easily implemented during field studies and complementary to more costly research programs. Nevertheless, here, local team leaders (marine scientists) were able to implement a "Reef Check+ bleaching" protocol, more accurately to report the coral genus that has been concerned. Three protocols are thus adequate and efficient tools to rapidly assess a bleaching event and so help decision makers in management issues.

MODERN MICROGASTROPOD COMMUNITIES DRIVEN TO DEEPER WATER IN RESPONSE TO DECLINING WATER QUALITY IN THE MORETON BAY MARINE PARK, QUEENSLAND, AUSTRALIA (Abstract ID: 29540)

Subtropical marginal reefs in Moreton Bay Marine Park (MBMP), have experienced episodic reef growth during Holocene related to periods of sea level and natural climate change. To explore patterns of ecosystem change during these periods of reef growth, we examined the community structure of microgastropod assemblages throughout 7500 years of the Holocene, using data from six sediment cores and 30 grab samples collected at three sites, Wellington Point, Peel Island and Myora Reef in MBMP. Sample age was estimated by interpolating 35 radiocarbon dates. Non-parametric analysis of microgastropods indicated no overall change in community structure over almost the entire temporal sequence (~7500 to ~160 years BP). Despite this apparent ecological persistence through time, analysis of microgastropods from individual reef sites shows significant differences in community structure, both among reefs over time as well as between fossil and modern assemblages. When comparing Holocene microgastropod assemblages in 'shallow' and 'deep' paleodepths with modern 'shallow' and 'deep' depths, we observed modern 'deep' microgastropods communities from Myora Reef occurring in deeper waters than their fossil counterparts. These results suggest a decline in water quality in the modern habitat (~1840) causing habitat shift from shallower subtidal to deeper subtidal waters. Paleoecology and modern ecology studies can help identify natural variability versus anthropogenic impact to improve understanding of the future response of benthic marine communities to human and climate change impacts.

VARIATIONS IN CORAL MICROBIOMES AMONG INDONESIAN REEFS WITH DIFFERENTIAL LEVELS OF BLEACHING (Abstract ID: 29884)

In some Indonesian waters, corals have suffered mass bleaching due to increasing ocean temperatures, especially during El Nino events. However, corals in different regions of Indonesia appear to respond differently to this thermal stress. Corals have a flexible relationship with their symbionts, which vary in their ability to withstand or recover from environmental stress. In addition to Symbiodinium, corals also host other types of symbionts, including bacteria and archaea, that might have roles in affecting the coral's response to elevated temperature. In order to evaluate the relationship of associated bacteria and archaea to the coral's response to elevated temperature and subsequent bleaching, we conducted a temperature stress experiment on three species: Acropora millepora, Pocillopora verrucosa, and Porites lobata, from a reef in West Papua that experienced very mild bleaching during 2010 El Nino event followed by recovery, as well as Porites lobata from two locations in Bali that experienced different levels of bleaching. Following a common garden experiment in which coral fragments were exposed to temperatures of 30oC as control, 32oC, 34oC, and 36oC, we sequenced 16S to assay changes in microbial diversity. Deep-sequencing analyses revealed substantial variation in microbial reefs associated with different levels of bleaching stress, with strong host-specific microbiome profiles. Variation of microbial communities associated with differential host responses to temperature stress indicates the potential role of the microbiome in aiding the coral's response to environmental stress.

INFLEXIBILITY OF THE MICROBIOME DRIVES HOLOBIONT BREAKDOWN DURING EXCESS NITROGEN AVAILABILITY (Abstract ID: 28556)

The symbiosis between corals and photosynthetic algae of the genus Symbiodinium provides the foundation to the success of corals in tropical oligotrophic waters. The persistence of this symbiosis is facilitated by a constant nitrogen (N) limitation of the algal partners, adjusting symbiont cell division rates to those of the coral host. Recent studies proposed that shifts in the coral microbiome and associated microbial N-cycling pathways may help corals to maintain this N-limitation even under eutrophic conditions. To test this hypothesis, we aimed to release Symbiodinium populations from N limitation in hospite by exposing colonies of Pocillopora verrucosa to excess N-enrichment in a two-week aquaria experiment at the Central Red Sea. Strikingly, the overall structure of bacterial and Symbiodinium communities was stable throughout the experiment, thereby suggesting that the ability of the microbiome of P. verrucosa to adjust to changes in environmental conditions is limited. Consequently, Symbiodinium densities tripled over the course of the experiment. This likely resulted in retention of photosynthates, and starvation of the coral host, as further highlighted by tissue lesions in week two. We argue that the inflexibility of the microbiome may limit the potential of P. verrucosa to counteract excess N enrichment making it highly susceptible to eutrophication.

THE INFLUENCE OF UPWELLING ON THE TROPHIC STATUS OF CORALS FROM THE SHALLOW AND DEEP SLOPE IN THE CENTRAL MALDIVES (Abstract ID: 28980)

Upwelling stimulates primary productivity, which is known to support megafauna but the influence of upwelling on coral is understudied. Nutrient availability and light are important for coral symbiosis with increasing depth. Here we use natural abundance stable isotopes to examine the assimilation of carbon (d13C) and nitrogen (d15N) by the coral host and algal symbiont. We investigate how depth, reef exposure and atoll position affects the trophic status of three corals. The central Maldives is a unique location to study

the influence of upwelling on coral reefs due to its bathymetry and monsoonal climate. Temperature records reveal cold-water influxes extend to the deep (30 m) slope, but not shallow (10 m). Depth and genus significantly affected both isotope compositions. d13C values significantly differed among coral, with a spectrum of heterotrophy to autotrophy for Pocillopora and Pachyseris, respectively. Depth significantly affected coral trophic status, particularly Galaxea, which relied more on heterotrophy at 30 m. Differential d13C may also indicate diverse fractionation patterns in the symbiont, which we investigate next. d15N suggest that deep-water nitrate is a primary nitrogen source for these corals. Moreover, the interaction of i) coral, depth, and atoll position, ii) coral and reef exposure, and iii) reef exposure and atoll position had a significant effect on both isotope values of host and symbiont. Our results provide insight into factors influencing coral trophic status, which is important to consider for coral fitness especially during thermal stress.

FISH DIVERSITY OF THE ANDAMAN AND NICOBAR ISLANDS (Abstract ID: 27777 | Poster ID: 81)

ABSTRACT Andaman and Nicobar islands situated in the Bay of Bengal between 6o45´ - 13 o 45´ N and 92o10´ – 94o15´E, consist of 572 islands, islets, rocks and cover a distance of almost 800 km over North-South, with a coastline of 1962 km, and bring in for India an Exclusive Economic Zone (EEZ) of 600 thousand km². The shelf topography of these islands show frequent rises supporting coral reefs, which are characterised as fringing reefs on the eastern side and barrier reefs off west coast; the depressions are known as passages and straits. Besides coral reefs, the shore is composed of rocky and sandy areas and vast stretches of mangrove swamps. Owing to the varied marine habitats, ichthyofauna of these islands is observed to be one of the most diverse in the world. The fish diversity in these waters also receives special attention in terms of marine zoogeography because of the confluence of Andaman Sea fishes with Western Pacific and the Indian Ocean. A total of 1489 species of fishes belongs to 580 genera and 165 families were reported from Andaman and Nicobar Islands, of which 139 species belonging to 57 genera are gobies. Family Gobiidae, the largest group in perciformes, includes approximately 2000 species which belong to 212 genera and nine families. As of today from these islands, as many as 62 species of marine fishes are threatened (IUCN, 2014), 4 of them Critically Endangered, 2 Endangered and 40 Vulnerable. Of the 62 threatened species, most of them (46) are cartilaginous fishes or elasmobranchs—sharks, skates and rays—and the remaining 9 are teleost, i.e. bony, fishes. KEY WORDS: Fish diversity, Distribution, Conservation, Andaman and Nicobar Islands

SIGNIFICANT INCREASE OF ALCYONACEANS IN VILANGUCHALLI PATCH REEF, GULF OF MANNAR, INDIA (Abstract ID: 28782)

Alcyonaceans are an integral part in any healthy reef ecosystem, but have been given very little attention. Here we report a significant increase of alcyonaceans in Vilanguchalli patch reef of Gulf of Mannar, India where alcyonaceans have been poorly documented. Data collection was done between 2013 and 2015 on three permanently marked line intercept and belt transects. Significant fluctuation in both scleractinian and alcyonacean cover was observed along the transects. Scleractinians decreased from 29.81 to 21.75% whereas alcyonaceas increased from 19.63 to 30.47%. A total of 7 alcyonacean species belong to 4 genera were recorded and Sinularia (79.28%) followed by Cladiella (13.91%) were the dominant genera. Alcyonaceans outgrew the scleractinians making considerable coral mortality in Vilanguchalli patch reef. Acropora formosa and Montipora divaricata were the affected scleractinian species with an average mortality of 8.61 and 1.01% respectively. Corals in Gulf of Mannar show resilience after the halt of coral mining in 2005. Substrate availability and fast growing nature have resulted in increased alcyonaceans cover. Studies are in progress to understand their reproductive season and recruitment.

A NOVEL GLOBAL PLATFORM FOR MONITORING CORAL HEALTH: CORALSPEQ (Abstract ID: 28663)

Peter Ralph, Atsuko Kanazawa, David Kramer, Milan Szabo, Joey Crosswell, Mathieu Pernice, Madeline Combe, David Suggett CoralspeQ is a novel optical sensor array that has been deployed to assess reef condition exposed to the 2016 El Niño mass bleaching event. The sensor is a handheld, submersible, low cost device, which comprises a microspectrometer with a series of LEDs to measure fluorescence and reflectance of algal and host pigments. Corals are exposed to a combination of excitation light and the resulting emission spectra are captured for analysis, including the ratio of fluorescence emission required to yield photosynthetic health. Field validation trials have shown the utility of this instrument to identify shifts in both host and symbiont pigments (green and orange fluorescent pigments), as well as assessing changes in the photosynthetic properties of the symbiont. Data processing is performed by cloud-based analytical routines available to all users, such that once the data archive becomes significantly large it opens the possibility for "big data" style analysis. We have already distributed units to marine park rangers around the globe. This novel sensor provides the first globally operational platform for long-term community-based monitoring of reef health, as well as a synoptic but standardised and "on the ground" measure of coral condition desperately needed to improve predictive algorithms of bleaching and disease susceptibility. The CoralspeQ is part of the PhotosynQ family of instruments developed by the Kramer Lab at Michigan State University.

PLASTICITY OF ESCAPE RESPONSES: HOW EXPERIENCED CORAL REEF FISH ALTER THEIR ESCAPE PERFORMANCE (Abstract ID: 28283)

Teleost and amphibian prey undertake fast-start escape responses during a predatory attack in an attempt to avoid being captured. Although previously viewed as a reflex reaction controlled by the autonomic nervous system, the escape responses of individuals when repeatedly startled are highly variable in their characteristics, suggesting some behavioural mediation of the response. Previous studies have shown that fishes are able to learn from past experiences, but few studies have assessed how past experience with predators affect the fast-start response. Here we determined whether prior experience with the smell or sight of a predator (the Dottyback, Pseudochromis fuscus) affected the escape response of juveniles of the Spiny Chromis (Acanthochromis polyacanthus). Results show that individuals exposed to any of the predator cues prior to being startled exhibited a stronger escape response (i.e., reduced latency, increased escape distance, mean response speed, maximum response speed and maximum acceleration) when compared with controls. This study demonstrates the plasticity of escape responses and highlights the potential for naïve reef fish to take into account both visual and olfactory threat cues simultaneously to optimise the amplitude of their kinematic responses to perceived risk.

COASTAL MULTI-SPECIES SMALL-SCALE FISHERIES: INTERACTION AMONG CORAL REEF, SEAGRASS AND ARTIFICIAL REEFS (Abstract ID: 29729)

Management of small-scale fisheries usually involve monitoring and control of landings. However, the link between fisheries and habitat remains poorly studied and understood. In order to evaluate the effort led by fisheries on resources and on the sea bottom of coastal areas, the Amerindian Wayuu community of the Colombian Caribbean performed a participatory monitoring. Along the 90 km stretch of coastline, 51.117 daily trips were recorded from 2006 to 2014. The removed biomass of target species by gear as well as used habitat by fleet were studied through multivariate analyses using PRIMER and PERMANOVA routines. Our findings show that in early studied years, the target species (snappers, grunts and lobsters) werelargely caught on coral reefs and hard bottom. However, since 2009 an uncontrolled deploying of artificial reefs upon seagrass and coral reef was promoted by the speargun and encircling gillnet fleets, respectively. Consequently, a strong impact is occurring on both target species and habitat. The lane snapper and the white grunt, which are the highest valued and the most landed species, respectively, largely reduced their total catches. Besides, several species of parrotfish that contribute to coral reef health were greatly removed from ecosystem. Additionally, the artificial reefs were involved in the largest catches of small sizes of spiny lobster. Consequently, coral reef and seagrass were affected by fleet operations and deployment of artificial reefs. An adequate sustainability of fisheries should involve management of fishing substrate.

FUNCTIONAL REDUNDANCY IN EASTERN TROPICAL PACIFIC REEFS (Abstract ID: 29435 | Poster ID: 511)

Analysis of functional diversity in coral reefs have been mainly based in the study of fish communities without considering the ecological role of macroinvertebrates. In this study we calculated functional diversity of an assemblage of fish and macroinvertebrates species resident in the tropical eastern Pacific (TEP) on the basis of morphofunctional groups (MFG) formed from information of trophic level and body measures. Visual census (n= 854) were performed in 18 sites of the TEP distributed in four biogeographic provinces: Cortes, Mexican, Panamic and Oceanic islands. Functional richness, diversity and evenness were calculated for each province and compared statistically, and a regression analysis between taxonomic and functional diversity was made to evaluate ecological redundancy. A total of 257 species were recorded, resulting in 27 MFG. There were significant differences in all indices, with the highest total biomass and richness of MFG occurring in the Cortes and Oceanic islands provinces, and the highest functional diversity in the Mexican province. Finally, there was a positive relationship between species and functional diversity, which followed a power model and presented similar slope values for all provinces. This result represents the evidence of functional redundancy in the TEP reef assemblage at similar levels in all the region. However, the dominance and distribution of biomass in the MFG is different between provinces: Oceanic island's reefs presented higher biomass of predators attributed to less fishing pressure in these areas.

FIVE MPAS, ONE NETWORK: DESIGNING PUERTO RICO'S NORTHEAST MARINE CORRIDOR (Abstract ID: 29571 | Poster ID: 647)

Puerto Rico's Northeast Marine Corridor is a network of five marine protected areas encompassing an area of over 100 square miles. It has high coral cover, extensive seagrass beds, endangered coral species, marine mammals and important turtle nesting beaches. It also provides an economically and culturally important area forrecreation including tourism and commercial fishing. The main human threats are boater activity, fishing pressure and land-based sources of pollution. A management plan and a local management support group are being developed after three years of research, including coastal hydrodynamics, ecological characterization, and social and economic uses of the area. Several management measures being considered for implementation are no-anchoring zones, expansion of existing no-take areas, and restriction of human uses in ecologically sensitive areas. Given the large extent of the reserve network, a co-management structure based on "ridge-to-reef" approach is being considered for the several territorial and federal agencies with jurisdictional responsibilities over the area. The marine corridor along with the management approach being taken is the first of its kind in Puerto Rico. The design and approach could provide and example for use not only in the broader Caribbean region, but globally as well.

THE EFFECTS OF A CHANGING MARINE ENVIRONMENT ON THE BIOERODING SPONGE *CLIONA ORIENTALIS* (Abstract ID: 28862)

Excavating sponges, such as *Cliona* spp., break up the coral reef substratum thereby influencing net reef accretion. Sponge erosion is expected to accelerate as oceans become warmer and more acidic, with *Cliona* expected to play a major role in future reef growth. In addition, a greater abundance of *Cliona* is evident at sites with poor water quality, suggesting that sponge erosion will have a greater impact on inshore reefs. This project investigated the effects of temperature, dissolved nutrients, and ocean acidification on *Cliona orientalis* and its associated *Symbiodinium*. Sponges were exposed to temperatures increasing from 23-32C to quantify the ability of *C. orientalis* to acclimate to elevated sea surface temperature. As seen in many coral species, the sponge symbiosis bleached at high temperatures and the photosynthetic capacity of *Symbiodinium* was compromised. In a separate experiment, cores of *C. orientalis* and *Porites* sp. were simultaneously exposed to elevated $pCO_2$ and dissolved nutrients to evaluate whether the two taxa respond similarly to stressors associated with inshore coral reefs. Erosion, calcification, respiration, and photosynthetic rates indicate that the two taxa exhibit differential responses to the combined stressors. *C. orientalis* had less severe responses to elevated nutrients and elevated $pCO_2$ than *Porites*sp., suggesting that the bioeroding sponge is more likely to tolerate future conditions on inshore reefs.

*BRIAREUM ASBESTINUM*: A TALE OF ONE HOST WITH TWO MORPHOLOGIES AND *SYMBIODINIUM* (Abstract ID: 28299)

The octocoral *Briareum asbestinum* exhibits branching and encrusting morphologies at the same shallow water Caribbean habitat. We investigated the symbiosis between *Symbiodinium* and these morphs at ambient and elevated temperatures. The branching and encrusting *B. asbestinum*harbored *Symbiodinium* types B21 and B19, respectively. Encrusting fragments exhibited lower algal photochemical and light absorption efficiencies, in part due to colony orientation and the nearly three times higher irradiance levels experienced by their polyps. But, the *Symbiodinium*in both morphs were probably acclimated to similar irradiances, as evidenced by the light-limited portion of photosynthesis-irradiance curves and the intracellular chlorophyll concentrations. Encrusting *B. asbestinum*had more *Symbiodinium* and chlorophyll *a* per host surface area, leading to higher photosynthetic rates $cm^{-2}$. Unlike in many scleractinian corals, elevated temperature did not cause bleaching in either *B. asbestinum*morphology, although the coping mechanism differed. At the elevated temperature, *Symbiodinium* in the branching morph made small changes to photochemical efficiency and exhibited a lower photosynthesis to respiration ratio while the algae in the encrusting morph reduced maximum photochemical efficiency. The host morphologies also differed in polyp expansion behavior and protein content. *B. asbestinum* demonstrates different strategies dependent on host morphology and the host-*Symbiodinium* genotypic combination.

HINDCASTING RELATIONSHIPS BETWEEN THE ENVIRONMENT AND OUTBREAKS OF CORAL DISEASES IN THE CARIBBEAN (Abstract ID: 29643)

Disease outbreaks have contributed to the significant loss of coral populations in the Caribbean, and occur when the tripartite relationships among the coral hosts, the pathogens, and the environment are altered. Yet, it is unknown what role historical and contemporary environmental conditions play in driving coral-disease dynamics. Here we used boosted-regression tree models to hindcast the relationships between outbreaks of four Caribbean-coral diseases and a suite of abiotic and biotic predictors. We parsed the data into temporal windows — before and after major thermal-stress events — to examine whether the relationships changed through time. In general, the predictive performance of the models weakened from 1997 to 2012. This weakening could be indicative of: (1) the potential adjustment of coral populations to local conditions, (2) the loss of susceptible individuals from the populations, or (3) a decrease in disease-transmission due to decreased coral densities. A cyclical pattern was observed in the response of yellow-band disease on Orbicella spp. to maximum sea-surface temperature. Relationships were weak before the thermal-stress events, whereas after 1998 and 2005, there were strong negative relationships. A similar cyclical pattern was observed in the response of white-band disease on Acropora spp. to sea-surface temperature metrics. These results suggest that Caribbean-coral diseases experience long-term fluctuations, but whether these interactions with the environment are biased toward the hosts or the pathogens will determine future trends.

INTEGRATING CORAL RESILIENCE PRINCIPLE TO CLIMATE CHANGE INTO MARINE PROTECTED AREAS MANAGEMENT: A SUCCESSFUL EXAMPLE OF ADAPTIVE MANAGEMENT IN THE WIO (Abstract ID: 30165)

The first MPAs in Madagascar were established before the 1990s, when the notion of coral reef resilience was not yet popularized. In recent decades, the concept of resilience became more salient and essential for improving coral reef conservation. Effective management requires continuous feedback to reach the established goals and achieve tangible conservation benefits. Here we demonstrate how the integration of coral reef resilience concepts into MPA management led to successful conservation actions by the park authorities in Madagascar. In March 2014, monitoring for reef resilience was conducted in four of Madagascar's oldest MPAs (Nosy Antafana, Tanjona, Masaola and Tampolo). Two stations in each MPA were sampled to assess six parameters of reef resilience: benthos cover, coral recruitment, coral Shannon-Wiener diversity index, coral bleaching, invertebrate abundance and herbivorous fish biomass. The results indicated a similar biomass of herbivorous fish in all sites (380.84±80.78 kg/ha). Coral recruitment (colonies of juveniles/m2) was significantly higher in Tanjona (16.69 ±4.3) compared to the 3 other sites (range of 5.2 - 8.2). Macro-invertebrate abundance (individuals/500m2) was found to be significantly higher in Nosy Antafana (825.8±918.7) compared to the

other three, with a minimal value at Tampolo (18.5±7.8). Overall, coral reef resilience indicators were higher for Tanjona, whereas Tampolo had the lowest values. In order to maintain the resilience of these marine parks, the park authorities undertook to update the conservation measures.

MAIN SPECIES OF POCILLOPORIDAE (CNIDARIAN, SCLERACTINIAN) ON THE NOSY TAFARA REEFS, GREAT REEF OF TOLIARA, SOUTH-WESTERN REGION OF MADAGASCAR (Abstract ID: 28576 | Poster ID: 554)

A study on the Pocilloporidae family (Cnidarian, scleractinian) have been conducted on the reefs of Nosy Tafara (Southwest, Madagascar) from March, 2nd until Mai 4th, 2015. It aims to inventory as exhaustive as possible scleractinian to know the site's condition, stand characteristics, the coverage rate compared to other groups. Two stations were selected: Nosy Arakaivo on the platform of the outer slope between 10 to 15 m and Nosy Velomitahy, in a channel between 8 to 12 m deep. The method "Point Intercept Transect (PIT)" to 5 cm intervals placed along a line of 10 m, composed of 15 replicas were applied to each station. Fragments of species and / or colonies intercepted by the line were inventoried, sampled and photographed. Fragments of corals were collected and identified under a dissecting microscope. The results show the outer part of the reef Nosy Arakaivo has 75.20% of living coral. It is 70.20% for the reef Nosy Velomitahy. 16.17% of corals Nosy Arakaivo belong to the family of Pocilloporidae and 8.81% for the Nosy Velomitahy. 9/34 Pocilloporidae species identified throughout the Indo-Pacific region were surveyed, of which 7 species on the Nosy Arakaivo and 6 species on the Nosy Velomitahy. These species are divided into 3 genus: Pocillopora, Stylophora and Seriatopora.

CRYPTIC CORAL REEF DIVERSITY AND FUNCTION ACROSS THE PACIFIC ASSESSED USING AUTONOMOUS REEF MONITORING STRUCTURES (ARMS) AND METAGENOMIC METHODS (Abstract ID: 29942)

Coral reefs provide essential habitats for rare, cryptic and symbiotic species that make up the vast majority of reef diversity. However, the complexity of reef habitats and lack of standardized measures are major obstacles in assessing these communities. As a result studies of the processes that drive biodiversity, ecosystem shifts and eukaryote-microbial associations have mostly relied on conspicuous species, e.g. corals and fish. Standardized 3-dimensional samplers (ARMS) mimicking the structural complexity of reefs were deployed at 60 sites across 5 environmental gradients in the Pacific. After 3 years living organisms were quantitatively extracted from these ARMS, each yielding 3 bulk-collected samples — sessile organisms and motile species of 2 size classes (100-500µm and 500µm - 2mm). Three amplicon libraries were constructed per sample for high-throughput sequencing: COI and 18S rRNA genes for Metazoans and the 16S rRNA gene for their associated bacteria. Metagenomic libraries were constructed at selected sites to examine microbial metabolism and changes in functional gene families across gradients of environmental impact and species composition. This data allows us to characterize cryptic Metazoan diversity across Pacific reefs and establish patterns of bacterial diversity, which clusters foremost by island chain. We investigate the fundamental links between Metazoan communities and their associated microbiota and between species diversity and ecosystem function at a time when understanding the effects of environmental shifts on marine ecosystems is paramount.

THE FAST-GROWTH PROTOCOL: ACCELERATING CORAL GROWTH FOR REEF RESTORATION IN THE HAWAIIAN ARCHIPELAGO (Abstract ID: 28205)

Tropical coral reefs worldwide have a high economic and environmental value. Changes due to natural and anthropogenic factors have led to numerous reef restoration efforts. The success and scale of these projects have been highly variable. The majority of work has focused on in situ nurseries where larger colonies are fragmented and allowed to grow in a natural setting. This has shown promise where growth rates are high, but in Hawaii, calcification rates are amongst the slowest globally. We have developed a new strategy that utilizes an ex situ approach to accelerate the growth of common reef-building corals found around the Hawaiian Islands. We aim to mass produce fragments and modules in a nursery by manipulating variables including temperature, light, water chemistry, and heterotrophic food intake, while reducing sedimentation, disease, competition, and parasitism. Using this technique, coral fragments can rapidly grow at rates higher than those found in situ. These genetically-identical fragments will then be re-aggregated onto various forms to recreate single colonies via colony fusion and transplanted back onto impacted reefs. The result is larger corals that would have taken a decade or more to grow naturally, providing an effective method to restore Hawaiian reefs.

CORAL DISEASES: TEASING OUT THE ROLE OF BACTERIA AND FUNGI (Abstract ID: 28169 | Poster ID: 144)

Coral reefs are rapidly declining due to increasing anthropogenic stressors and environmental changes. A major consequence of human pollution is coral diseases, the underlying pathological causes of which are mostly unknown. Most studies related to the holobiont and disease focus on bacteria, however, very few studies have investigated the role of fungi in compromised coral health. There are few studies on coral diseases in South China Sea. Vietnam's coral reefs experience rapid deterioration, which is easily observable in Central and Southern Vietnam (e.g. Nha Trang & Phu Quoc Island). Vietnam provides a good comparison of stressed and non-stressed areas with heavily developed cities compared to the Marine Protected Areas. This study aims to identify coral fungi and bacteria in stressed and non-stressed habitats in *Porites* spp., comparing the portfolios between different habitats in southern Vietnam, and identifying pathogenic bacterial and fungal growth in sick and healthy corals. The fungal and bacterial profile of the holobiont will be determined through metabarcoding with MISeq sequencing. Water samples were collected to provide a background of the microbes in the coral's environment. The results will provide identification of bacteria and fungi in corals within different stress regimes, and additionally, on a smaller scale, identify fungi and bacteria associated with disease. This is a step forward towards the understanding of the complex holobiont and drivers that influences the heath of the corals.

IDENTIFYING COMMUNITY MANAGEMENT PRIORITIES USING PHOTOGRAPHY (Abstract ID: 29114)

Effective marine protected area (MPA) management requires the support of local communities. To achieve this, community concerns and knowledge must be understood and incorporated into management plans. Photovoices has developed a powerful tool to assess community priorities, which provides a way to hear villagers' unfiltered opinions and allows managers to learn from their expertise. We implemented this tool in a grassroots planning process in a highly touristed area on the east coast of Bali, Indonesia. Villagers in two communitities in the Regency of Karangasem were given cameras and encouraged to take photographs of any issues related to coral reef management. Trained facilitators gathered the stories behind the pictures, creating a visual and narrative compilation of local issues. Through this process, the community was able to identify three priority management areas: sedimentation, trash, and poor regulation of tourism activity. These key concerns are being incorporated into marine conservation strategies and management plans. The collection of information has been done by the community voluntarily, which has contributed to building a spirit of partnership within and between local communities that will foster collaborative co-management. We will present our approach, successes to date and lessons learned.

HERBIVORE DISTRIBUTIONS MAY NOT ACCURATELY REFLECT HERBIVORY PATTERNS IN RECOVERING REEFS (Abstract ID: 28619 | Poster ID: 291)

As the uncertainties of a changing climate increasingly threaten the fate of coral reefs, understanding the inherent ability of reefs to recover from disturbances becomes critical. Herbivore fish populations are key drivers of reef resilience, mediating competition between coral and algae and promoting coral recruitment. However, herbivores represent a diverse assemblage,encompassing a range of feeding preferences, movement patterns

and behaviours; how these distribute across the reefscape can have important implications for reef recovery. Herbivores range widely, and their distribution can be highly variable in space and time, associated with different uses of the reefscape – for foraging, refuge, social interactions and others. We examined patterns of herbivore abundance and function in the Lakshadweep Archipelago, a few years after a coral mass mortality, to determine if their distribution between depths linked directly to herbivory rates at reefs. There was a strong relationship between abundance and herbivory in shallow reefs but not in intermediate and deep reefs, suggesting that herbivore distributions do not link completely with the distribution of ecosystem function. Behavioural observations showed that herbivores spent most of their time foraging in the shallows; in deeper reefs they were more than twice in density but spent most of the time skulking, potentially due to the availability of refuge which was extremely patchy in shallow reefs. Understanding how herbivores use the reefscape may be critical to determining their functional roles in recovering reefs.

PHOTO PROTECTIVE EFFECT OF RU (II) AND CO (III) COMPOUNDS ON THE SYMBIOTIC ZOOXANTHELLAE ISOLATED FROM THE SEA ANEMONE STICHODACTYLA HADDONI (Abstract ID: 29185 | Poster ID: 496)

As a result of increasing threat to the survival of corals due to changing climate, efforts are being made to mitigate the effects of stress on corals and its symbionts. While increased seawater temperature results in coral bleaching, high irradiance effects the cellular mechanisms in zooxanthellae. In this study, zooxanthellae cells were treated with two photo-protective compounds to understand their effect on the ability of zooxanthelle to resist irradiance stress. we isolated and cultured zooxanthellae cells (clade C) form the sea anemone Stichodactyla haddoni. The cultures in log phase were treated with two photo-protective compounds namely, Ruthenium complex [Ru(bpy)2imbenzim](ClO4)2 and Cobalt complex [Co(bpy)2imbenzim](ClO4)3, where bpy is bipyridyl and imbenzim is imidazolylbenzimidazole ligand, at different concentrations (10, 50 and 100 µm l-1) and maintained under culture conditions for seven days. Results showed that the cultures treated with Ru (II) remained viable and the Co (III) treated cells showed cellular disruptions. Ru (II) complex treated cells exposed to high irradiance conditions (1000 µmol m-2s-1) showed that the cells treated with 10 µm l-1 and 50 µm l-1 concentrations were more viable and retained the photosynthetic pigments without any cellular damage compared to the control cells that were not treated with photo-protectant. The results of this study could have merit in terms of proactive conservation strategy of coelenterates such as corals that are frequently affected by the bleaching events.

OLD WOUNDS TAKE LONG TO HEAL: SHIP GROUNDINGS AND CORAL DISEASE ON A PRISTINE CORAL REEF (Abstract ID: 28534)

The coral reefs of Tubbataha, Sulu Sea, are among the most pristine reefs remaining in the world, supporting 72% live coral and the highest fish biomass in the Philippines. In 2013, two ship groundings occurred within four months: the US minesweeper USS Guardian (USSG) on the South Atoll and the Chinese fishing vessel F/V Min Ping Yu (MPY) on the North Atoll. An estimated reef area of 6,248 m2 was critically damaged. In April 2015, we tested the hypothesis that physical damage to corals increased subsequent susceptibility to disease. We identified three zones associated with each grounding site: a "ground zero" zone of coral obliteration, where ships had pulverized underlying reef; a border zone on either side of ground zero where ship shifting caused additional damage to existing coral; and adjacent intact zones outside the footprint of ship impacts that served as control sites. 'Ground zero' zones had low coral density and recent recruits with little to no disease. Border zones had lower coral density than intact zones, but significantly higher prevalence of the coral disease white syndrome and chronic partial mortality (USSG WS: border zone=13.6%, control site=3.2%; partial mortality: border zone=33.7%, control site=7.4%; MPY WS: border zone=16.2%, control site=7.6%; partial mortality: border zone=27.8%, control site=16%). Our results suggest that, despite pristine reef condition, and high recruitment and herbivory, impacts of these physically destructive events extended beyond the immediate obliteration of coral and loss of reef structure, to persistent effects on coral health.

AMERICAN SAMOA'S MARINE MANAGED AREAS: DESIGNING AND ASSESSING MARINE RESOURCE MANAGEMENT IN A MULTI-LEVEL GOVERNANCE SYSTEM (Abstract ID: 27770 | Poster ID: 639)

The U.S. territory of American Samoa has established a goal to protect 20% of its coral reef area under no-take MPAs as a primary marine conservation strategy. The territory implements MPAs through the use of diverse governance approaches, involving a range of institutions operating at different scales and including federal, territorial, and local village entities. This innovative approach to management takes advantage of the territory's traditional marine tenure system while drawing upon resources available from the U.S. federal government. Since 2000, total MPA coverage in American Samoa has expanded to encompass approximately 25% of coral reef area in the territory, with nearly 7% of reefs in no-take reserves. This represents a level of resource protection and inter-institutional collaboration that is unusual in the Pacific, and indeed worldwide. The innovative institutional arrangements developed to implement this system of MPAs present both unique challenges and opportunities in the management of the territory's marine resources. This paper represents the first comprehensive description and governance analysis of the MPA system in American Samoa, including the opportunities and challenges involved in combining Western management approaches with Samoan cultural institutions and tenure systems, compliance with and enforcement of village, territorial, and U.S. federal rules and regulations, interagency coordination and leadership, and consideration of scale in MPA planning, design, and implementation.

EVALUATING THE EFFECTIVENESS OF THE AMERICAN SAMOA COMMUNITY-BASED FISHERIES MANAGEMENT PROGRAM (Abstract ID: 29002)

The Community-Based Fisheries Management Program of the American Samoan Department of Marine and Wildlife Resources was adapted from a Samoan model in 2005 in order to establish co-managed MPAs with communities throughout the territory. Ten communities are currently involved and they have requested assistance in improving their fisheries. In response, we designed a multi-phase process to assess management of CFMP sites based on published templates, the program's specific needs, and the available site specific information. Phase I focuses on reorganizing and enhancing record keeping and was carried out for several sites so far. Phase II was designed to further analyze site management in order to readdress social and ecological design and set realistic goals for the future. Both phases of assessments are presented in a score card format so that progress can be tracked over time, sites can be ranked, and management efforts can be prioritized. While the program successfully encourages coral reef management in American Samoa, our preliminary assessments point to major concerns for underutilization of available social and ecological data to drive the direction of management. Literature on MPA design and effectiveness suggests that only one CFMP MPA is likely to be large enough to protect commercially targeted fish. Seasonal openings of the majority of MPAs also raises concerns for their effectiveness in meeting fisheries related goals. In this presentation we discuss social complexities specific to American Samoa, lessons learned, and future directions for the CFMP program.

SEASONAL PATTERNS OF GROWTH IN THE ROBUST BRANCHING CORAL ISOPORA PALIFERA FROM THE CENTRAL GREAT BARRIER REEF, AUSTRALIA (Abstract ID: 28526 | Poster ID: 234)

Studies on the growth response of corals to changing climate have largely focused on long-lived corals with relatively distinct density bands such as massive Porites. Little is known about the climatic response of other more abundant growth forms, such as branching Acropora corals, largely because of the absence of density bands. Using a combination of X-radiography, gamma-densitometry, Sr/Ca analysis and U-Th dating, we quantified growth patterns in the branching Isopora palifera from the central Great Barrier Reef, Australia. Visual analysis of positive X-radiographs revealed patterns of high-low density bands along the main growth axis, although gamma-densitometry was unable to detect a clear annual pattern in all samples. Skeletal Sr/Ca ratios consistently revealed clear patterns of seasonality matching local seawater temperatures, providing a growth chronology to calculate extension rates (averaging 2.07±0.09 cm yr-1). Using the Sr/Ca maxima, we were able to calculate annual density (1.57±0.03 g cm-3) and calcification rate (3.24±0.13 g cm-2 yr-1). Calibrations of monthly average SST and

monthly average coral Sr/Ca revealed a similar Sr/Ca-SST calibration for I. palifera to that of Porites from the same location, implying that the relationship between skeletal Sr/Ca and SST is highly robust among taxa, morphology, and growth rate. Our approach provides a robust method for assessing changes in growth for a common Indo-Pacific branching coral, and provides a valuable framework for quantifying past and future changes in skeletal growth in response to climate change.

### SHIFTING THE MANAGEMENT PARADIGM AT RAINE ISLAND, THE WORLD'S LARGEST GREEN TURTLE ROOKERY – TO INTERVENE OR NOT TO INTERVENE? (Abstract ID: 29176)

Raine Island, a tiny cay in the northern Great Barrier Reef Marine Park, Australia, supports the largest aggregation of nesting green turtles in the world. There have been population studies on the nesting green turtles since the mid-1970s and this work has made significant contributions to informing our understanding and management of this species. However, studies in the late 1990s indicated that nesting and hatching success of the green turtles at Raine Island was very low when compared with other rookeries and that levels of adult mortality due to heat exhaustion, toppling over phosphate cliffs and getting caught in beachrock crevices were elevated. In order to improve the resilience of the nesting green turtle population at Raine Island, it was clear management agencies needed to do something to reverse the observed trends. Getting to the point where everyone agreed on intervention, however, was not a simple process. It required on-going effort and investment to overcome beliefs that these were natural processes and we should let nature take its course. Changing the management paradigm was assisted by targeted research and monitoring and by completing a resilience plan to identify those management actions we could take that would have the greatest benefit to the nesting green turtles. Ultimately, it came down to the management agencies being prepared to accept the risk of intervening; recognising that it would be difficult to make the situation much worse; to make decisions in the absence of perfect data and committing to and implementing a recovery plan for Raine Island.

### EXAMINING PATTERNS OF BRACHYURAN CRAB DIVERSITY ACROSS US PACIFIC CORAL REEFS USING AUTONOMOUS REEF MONITORING STRUCTURES (Abstract ID: 29515 | Poster ID: 59)

Coral reefs are the most biologically diverse of all marine ecosystems. However, current understanding and assessment of reef systems is largely limited to the well-known and accessible biota, especially fishes and corals. The majority of reef diversity is comprised of small cryptic invertebrates living within its complex architecture. Autonomous Reef Monitoring Structures (ARMS) were developed as a systematic and standardized tool to assess and monitor the understudied cryptobiota. Here we examine the abundance, diversity and distribution of brachyuran crabs recovered from ARMS units deployed across the U.S. Pacific Islands and examine their assemblages across biogeographic, environmental, and anthropogenic gradients.

### TEMPORAL VARIATION AND COMPARISON OF THE STATUS OF CORAL REEFS IN SELECTED SITES IN THE PHILIPPINES (Abstract ID: 28548)

This study investigates the temporal changes of the condition of coral reefs in two sites from three regions in the Philippines. Results showed a significant increase in coral cover in the southern side of Baladingan, Masbate from poor (14+4%) in 2009 to fair (28+3%) in 2015. Comparatively, coral cover in Guang-guang, Davao Oriental showed no significant difference despite the seeming increase from 27+10% in 2010 to 38+6% in 2015 while the northern side of Pujada I. experienced a decline from 75+3% to 49+7%. In Negros Oriental, a long-term study of Apo Chapel revealed a significantly increasing trend over a 17-year period from 19+8% in 1999 to 60+19% in 2005 and since then has remained in good condition for 11 years. This site also has the highest species diversity. No change was observed in Bantayan marine sanctuary for over 21 years with only 18+15% in 1995 to 24+8% in 2015. Comparison of current data between sites in each region showed statistically similar coral cover in Masbate and Davao Oriental. In Negros Oriental, Apo Chapel has significantly higher cover than Bantayan marine sanctuary. All sites exhibited good condition indices despite the low coral cover in some. Reef development was good in Apo Chapel and the sites in Davao Oriental. Poor reef development in Masbate and Bantayan was due to high abitoic-related components. Mortality indices were highest and species diversities lowest in Davao sites and Bantayan. Factors, i.e. level of protection, exposure to natural and anthropogenic disturbances and species composition influencing these changes are discussed.

### FISHING WHAT'S LEFT: IMPACTS OF FISHING ON TROPHIC STRUCTURE OF REEF FISHES (Abstract ID: 29129)

Intensive fishing is believed to result in disequilibrium in ecosystem function with cascading impacts on the trophic structure of a marine system. Fishing tends to target large-sized top trophic level species due to size and market value. Fishery removal of large carnivores may result in increased abundance or biomass of lower trophic level species. In this study, we used information from underwater fish visual census and focus group discussions with fishers from over 20 localities across the Philippines to assess impacts of fishing on trophic structure of reef fishes and with emphasis on reef protection. Initial analyses show that density and biomass proportion of carnivorous species were relatively lower than herbivores in heavily fished sites, with few exceptions but represented by small-sized non-targeted carnivores, while the otherwise is observed in low fished areas or protected reefs. Density and biomass of fishery-targeted fish families were significantly low in heavily fished areas. Mean trophic level in these heavily identified sites have relatively low trophic index, suggesting that target fishes belong to small size class regardless of trophic level. High mean trophic level index in protected reefs suggest that no fishing preserve the interaction between trophic groups highlighting the need for management to conserve resources and sustain coral reef fisheries. The impacts of intensive fishery removal of biomass and the complex process of trophic interactions across larger spatial scale need to be investigated further.

### THE IMPACT OF HETEROTROPHIC FEEDING ON THE PHYSIOLOGY OF THE CORAL HOST AND THE ASSOCIATED SYMBIONT UNDER DIFFERENT NUTRIENT ENRICHMENT CONDITIONS (Abstract ID: 28655)

Localised enrichment of dissolved inorganic nutrients are a considerable threat to coral reefs and have been associated with reduced diversity, abundance, and physiological tolerance. Past studies have often focussed on the influence of dissolved inorganic nutrients on the harboured zooxanthellae or the host coral, while the combined effects of heterotrophic feeding and dissolved inorganic nutrient uptake on the physiology of

both the host and symbiont remains understudied. To investigate these effects, we exposed corals associated with Symbiodinium sp. (clade C) to different levels of dissolved inorganic nitrogen (DIN) and phosphate (P). Specifically, we studied the response to low nutrient (low DIN: low P), nutrient replete (high DIN: high P), and imbalanced (high DIN: low P) conditions. After long-term acclimation to the different nutrient environments and feeding regimes, the density of Symbiodinium cells, their neutral lipid accumulation, and fluorescent host pigment content were measured as proxies of nutrient stress. Our results indicate a change in physiological condition of both the host coral and symbiont which may be exacerbated by feeding in nutrient enriched conditions, and could significantly impact on the functioning of the coral-alga symbiosis, and the resilience of the holobiont during temperature stress events.

SYNTHESIZING GEOCHEMICAL AND GROWTH BANDING PROXIES FROM GREAT BARRIER REEF CORAL RECORDS (Abstract ID: 28894 | Poster ID: 8)

The growth response of reef-building corals to past environmental conditions is the subject of ongoing discussion, and could help researchers better anticipate the impacts of current climate change on reef health. In their skeletal banding, corals preserve a record of growth changes in response to past climate variability. Previous studies have used geochemical methods or growth banding analysis as coral paleoclimate proxies. However, few studies have combined these approaches, which would provide more comprehensive insight into the historical impact of environmental variability on coral growth. Our study combines geochemical analysis (δ18O, δ13C, and Sr/Ca) with luminescence and density measurements on five corals of the genus Porites from the Great Barrier Reef. These measurements track sea surface temperature, salinity, runoff, and coral growth at monthly resolution from ~1971 to 2008. The coral geochemistry tracks seasonal changes in climate, including temperature and precipitation, that vary with El Niño and La Niña events. These results allow us to evaluate the variable timing of density banding in relation to seasonal temperature extremes and highlight the role of location, such as proximity to rivers, in capturing a regionally representative climate signal. Our work establishes a methodology for multi-century coral paleoclimate records and demonstrates the value of combined datasets in coral climate reconstructions. These results lay the groundwork for much longer, paired reconstructions of climate and coral growth variability.

RESILIENCE OF A UNIQUE MESOPHOTIC REEF IN THE GULF OF MEXICO, USA: A 30-YEAR HISTORICAL PERSPECTIVE OF THE CORAL COMMUNITIES AT PULLEY RIDGE REEF (Abstract ID: 28799)

A five-year study was funded by NOAA ("Connectivity of the Pulley Ridge - South Florida Coral Reef Ecosystem") to understand coral ecosystem connectivity in the southeastern United States, from mesophotic reefs at Pulley Ridge (PR) in the Gulf of Mexico to the shallow water reefs in the Florida Keys. This paper uses these data from ROV photographic transects over a four year period (2012-2015) to characterize the scleractinian coral community at Pulley Ridge mesophotic reef and to compare the coral community with historical surveys completed in 1980s and 2003. Our ROV surveys in 2012-15 document a biologically diverse and dense community dominated by algae (49% cover), diverse sponges (92 taxa), and hard corals (over 60,000 counted; e.g., Agaricia spp., Helioseris cucullata, Montastraea cavernosa, Madracis spp.). We discovered a catastrophic 93% loss of coral on main PR since 2003 (mean coral cover from 12.83% to 0.82%). However, in 2015 additional surveys discovered dense populations of argaricid corals outside of the PR Habitat Area of Particular Concern (HAPC) where average coral density was 18.46 colonies m^-2 (3.5% mean coral cover; max. 6.8%). Overall PR a relatively small percentage had signs of White Syndromes disease (mean 1.0%, max 4.04%) or bleaching (mean 0.76%, max 3.03%). Potential causes for the coral loss include cold water upwelling, hurricanes, disease, and river runoff. Kernel Smoothing Model in ArcGIS was used to plot the new coral distribution and was used in part to support a proposal to extend the boundaries of the PR HAPC.

DO THE SHUFFLE: CHANGES IN SYMBIODINIUM CONSORTIA THROUGHOUT JUVENILE DEVELOPMENT (Abstract ID: 29636)

Previous studies of symbiotic associations between scleractinians corals and Symbiodium have demonstrated that hosts alter the consortium of symbionts in response to environmental conditions. However, less is known about symbiont shuffling during early development in corals, particularly for brooding species. This study examined whether Symbiodinium consortia varied (1) in Porites astreoides on shallow (10m) and upper mesophotic (30m) reefs, (2) changed during coral development and (3) influence growth of juveniles in different environments. Symbiodinium ITS2 sequences were amplified using universal primers and analyzed using phylotype-specific primers designed for phylotypes A, B, and C. Adults from both depths were found to host either only phylotype A, phylotypes A and B, or phylotypes A, B, and C and the frequency of the phylotype composition did not vary with depth. However, phylotype A was the dominant symbiont vertically transmitted to the planula. The presence of phylotypes B and C was detected in juveniles transplanted onto the shallow and upper mesophotic reef but not when juveniles were reared in outdoor aquaria. In addition, growth of juvenile P. astreoides harboring different combinations of Symbiodinium phylotypes did not vary. These results show that Symbiodinium consortia change during development and are influenced by environment.

PROTECTING THE GREAT BARRIER REEF IN THE 21ST CENTURY: MANAGING COMPLEXITY AND RISK IN UNCERTAINTY (Abstract ID: 28948)

The greatest long-term risk to the Great Barrier Reef is global climate change. Regionally, the greatest policy challenge is to measure and respond to the many factors, in addition to climate change, which lower the resilience of the Great Barrier Reef and prevent its recovery from long-term decline in areas of highest pressure. While existing approaches to environmental impact assessment and marine spatial planning are providing positive protection benefits, they are insufficient. Many of the current pressures began last century and recent monitoring shows a resilient system, that while stable in some areas, is in long-term decline in others. Future environmental management will need new measures. At ecosystem scale, delivering conservation outcomes is not a linear set of steps taken by a few agents. The Authority and its partners will build a comprehensive monitoring and reporting system to inform on progress against the Reef 2050 Plan, and are now developing policies to guide future actions. These will redefine how activities are managed in the Reef region and guide responses to cumulative impacts. Building on a strong foundation of existing protection measures, new tools will include measures for: achieving reef recovery rather than halting decline; increasing knowledge of cumulative effects and building responses that are multi-sector and multi-jurisdictional; and increasing public awareness and knowledge of the factors affecting the Reef and options for building the Reef's resilience.

EFFECTS OF MICROPLASTIC EXPOSURE ON GROWTH AND SURVIVAL RATES OF SCLERACTINIAN CORALS INFERRED WITH 3D SCANNING (Abstract ID: 28703)

Microplastics (i.e. fragments <5 mm) gained recent attention in public and science as they are considered to be a major threat to marine ecosystems. As these plastic particles are mainly of terrestrial origin, coastal ecosystems, such as coral reefs are particularly threatened. Previously it has been shown that scleractinian corals ingest microplastic particles. However, little is known about their subsequent effects on health and survival of the coral holobiont. Thus, the influence of microplastics (polyethylene, size 35 to 650 µm) on scleractinian corals (*Acropora*, *Pocillopora* and *Porites*) was examined in a series of fully controlled lab experiments. In particular, we studied the reactions of different coral species to particle contact. By the application of high-end 3D scanning and 3D model analyses coral growth was monitored. The species responded differently to microplastic exposure. Corals overgrew, took up and rejected plastic particles. Our preliminary results further indicate that microplastic exposure causes a decline in growth and

survival. We suggest that the exposure to microplastics leads to a reduction of energy reserves as handling of particles is energetically costly for the coral. Moreover, microscopical observations of the particles showed a strong bacterial load that can promote pathogen invasion. This is the first detailed monitoring of scleractinian corals from three different genera showing the adverse impacts of microplastic exposure, calling for further investigations of the effects of microplastics on the integrity of the coral holobiont.

DIVERSITY OF SYMBIODINIUM SPP. IN THE ZOANTHARIAN ZOANTHUS SANSIBARICUS ACROSS VERTICAL GRADIENTS IN THE WESTERN PACIFIC (Abstract ID: 29819)

The zoantharian Zoanthus sansibaricus is widely distributed in the western Pacific from the intertidal zone to depths of more than 50 m. Research has indicated there is diversity in its association with endosymbiotic Symbiodinium spp., but fine-scale investigations across both depth gradients and geographic ranges are needed clarify the distribution of this diversity, as well as provide a basis for discussing the wide range of habitats and depths over which the host species thrives. In this study, we collected specimens from subtropical Okinawa, Japan, and tropical Palau, from the intertidal zone to >30 m. Molecular phylogenetic data from the non-coding region of the plastid mini-circle and other markers were contrasted between the primary locations, as well as a smaller set of samples from the Maldives, Hong Kong, and the Red Sea. In Okinawa, Z. sansibaricus in <5 m hosted two different species of Symbiodinium, while deeper colonies (>10 m) hosted another, different species, with transplant experiments suggesting no switching or shuffling between 'deep' and 'shallow' Symbiodinium. In Palau, shaded intertidal colonies in unique notch habitats hosted the same Symbiodinium as colonies from 20 m. Combined with population genetic data showing a lack of structure between host Z. sansibaricus populations across depth, these results suggest that 1) Z. sansibaricus has limited but important flexibility in its Symbiodinium associations, allowing it to exist in a variety of environments, and 2) the partitioning of Symbiodinium is driven primarily by micro-environmental light levels.

NUTRIENT STIMULATION OF EXUDATES FROM DOMINANT CORAL REEF PRODUCERS AND IMPACTS ON MICROBIAL BIOFILMS (Abstract ID: 29789 | Poster ID: 139)

Shifts in reef benthic communities from calcifiers to fleshy algae have been documented on reefs worldwide. While it is well established that these phase-shifts have severe consequences for ecosystem services, the impacts of shifting benthic structure on reef microbial ecology is an area of active research because microbes recycle nutrients and are symbionts of corals. We hypothesized that differences in the dissolved organic matter (DOM) exudates of reef primary producers may determine the characteristics of conditioning films that provide the basis of marine biofilm formation necessary for larval settlement. We subjected four dominant benthic producers of tropical reefs – 1) corals, 2) macroalgae, 3) sediment-associated microphytobenthos and 4) rubble-encrusting algae (primarily CCA and turfs) - to two levels of nitrate and phosphate over several weeks. We characterized the community composition of biofilms using metagenomics and the composition of DOM using bulk elemental analysis and fluorescence spectroscopy. Dissolved organic carbon and nitrogen increased with nutrient enrichment on all substrate types; corals also exhibited increased organic concentrations in control (unenriched) treatments. DOM exudates from each substrate type were compositionally distinct from ambient water and enriched in fluorescent regions that indicate differential production of organic compounds by corals and algae in response to nutrients. Our results advance understanding of marine biofilm formation and organic production and consumption dynamics on reefs undergoing community shifts.

ARE CORAL REEFS VICTIMS OF THEIR OWN PAST SUCCESS? (Abstract ID: 29241)

Sea-level fluctuations have been a driving force in community assembly of coastal ecosystems. For example, only ~20 thousand years ago all places where coral reefs grow today were emerged. In this talk we discuss the geological history of one of the most prolific reefbuilders in modern reefs, the staghorn corals. We demonstrate that these corals have a long and diverse history in the fossil record. The earliest representatives are of Paleocene age, and most of the present-day taxonomic groups were already present in the Late Miocene, long before the intensification of sea-level fluctuations as the result of the waxing and waning of continental glaciations. By evaluating the occurrence of staghorn coral dominated deposits in the geological record we demonstrate that even though the staghorn corals were highly diverse, they only contributed a small portion to the coral assemblages during the Miocene and Pliocene. Only following the onset of large-scale sea-level change in the early Pleistocene staghorn coral dominated units become abundant in both the Indo-Pacific and West Atlantic reef provinces. High growth rates and propagation by fragmentation has favored staghorn corals since this time. In contrast, staghorn corals are among the most vulnerable corals to anthropogenic stressors, with dramatic global loss of abundance worldwide. With continued decline in staghorn coral abundance, the mounting challenges from both local anthropogenic stress and climate change will limit the ability for coral reefs to provide ecosystem services.

INTEGRATIVE ANALYSIS OF SUSTAINABLE TRAJECTORIES IN HEAVILY USED INDONESIAN CORAL REEF SYSTEMS (Abstract ID: 29555)

Many coral reefs in Indonesia are overexploited and heavily impacted by direct and indirect human use. The Spermonde Archipelago in the south-west of Sulawesi has about 70 small islands and is an example of such a heavily impacted system. The archipelago is situated off Makassar city, which, with its over 1.5 million inhabitants is an important regional centre for exporting sea products. Most of Spermonde's islands are densely populated. Fishing is the main source of income, and fishers employ over 20 gear types, targeting a wide range of species. Gear types differ in their impact on the reef ecosystem and in the social networks fishers work, either within the patron-client system which limits their decision-making options, or as more independent entrepreneurs. We will present an overview of a long-term, multi- and interdisciplinary approach to analyse the development of the Spermonde Archipelago reefs and focus on the drivers of system dynamics under multiple environmental and social conditions. Overall results show: a) the use of a wide variety of gears as well as the prevalence of destructive fishing methods, b) clear temporal changes in target species indicating changes in demand as well as in resource availability, and c) gradients in biotic community compositions and processes as well as physical conditions. Results are integrated into a spatially explicit simulation model and are holistically analysed in their feedback relations under multiple stressors to identify drivers of systems dynamics and pathways for sustainable marine resource management

SURVIVAL AND GROWTH MONITORING OF TRANSPLANTED CORALS IN SPECIAL RESERVE, REPUBLIC OF SEYCHELLES (Abstract ID: 29305 | Poster ID: 481)

A large-scale coral reef restoration project was conducted in the Cousin Island, to recover coral loss due to massive bleaching from the 1998 El Nino-Indian Ocean Dipole event and coral breakage from the 2004 Indian Ocean tsunami. Using the "coral gardening" concept, first, we harvested coral fragments from donor colonies or corals of opportunity in nearby

areas and reared them in mid-water rope nurseries for about 1 to 2 years. Secondly, in March 2013 corals of which: Pocillopora grandis and Acropora cytherea were transplanted to the degraded reef site. We used a unique cement mix developed by C. Reveret and inspired by F. Seguin and the Creocean team. Briefly, Portland marine cement was mixed with sikacrete ® UCS. Sikacrete is a stabiliser powder that increases cohesion and reduces washout when cement is applied underwater. In March 2014, after allowing corals enough time to attach, a monitoring was initiated 1 year after transplantation ensuring that we are measuring the net growth rate. 35 colonies of each species were tagged in 2 plots (#6 and #7) distant of 20m at 9m depth. In April 2015 another monitoring was realised after 14 months. The survivorship of P. grandis is 100% in both plots and 87.5 and 57.1% for A. cytherea respectively in plot #6 and #7. A sand movement could however increase the mortality in plot 7. The change in ecological volume index using the formula as per Shafir et al. (2006) is: 64± 12% and 57± 14% for P. grandis respectively in plot #6 and #7. This outcome shows favorable results of survival rate with a transplantation with cement.

BUTTERFLYFISH-MONOGENEAN INTERACTIONS: FROM BIOGEOGRAPHY TO ANALYSIS OF PARASITE SPECIFICITY THROUGH THE FISH MUCUS CHEMICAL FINGERPRINTS. (Abstract ID: 28653)

Interactions between hosts and parasites have been rarely studied in coral reefs and represent a major feature for the evolution, adaptation and ecology of interacting species. We studied the biogeography of gill monogenean parasites from 27 butterflyfish species in the South Pacific and our results show a conserved parasitism pattern over space, with clear differences between sympatric butterflyfish species. Among the 27 analyzed species, only Chaetodon lunulatus, was never parasitized. Although butterflyfish ecology has been extensively studied, parameters explaining parasite specificity between sympatric butterflyfish species are not well understood. Fish mucus is often described as the first line of defense against external attacks and several molecules with protective roles have been characterized. To study the possible chemical role in the specificity of monogeneans we studied the gill mucus of several butterflyfish species. First of all, we conducted an in vivo test and results showed that fish treated with C. lunulatus mucus displayed a decreased number of monogeneans. Then, we developed a non-targeted metabolomic approach to study the chemical fingerprint from gill mucus of several butterflyfish species with significant differences in their parasite loads. Results show differences in chemical composition between different Chaetodon species, but also between different ecological traits like diet and genetics. Finally, differences were found between parasitized and non-parasitized fish and further analysis are being performed to identify the responsible molecules.

FLAVOBACTERIA-TURF ALGAE SYNERGISM (Abstract ID: 28821 | Poster ID: 138)

Coral reef degradation is often associated with overgrowth of ungrazed fleshy turf and macroalgae. While some mechanisms of microbially-mediated coral mortality at the coral-algal interface have been illustrated (e.g. hypoxia), less is known about how macroalgae and turf algae on the enrichment of specific coral pathogens. Recent studies demonstrate that turf algae foster specific copiotrophic guilds, including Alteromonadales and Flavobacteriales. Some species of Flavobacteria are known pathogens, causing a variety of well-documented marine fish diseases and are suggested to play a role in polymicrobial coral diseases such as Black Band, White Band, and White Plague. This study investigates the role of Flavobacteria in promoting a competitive advantage of turf over corals. Flavobacteria isolates were cultivated from turf algae enrichment cultures setup in Kaneohe Bay, Hawaii. The genomes of 15 different species of Flavobacteria were sequenced using the Illumina Miseq sequencing platform. These genomes are being annotated for the functional capacity to metabolize turf algal derived organic exudates, as well as genes involved in pathogenicity.

LIMITED MORTALITY IN REEF CORALS OF THE GULF OF CALIFORNIA DURING THE 2015 EL NIÑO: EVIDENCE OF ADAPTATION? (Abstract ID: 30098 | Poster ID: 361)

A strong El Niño Southern Oscillation event affected the tropical eastern Pacific in 2015, causing sea temperature to rise above the coral bleaching threshold for several months. The objective of this study was to quantify the effect of the ENSO-induced warming in the Gulf of California, an area that was severely impacted by the 1987-88 and the 1997-98 events, when thermal anomalies were similar or even lower than those observed in 2015. We monitored four reef areas from July 2015 to January 2016, analyzing the status of over 200 tagged colonies and quantifying coral community structure in transects of 25 x 1 m. In addition, we surveyed over 20 locations in October 2015, to quantify bleaching at the peak of the event. Although historical records indicated that loss of coloration in years of excessive warming was noticed since August, actually the first damaged corals were seen until early October, and bleaching affected less than 30% of the colonies of Pocillopora and Porites. By January 2016 no discolored corals were observed, and comparisons of ecological indices between July and January showed no significant differences in any site. The delay in timing of the damage, the lower than expected incidence of bleached corals and the minimal mortality detected, indicates that reef corals in the southern Gulf of California are much more tolerant to excessively warm waters that they were in past decades. We suggest that repeated bleaching events, low population sizes, and high connectivity among populations, have served to facilitate adaptation of corals to thermal stress.

ALTERING THE CALCIFYING FLUID STOICHIOMETRY INFLUENCES THE RATE AND MORPHOLOGY OF CALCIUM CARBONATE PRODUCTION (Abstract ID: 29362)

The calcifying fluid presents one of the most elusive areas of the calcifying processes among marine biota due to the often-impenetrable ability to measure the process *in situ*. Therefore, chemo-static growth experiments were conducted at fixed pH (8.7) and super-saturation ($omega^{aragonite}$ = 10), while varying the $Mg^{2+}$, $Ca^{2+}$, and carbonate stoichiometry. The $CaCO_3$ growth rate and crystal morphology is strongly depended on the solution stoichiometry. At a constant super-saturation, the growth rate was highest when the solution concentration ratio, r = $[Ca^{2+}]$/[carbonate], equalled 0.0625 (1:16) without $Mg^{2+}$, growth rate decreased when r = 1 without $Mg^{2+}$, and no difference was observed between the different stoichiometry of $Ca^{2+}$, and carbonate when various concentrations of $Mg^{2+}$ were incorporated. Corresponding to the stoichiometry a number of different $CaCO_3$ morphology were observed including rhomobohedral, elongated prism rhomobohedral, orthorhombic, laminate amorphous $CaCO_3$ (ACC) and cemented ACC.

HOW CORAL REEF TRADE DATA CAN HELP INFORM POLICY DECISIONS (Abstract ID: 29519 | Poster ID: 696)

Recent ESA petitions have sparked intense debate within governments and the conservation community about industries that trade in these petitioned coral reef species. One of these industries is the marine aquarium trade, which has grown into a major global enterprise. Since the 1990s, the aquarium hobby has rapidly shifted focus from fish-only systems to miniature reef ecosystems. Millions of marine fishes and invertebrates, including corals, are removed from coral reefs and associated habitats each year for sale to home aquarists. Data collection for non-CITES-listed species is not mandatory and thus data are often nonexistent. Furthermore, CITES trade data are often confounded and/or confusing, and this lack of accurate and timely information about trade pathways, volume, and species diversity makes it nearly impossible to understand or to manage the trade sustainably, let alone inform the ESA petitions process. Here we examine the open-access Marine Aquarium Biodiversity and Trade Flow online database (https://www.aquariumtradedata.org/) for its ability to expand our knowledge and understanding of this trade and to effectively communicate this deepened understanding. We examine trade data for the Banggai cardinalfish (Pterapogon kauderni), the anemonefishes (Amphiprion ocellaris and A. percula), and the scleractinian corals, and we will show how trade data can be used to inform policy decisions and make management of traded coral reef species more effective for the conservation of species, and also for the well-being of communities that depend on this trade.

STICKING AND SINKING: A MECHANISTIC APPROACH TO HOW CORAL GAMETES OFTEN LOSE AGAINST SEDIMENT EXPOSURE. (Abstract ID: 28318 | Poster ID: 431)

Sediments can impact the reproduction and developmental stages of coral and therefore threaten the resilience and recovery of reefs following disturbances. In a series of controlled experiments, we examined how suspended sediments typical of dredging operations may affect the ascent of coral egg-sperm bundles and impede fertilisation on the water's surface. We reveal that sediment grains can ballast and delay the ascent of egg-sperm bundles during spawning, and quantitatively model scenarios to predict the conditions that cause ballasting, and the subsequent reduction in egg-sperm encounter rates. Next, we reveal that successfully surfaced gametes are also threatened by sediment exposure due to sperm-limitation. Using multiple lines of evidence, we propose that the formation of sediment-sperm flocs is the primary mechanism responsible for a decrease in fertilisation success during sediment exposure, and detail the conditions that trigger this mechanism. This research forms part of a broader question of how sediments impact the early life history stages of corals and quantification of each of these interactions are improving our understanding of the risks that sediments from dredging, river plumes and resuspension pose, allowing for improved management around these events.

PLASMA MEMBRANE PROTEOMIC RESPONSE OF THERMALLY STRESSED SYMBIODINIUM: IMPLICATIONS FOR SYMBIOSIS BREAKDOWN DURING BLEACHING (Abstract ID: 28775)

The endosymbiosis between corals and Symbiodinium range from resilient to fragile, with fragile partnerships often resulting in coral bleaching. Different factors affecting symbiosis have been extensively studied (increased temperatures, sedimentation, etc.) but the underlying mechanisms determining resilience deserve further attention. Because symbioses between the alga and host are initiated by cell-cell contact, extracellular membrane protein interactions between partners play important roles in recognition and downstream retention or rejection of the algal symbiont. Our overarching questions involve determining protein types present, what their possible roles in symbiotic mediation might be, and how these are affected by different stressors. We approach this by isolating cell surface membrane proteins using a membrane-impermeable biotin probe on intact cells and purifying the labeled proteins with avidin. These proteins are then tryptically digested and analyzed using nanospray LC-MS/MS. In Symbiodinium experimentally subjected to a 48-hour heat stress, preliminary results identify proteins containing important extracellular domains such as extracellular chaperones, recognition domains important for plant-Rhizobium symbioses, and domains known to participate in biogenesis of extracellular structural elements. Quantitative and qualitative changes in isolated proteins between heat-stressed and control samples will be presented, highlighting Symbiodinium changes that potentially affect communication between partners and providing further insight into symbiosis breakdown.

HIGH CRYPTIC DIVERSITY, TAXONOMIC UNCERTAINTY AND THE RISK OF SILENT EXTINCTIONS IN CORALS (Abstract ID: 29247)

To prevent regional extinctions and potential losses of diversity and evolutionary novelty, accurate inventories of coral diversity assets must be established. For most Indo-Pacific coral communities taxonomic uncertainty is a recurring challenge that precludes the documentation of species trend data. Without this information, species are unlikely to be included on national threatened species lists even when they have been flagged as vulnerable or endangered at the global level. As a result, the combined absence of robust species delimitations, lack of demographic data and a shortfall of targeted conservation action at appropriate scales increases the risk that silent extinctions will occur. If globally threatened species were endemic to a particular country however, this could provide the necessary trigger for inclusion in national threatened species management plans, which would aid their conservation. Nevertheless, to date the overwhelming majority of Indo-Pacific corals are thought to occupy expansive, demographically linked geographic ranges and few are recognized as endemic to a single country. Here I will present new phylogeographic and phylogenomic data to demonstrate that extremely high levels of genetic divergence, indicative of cryptic speciation, occurs within several well-recognized and widespread 'species' of reef building coral. I aim to raise awareness about the implications of misunderstanding species boundaries and geographic ranges and discuss the opportunities for more efficacious conservation of coral diversity.

STRUCTURAL COMPLEXITY MEDIATES FUNCTIONAL STRUCTURE OF REEF FISH ASSEMBLAGES AMONG CORAL HABITATS (Abstract ID: 27817)

Coral community composition is changing on coral reefs worldwide. Direct anthropogenic stressors and climate change have differential effects among coral species, causing increased dominance of more stress-resistant and/or weedy coral species. The extent to which altered composition of coral assemblages influences reef fish assemblages remains largely unknown. We investigate how the functional structure of fish assemblages varies among six distinct coral habitats. An ecological traits-based analysis was used to compare the functional richness, functional evenness, and functional divergence of fish assemblages among these coral habitats. Our results reveal differences in the functional richness and functional divergence, but not functional evenness, of fish assemblages, with structural complexity of coral habitats being the best predictor of these differences. Fish assemblages in branching *Porites* habitat were functionally richer than those in*Pocillopora* and soft coral habitats, largely due to the presence of nocturnally active, schooling cardinalfishes in the branching *Porites* habitat. Massive and branching *Porites* habitats displayed greater functional divergence in fish assemblages than *Pocillopora* habitats because of a greater abundance of small, schooling planktivores which were rare or absent on lower complexity *Pocillopora* habitats. Our results indicate that coral composition may act as a habitat filter, affecting the distribution and abundance of associated species traits, particularly those of small-bodied schooling fishes.

USING MOLECULAR TOOLS TO DIAGNOSE AND TREAT THE CAUSES OF CORAL REEF DECLINE (Abstract ID: 28226)

Coral reefs throughout the world are exposed to multiple stressors from local and global sources. Tools for the assessment and monitoring of coral reefs have been good for measuring losses or gains in percent cover and species diversity, with mortality as the key indicator of stress. In order to effectively address problems prior to outright mortality, better health indicators are needed that can measure changes at the cellular and organismal levels, rather than at the community or ecosystem levels and with response times of weeks to months rather than years to decades. Protein expression in corals can detect stress responses at the sublethal level, when intervention can yield the most promising results. Coupled with genetic information, effects at the population level can also be determined and evaluated. Analyses of coral tissue samples collected from three areas in Hawaii, Honokowai, Wahikuli (west Maui) and Maunalua Bay, Oahu, demonstrate the value of molecular tools in identifying stress exposure qualitatively and quantitatively and in providing a framework for assessing the effectiveness of mitigation activities. The data demonstrate that both adaptation and selection are occurring on these reefs, and raise the concern that while species of corals may persist, genetic diversity is being lost, and hence, so is population resilience to changes in stress profiles. Molecular tools provide data, which can help in the proper allocation of limited human, financial and institutional resources to enhance the ability of corals and coral reefs to persist and thrive.

CHANGES IN FISH WARINESS ACROSS A GRADIENT OF INTENSITY IN SCUBA DIVING ACTIVITY (Abstract ID: 28408)

Human recreational activities like hiking can elicit anti-predator responses in prey species that are similar in nature and magnitude to those elicited by hunting, sometimes triggering dramatic shifts in the surrounding ecosystem via behaviorally mediated cascades. Studies that test analogous hypotheses about the effects of recreational activities in marine systems are rare, but provide evidence that SCUBA diving activities elicit anti-predator behavior in some marine fish. While exposure to spear fishing activity has been correlated to increased wariness in coral reef fish even inside areas that are protected from fishing, the effects of different chronic levels of intensity in SCUBA diving on reef fish behavior remains virtually untested. We measured the wariness of herbivorous coral reef fish to recreational diver presence and approaches across a gradient of chronic intensity in diver activity surrounding Little Cayman Island, where spear fishing is prohibited and SCUBA diving tourism is popular. We compared the flight initiation distances (FID) and changes in pre-flight behavior of reef fish among sites with different historical levels of tourist visitation to determine the impact of different levels of intensity in recreational diving on the behavior of reef fish. We discuss the applicability of our results to the management of recreational activities on coral reefs, which currently assume negligible impacts from SCUBA diving activities, and potential interactions between fishing and recreational diving effects in coral reef systems worldwide.

DISTURBANCE DYNAMICS AND MARGINAL REEF CORAL POPULATIONS (Abstract ID: 28095)

Marginal coral reefs are controlled by frequent disturbances that lead to a progressive "weeding out" of otherwise dominant taxa capable of reef-building. Empirical observations and models have shown that the structure of marginal, non-accreting reefs is environmentally-controlled either via repetitive mass mortality or sub-optimal environmental conditions stunting coral growth. This controls the local species pool and does not allow competitive networks to reach climax. Using stage-based models it is shown how coral population dynamics relates to disturbance frequency and how variable disturbance and connectivity can control persistence or disappearance. At least some marginal reefs show signs of high local recruitment, which facilitates phase-shifts away from corals after multiple, severe disturbances that disrupt inflow of larvae. Naturally high and, with climate change, increasing disturbance-frequencies primarily skew size-distributions towards the smaller classes, which opens space for potential competitors (corals, algae or other organisms) and reduces fecundity exponentially. Shift in size classes, community composition and competition can rapidly lead to changes in stability patterns with the emergence of alternate states by acting alone or in concert. Steepness of thresholds and mechanisms determines whether alternate states are reached via bifurcations and are relatively stable, or gradually and are reversible. Examples of marginal or pauci-specific coral systems from all oceans are examined.

SKELETAL GROWTH TRENDS OF TWO MASSIVE REEF-BUILDING CORALS ON THE FLORIDA REEF TRACT: ARE INSHORE CORALS BETTER OFF IN A WARMING OCEAN? (Abstract ID: 28785)

Through the slow, continuous growth of their calcium carbonate skeletons, corals record invaluable information about past environmental conditions and how they may affect colony fitness. As the warming global climate continues to threaten coral reefs throughout the tropics, these living archives can be used to help identify reefs that are particularly susceptible or resilient to environmental change. Mounting evidence suggests that nearshore corals may be better suited than their forereef counterparts to cope with warming ocean temperatures due to their acclimatization to highly variable thermal environments. To test this hypothesis, we compared skeletal growth records of inshore and offshore reef corals across ~200 km of the Florida Reef Tract using cores extracted from two widespread massive reef-building coral species, *Siderastrea siderea* and *Pseudodiploria strigosa*. In 2015-2016, ten cores of each species were extracted from four sets of paired inshore-offshore reef sites spanning the entire reef tract, and growth parameters were assessed using 3-D computerized tomography. Skeletal extension rates were estimated from the thickness of high- and low-density annual growth couplets and were combined with density measurements to yield calcification rate. This century-scale investigation of inshore-offshore differences in coral growth will provide critical insights into our understanding of how corals on the Florida Reef Tract are likely to respond to future climate change scenarios.

ACROPORA CERVICORNIS SPAWNING PROJECT: A PARTNERSHIP ACROSS ORGANIZATIONS PROVIDING ADDITIONAL SOLUTIONS TO REEF RECOVERY (Abstract ID: 30015 | Poster ID: 681)

Once abundant throughout the Florida Keys and Caribbean, Acropora cervicornis populations have drastically declined due to a variety of natural and anthropogenic stressors. Colonies still in existence are sparsely distributed only intensifying the issue of reef decline by inhibiting the successful fertilization or recruitment of new coral individuals. To increase A. cervicornis individuals on degraded reefs, restoration programs can outplant colonies growing in offshore nurseries to designated restoration sites. The manpower required to restore reefs to their previous state, may become a limiting factor in the amount of coral that can be outplanted. The integration of spawning processes may generate more effective coral restoration practices to enhance population sizes and facilitate the natural recovery of A. cervicornis. In 2010, an A. cervicornis spawning project was commenced by The Florida Aquarium, Coral Restoration Foundation, and University of Florida. Since its inception, the project has grown to include over 5 additional partners that meet annually for the predicted Caribbean Acropora spawn. Methods for the tracking of egg development, creation of spawning structures, efficient settlement materials, and tanks for grow out have all been developed from this project, building a foundation to expand upon for future applications to restoration programs. This project is a superlative demonstration of collaboration across organizations for the advancement of solutions for reef recovery, in excess of what any individual partner could have achieved working alone.

PROCESSES DRIVING CORAL RESILIENCE TO BLEACHING (Abstract ID: 29511)

Coral bleaching is increasing in frequency and extent on reefs around the world. Although these events are predicted to become more frequent with climate change, our understanding of the factors that drive resistance to and recovery from bleaching is incomplete. The last documented coral bleaching in Hawai'i was 1996, but in the summers of both 2014 and 2015 corals throughout Hawai'i experienced extensive bleaching. On Oahu, field surveys in both year showed that reefs in Kaneohe Bay experienced 40-80% bleaching. Species diversity surveys showed that *Pocillopora* spp. were the most susceptible and *Leptastraea purpurea* was extremely resistant in both years of bleaching. In October 2014, 150 coral colonies were tagged and monitored monthly to assess recovery from bleaching. *Porites compressa*and *Pocillopora damicornis* appeared fully recovered three months after the peak summer temperatures, but *Montipora capitata* had significantly slower recovery. Only three colonies of *Montipora capitata* and three colonies of*Pocillopora damicornis* died from bleaching during the two years of monitoring. Some corals remained unbleached through both events, suggesting adaptation or acclimatization to thermal stress. There is a pressing need to understand coral genetic and physiological mechanisms of thermal tolerance in these corals to better manage for reef resilience in the face of climate change.

LA PLATA ISLAND ECUADOR: REFUGE OF CORAL RESELIENCE (Abstract ID: 30121 | Poster ID: 55)

La Plata Island located in the Machalilla National Park, Ecuador, is perhaps one of the southernmost refuge of corals in the eastern Pacific. Its rich marine diversity represents a source of income for the local fisheries and tourism. This study presents an overview of the distribution, species richness and percent coral cover at La Plata Island. Macroinvertebrates and reef fishes are also reported as fauna associated to the coral formations. Twenty species of corals, one hundred and fifty-one species of fishes and thirty three species of macro invertebrates are registered. The massive Pavona clavus is the dominant species in La Plata, with coral formations of 6 m high. The two genus Pavona and Psammocora have the broadest depth range distribution from 1.5m to 15 m. The Pocillopora species are more common in shallow waters, especially P.meandrina and P. ligulata, not exceeding 5 m depth. The human impact is latent in the reef; nylon lines tangled in coral colonies, plastic trash, tourists articles and discarded fishing gear. Nevertheless, coral colonies maintain good health. The results of this study suggests that the island of La Plata has resilient coral formations, capable to resist the two strong El Niño events 1982/83 and 1997/98.

MOLECULAR PHYLOGENY OF THE CARIBBEAN SCLERACTINIAN CORALS: SOLVING THE PUZZLE (Abstract ID: 29836 | Poster ID: 33)

Scleractinian corals are the main reef-building organisms in both tropical and cold-water coral reefs. Paradoxically, complete phylogenetic analyses are lacking for all coral species in provinces as small as the Caribbean. These analyses constitute a powerful tool for defining systematics, taxonomy and relationships among different species, but when it comes to scleractinian corals, clear relationships have not been clearly established. The

paucity of studies for phylogenetic analysis in this group can be explained by the lack of DNA sequences with enough phylogenetic signal for most scleractinian genera. This study aimed to establish the most complete molecular phylogeny for Caribbean scleractinian corals using ITS2 sequences for 41 coral species, which have been corrected using their predicted RNA secondary structure. Secondary structures allow generating enhanced tree topologies. On the other hand, we assessed the divergence times on the ITS2-based phylogeny, in order to determine the approximate age of the taxa studied. Results show that, as it has been suggested before, the Scleractinia class divides into two major clades (robust and complex), but it also showed some differences. One of the most important results is the sister relationship between Leptoseris cucullata and Agaricia grahamae, which has not been reported before for Caribbean scleractinian corals, as well as likely new species in this clade. The clustering in the Agariciidae family helps to understand how this group can be potentially indivisible, suggesting a recent adaptive radiation in the Caribbean.

FEAST AND FAMINE: A STRATEGY FOR SURVIVING OCEAN WARMING (Abstract ID: 29820)

Enhanced warming of the central tropical Pacific is projected over the next decades, and efforts are underway to identify reefs that might survive this change. Stress bands, anomalously high density bands seen in skeletal cores of massive reef-building corals can provide insights into the persistence and variability of bleaching events across space and time. We tested the connection between stress band formation in Porites corals, the intensity of thermal stress and the scale of bleaching using both laboratory manipulation experiments and in situ field observations. Results provided a framework to interpret stress bands in corals from the remote island of Jarvis, central equatorial Pacific, in the absence of direct historical observations of bleaching. At Jarvis, stress bands appear consistently during strong El Nino events back to the early 1900's, indicating that Jarvis may have bleached regularly over the last century, yet maintains exceptionally high biomass and percent live coral cover. We visited Jarvis in November 2015 and observed bleaching across multiple taxa including Porites. Still, the majority of colonies were alive, after 30+ weeks of anomalies 1-3.5 C. A comparison of coral tissue thickness between non-El Nino and El Nino years suggests that bleached corals may be living off substantial energetic reserves accumulated during periods when ocean productivity is high. Whether this "feast and famine" strategy for surviving El Nino-induced thermal stress can carry corals through the unprecedented 2015 warming will be revealed in a return expedition in May 2016.

MANAGING AND PROTECTING CORAL REEFS THROUGH PAPAHĀNAUMOKUĀKEA MARINE NATIONAL MONUMENT'S PERMIT PROGRAM (Abstract ID: 27901 | Poster ID: 680)

Access and activities within marine protected areas (MPAs) typically are regulated by a permit system to manage and mitigate human impacts to resources. While some MPAs are managed by a single agency responsible for reviewing and issuing permits, Papahānaumokuākea Marine National Monument ("PMNM" or "Monument") has a multi-agency co-management structure. PMNM's joint permit program serves as the primary regulatory tool for how co-managing partners effectively manage and protect coral reef resources. Through PMNM's permit system managers have worked together to authorize essential studies for understanding coral reef ecosystems as well as activities aimed to protect corals. Additionally, through the Monument's permit program, co-managing partners have collaboratively developed various protocols to protect coral reefs as both natural and cultural resources. These include vessel hull inspections for alien invasive species and best management practices. From a native Hawaiian perspective, corals (and all natural resources) are considered cultural resources. All permitted individuals are required to attend a cultural briefing to learn about the significance of these resources to native Hawaiians and are encouraged to approach research activities with this perspective. This case-study explores the origins and evolution of PMNM's permit program, and how it has and continues to contribute to coral reef management and protection.

EXPERIENTIAL COURSES FOR HIGH SCHOOL STUDENTS AT THE HAWAII INSTITUTE OF MARINE BIOLOGY (Abstract ID: 29958 | Poster ID: 718)

Sustainable interactions between coastal communities and the marine environment begin with public education and the sharing of knowledge in marine science. At the Hawai'i Institute of Marine Biology (HIMB), inquiry-based summer courses are offered to high school youth with the objective of creating educational pathways for future scientists, managers, and stewards by increasing science and environmental literacy skills. Each summer, HIMB enrolls Hawai'i high school students in the Research Experiences in Marine Science (REMS) Program, as well as hosts students from around the world in the Science in Action (SiA) Program, both held at Moku o Lo'e in Kāne'ohe Bay. Post-baccalaureate interns, graduate students, high school science teachers, and UH faculty and staff develop and prepare lessons that include field and laboratory exercises in diverse disciplines such as coral reef monitoring, computer data processing, squid neuroethology, sea urchin spawning and fertilization, marine bioacoustics, fish larval development, and ocean acidification. For REMS, the course also includes an extended unit dedicated towards the development, execution, and presentation of original group research projects. Students work in small teams to plan an experimental design, complete field data collection, analyze data with statistical tests, and offer a formal presentation of their projects through a scientific paper and symposium talk. Student assessments and program evaluations show improvements in science literacy skills, including in the use of the scientific method and investigation.

DEMOGRAPHIC DYNAMICS OF THE COMMON DEMOSPONGE IRCINIA FELIX (Abstract ID: 30092)

Sponges are one of the principal benthic components of Caribbean coral reefs. Despite the fact that they have multiple functional roles, little is known about their demography and ecology. Here, we present a demographic study of the common demosponge Ircinia felix performed at Tamarindo Bay, Culebra, Puerto Rico. Preliminary studies comparing size structure of two populations within Tamarindo Bay, Tamarindo North (TN) and Tamarindo South (TS), indicate that sponges at TN are significantly larger than sponges at TS. These data served as baseline for the present comparative study in which we aim to determine whether such spatial differences in population size structure can be explained by differences in rates of survival, growth, and/or recruitment. Significant differences where only observed when comparing growth rates. The fact that rates of survival and recruitment where similar between localities may be the causal factor for the lack of significant difference in population growth rates ($\lambda$) which varied TN and TS (0.79 and 0.74, respectively). Interestingly, elasticity analyses suggest that the major contributor to $\lambda$ at TN was survival of large sponges whereas at TS survival of small individuals contributed the most; suggesting that I. felix is able to adapt to site-specific environmental conditions by means of life history traits plasticity. We are currently conducting a study to determine if the noticeably high presence of gorgonians in TN in comparison to TS may be responsible for site-specific growth rates.

CORAL BLEACHING IN TELA, HONDURAS AND THE MESOAMERICAN REEF REGION (Abstract ID: 29058)

The third global coral bleaching episode began affecting reefs worldwide in summer 2015. This study presents the first recorded bleaching event in a high coral cover reef system (≤69%) in Tela Bay, Honduras observed in September-November, 2015. This area is also exposed to high sedimentation, turbidity and nutrient inputs from ten bodies of water. To estimate bleaching, corals were originally surveyed using the AGRRA protocol and further evaluated with the bar drop method, which assesses a minimum of 150 colonies per site in shallow (5-7m) and deep sites (9-14m). Sea temperature (T°C) was obtained *in situ* using loggers from mid July to December and compared to satellite data (1km). A bleaching severity scale (normal, pale, partially bleached, bleached-over 80%) and percent mortality (new, transitory and old) was assessed in 6 sites. Preliminary results show that the most abundant and affected corals are *Undaria tenuifolia*, *Porites astreoides*and *Siderastrea siderea*, with primarily paling, partial bleaching and low mortality. The overall conditions of surveyed colonies were pale (43%), partially bleached (35%), normal (18%), and fully bleached (5%). The average T showed sept-nov as the hottest months (30.8°C) with a drop of 1.39°C in December. This study is included in a regional evaluation of 65 sites throughout the Mesoamerican Reef, as part of the Coral Bleaching

Emergency Response monitoring plan led by the Healthy Reefs Initiative and 19 partner organizations. Overall, bleaching status in the MAR region will also be presented. http://www.agrra.org

ANTIOXIDANT DEFENSE AND ACID-BASE REGULATION: PHYSIOLOGICAL TOLERANCE AND ACCLIMATIZATION TO OCEAN ACIDIFICATION AND WARMING IN POCILLOPORA DAMICORNIS (Abstract ID: 29667)

Given the rapid pace of global ocean acidification and warming, methods by which corals can use their existing physiological repertoire to tolerate changing environmental conditions may provide insight into their potential for acclimatization and longer-term persistence. Ocean acidification and warming may interact to challenge larval physiology through increased production of reactive oxygen species and modification of homeostatic intracellular pH. To examine physiological plasticity under this multi-stressor scenario, larvae of *Pocillopora damicornis* were exposed to levels of temperature and $pCO_2$ after which antioxidant defense and acid-base maintenance were assessed. Planulae had higher total antioxidant potential at High-$pCO_2$ than under ambient conditions, and planulae released at the peak of spawning had a greater response than those released two days later. Activity of catalase, an antioxidant enzyme was also measured. Partial activity of $Na^+/K^+$-ATPase did not differ significantly between treatments. One of the first examples of oxidative stress response and acid-base regulation in coral larvae, short-term plasticity of antioxidant defense in coral larvae may be an important mechanism underlying acclimatization to ocean acidification and warming.

DIFFERENTIAL RECYCLING OF CORAL- AND ALGAL-DERIVED DISSOLVED ORGANIC MATTER BY CORAL REEF SPONGES (Abstract ID: 28784)

Sponges are proposed to play a key role in the recycling of energy and nutrients on coral reefs by rapidly taking up dissolved organic matter (DOM) and transferring it as particulate detritus to higher trophic levels via the recently discovered sponge loop pathway. Corals and macroalgae release large quantities of DOM that, due to differences in quality and composition, exert differing effects on reef ecosystem functioning. However, the influence of various reef DOM sources on recycling via the sponge loop has not been investigated. Here we used stable isotope pulse-chase experiments to compare the processing of coral- and algal-derived DOM by three Red Sea reef sponges: Chondrilla sacciformis, Hemimycale arabica, and Mycale fistulifera. All three species assimilated both DOM sources, but incorporation rates were higher for algal-derived DOM. The two DOM sources were also differentially utilized by the sponge holobiont (i.e. sponge host + associated microbes). While algal-derived DOM was incorporated more into bacteria-specific phospholipid fatty acids (PLFAs), coral-derived DOM was preferentially incorporated into PLFAs specific to the sponge host. A substantial fraction of the DOM assimilated by the sponges was subsequently released as detritus, but again, algal-derived DOM was released at a higher rate. The more rapid uptake and transformation rates of algal- compared with coral-derived DOM suggests that reef community phase-shifts from coral to algal dominance may stimulate DOM cycling through the sponge loop with potential consequences for reef biogeochemical cycles.

CORAL MUCUS FUELS THE SPONGE LOOP IN WARM- AND COLD-WATER CORAL REEF ECOSYSTEMS (Abstract ID: 28777)

Scleractinian corals engineer the framework of shallow warm-water (WW) and deep-sea cold-water (CW) coral reefs and control biogeochemical cycles by releasing coral mucus in the form of particulate and dissolved organic matter (DOM). Caribbean reef sponges transform DOM into particulate detritus, thereby controlling the transfer of energy and nutrients in DOM up the reef food web via the recently discovered sponge loop. Thus, the dissolved fraction of released coral mucus may represent an important DOM source fuelling the sponge loop. We investigated the transfer of coral mucus into tissue components of the WW sponges *Mycale fistulifera* and*Negombata magnifica*, and the CW sponge *Hymedesmia coriacea* using lab-based stable isotope tracer experiments. Results revealed a direct trophic link between scleractinian corals and reef sponges, and showed that 21–40% of assimilated coral mucus C and 32–39% of N was transformed and released as particulate detritus. Follow-up experiments demonstrated the consumption of WW sponge detritus by sponge-associated detritivores, the ophiuroids *Ophiothrix savignyi* and *Ophiocoma scolopendrina*, and the polychaete *Polydorella smurovi*, thereby showing the transfer of sponge detritus to higher trophic levels. These findings of a coral mucus-fuelled sponge loop in ecosystems as different as WW and CW reefs provide evidence for its ubiquitous functional role in contributing to the efficient biogeochemical cycling of limiting nutrients and energy in these highly productive marine environments.

EFFECTS OF SEDIMENTATION ON SCLERACTINIAN CORAL SPECIES COMPOSITION ALONG A RIVER GRADIENT IN MACAJALAR BAY, NORTHERN MINDANAO, PHILIPPINES (Abstract ID: 29336 | Poster ID: 224)

Coral survival is dependent on several factors and sedimentation is one factor that can affect all others. Macajalar Bay in Misamis Oriental is a major fishing ground for 14 municipalities and 2 cities. There are three major rivers that empty into the bay bringing different kinds of river run-off that can affect biological, geological, physical and chemical processes. Eight sites were chosen (2 controls and 6 impacted) where the sediment accumulation rate varied for each site throughout the year (this included wet and dry seasons). Also notable was the difference in sediment characteristics, where control sites had mostly sand but the sites nearest to the river mouth were mostly silt. However some sites displayed a trend in different sediment accumulations through the wet and dry seasons. Coral assemblages also varied in colony sizes, life-forms, but most species were found in all sites.

THE POWER OF MICROBES: MICROBIAL BIOENERGETICS OF CORAL-ALGAL INTERACTIONS (Abstract ID: 28922 | Poster ID: 104)

The once steady-states of coral reef ecosystems are transitioning to algal-dominated states on a global scale. Thermodynamic theory predicts that as these systems undergo transition they will optimize their components to maximize power output. Thus, we hypothesize that perturbed areas far from steady-state such as the coral-algal interface will harbor microbial communities optimized to maximize their thermodynamic power output. To test this hypothesis, we used a novel combination of methods to provide a bioenergetic analysis of interaction zones. This study reveals that the energetic demands of microbial communities at the coral-algal interaction interface are higher than in the communities associated with either of the single organisms. This is evident through a) higher microbial power output, and b) lower oxygen concentration at interaction zones compared to areas distal from the interface. Increase in microbial power output is significantly correlated with the ratio of heterotrophic to autotrophic microbes but not microbial cell abundance. Finally, microbial metagenomes generated from coral-algal interactions suggest that a shift from efficient glycolytic pathways towards faster, less efficient alternative catabolic pathways is responsible for the change in power output.

Together these data suggest that coral-algal interfaces harbor higher proportions of heterotrophic microbes that are optimized to maximize the power output, as opposed to yield. This yield to power shift provides a thermodynamic mechanism underlying the global microbialization of coral reefs.

REVISITING DEPTH-DIVERSITY GRADIENTS IN REEF-BUILDING CORALS (Abstract ID: 28264)

Species are not distributed evenly across geographical space, and understanding the mechanisms generating species' distributions is a fundamental goal of ecology. Among the most prominent of these patterns are changes in species richness over gradients (e.g. latitude, altitude, or depth). Depth is a strong environmental gradient on coral reefs, with depth zonation recognized as a ubiquitous feature of coral ecosystems. However, depth ranges of reef-building corals at any particular site are influenced by a combination of factors (e.g. turbidity, latitude). Species richness is considered to either decline with depth, or peak at intermediate depths (15-35 m), mirroring altitudinal richness gradients in terrestrial ecosystems. Understanding depth-diversity patterns is a crucial component of revealing how species occupy ecological and geographical space. However, robust analyses of depth-diversity relationships have been compromised by a chronic under-sampling of deeper habitats (> 20 m), and considerable changes in coral nomenclature in recent decades. As such, the generality of this pattern is questionable. Here, we use modern statistical techniques and a novel comprehensive, species-level data set conducted over a large depth gradient (0-45 m) to revisit fundamental questions about depth-diversity relationships in reef-building corals. We show how species richness changes over depth, and identify ecological traits associated with coral depth ranges. Our results provide new insights into ecological factors influencing depth ranges and depth-diversity relationships in corals.

THE ANTIOXIDANT RESPONSES DIFFER BETWEEN *SYMBIODINIUM* STRAINS FROM DIFFERENT GEOGRAPHIC ORIGINS (Abstract ID: 28310)

Studies conducted these last two decades have revealed that high sea surface temperatures accompanied by high levels of solar irradiance are responsible for an over production of reactive oxygen species (ROS) leading to the disruption of the symbiosis between cnidarians and their symbiotic *Symbiodinium*. But, all coral species do not show the same sensitivity to stress. In this context we examined how the antioxidant network of different *Symbiodinium* species responds to oxidative stress. We bypassed the various thermal and light tolerances existing among the genus *Symbiodinium* by using a chemical approach (menadione). ROS produced during this oxidative burst reduced photosynthesis by 30 to 50% and significantly decreased the activity of superoxide dismutase. In addition, the low level of lipid peroxidation concomitantly with the decrease in the concentration of diatoxanthin and other carotenoids during the stress confirms their function of antioxidants and their role in the stabilization of membrane lipids. The analysis of the cellular damages also indicates that proteins were damaged and most likely eliminated by the ubiquitin-proteasome pathway. Finally, caspase-like activity decreased suggesting that cell death mechanisms are not initiated at the early stage of the stress. Although, the mechanisms at play seem to be the same, we found that the temperate *Symbiodinium* strain (A1) was less impacted by the treatment with menadione than the tropical strain (F1) suggesting that the variations observed are related to their geographic origin.

HOST IMMUNE SYSTEM POLYMORPHISM AND GENE EXPRESSION IN HOST-SYMBIONT RELATIONSHIPS (Abstract ID: 28816 | Poster ID: 140)

Across domains of life, immune system components display the highest rates of adaptive evolution and maintained polymorphisms. Within holobionts, population, local or individual-level host polymorphism and expression of immune system components allow flexible interactions and adaptive immune response to symbionts while potentially driving holobiont microbiota. To investigate immune system variation and immunity related gene-expression and to assess the role that these components might play in holobiont composition, metatranscriptomes and metagenomes were constructed from Porites spp holobionts from sites across the Southern Line Islands in the Central Pacific. Replicate samples were collected within individual coral colonies across multiple colonies at site and island scales. Individual coral genotypes across multiple loci were derived from transcriptomes and used to identify loci under selection. Polymorphism and heterozygozity for immune system components at the island and patch level are examined to test for heterozygote advantage and disruptive or balancing selection. Metagenomes are used to survey virulence factors or immunity-related genes within holobiont microbial communities. Target loci include putative epithelial attached mucin-like glycoproteins important in a range of host-symbiont specific interactions. Correlations between symbiont genes and host immune system gene expression at the intracolony to intercolony levels reveal potential host-symbiont gene by gene interaction and suggests mechanisms for host-bacteria interactions that drive holobiont composition.

SIZE-SELECTIVE FISHING OF CORAL REEF FISH COMMUNITIES (Abstract ID: 29604)

Coral reef ecosystems are a vital food resource for millions of people. Although the negative effect of fishing on total fish biomass is well documented, our understanding of the impacts of human disturbance on fish community structure is limited to studies at local scales. We analysed an extensive dataset of reef fish community body sizes collected at 38 Pacific islands and atolls to examine how reef fish community size structure and total community biomass varied across two metrics of anthropogenic disturbance and eight environmental covariates. Our results revealed that the slopes of fish community size spectra steepened with increasing human population density and proximity to provincial capital, consistent with a reduction in the biomass of large-bodied fish. Total reef fish biomass was substantially depleted even at low levels of human presence, though oceanic productivity and sea surface temperature were also important drivers. Our results indicate that across multi-gear, multi-species fisheries, exploitation of reef fish communities is size-selective. Furthermore, we observed substantial natural variation in reef fish biomass that suggests biomass-based management strategies may be difficult to implement across large spatial scales. In contrast, impacts on community size structure were consistent across diverse reef communities. Traditional fisheries concepts such as size spectrum indicators may help to develop successful approaches to the sustainable management of coral reef systems.

RECRUITMENT PATTERNS OF CORAL REEF FISHES IN THE CENTRAL RED SEA: DIFFERENCES ACCORDING TO SEASON AND REEF TYPE (Abstract ID: 28664)

The Red Sea is the world's northernmost tropical sea. The latitudinal extent of its deep, narrow basin and its limited connection to the world's oceanic system make for a unique environment with extreme temperature and salinity regimes. Yet the Red Sea harbors one of the largest and most biodiverse coral reef systems in our planet. In order to better understand the impact of these unique environmental conditions on the biology of coral reef fishes, a year-long light trap study was conducted on three reefs in the central Red Sea—one inshore, one midshore and one offshore—in order to quantify seasonal timing, biomass and biodiversity of incoming reef fish recruits. Collection took place during every new moon for five consecutive nights to capture seasonal variation in recruitment at different reef types and habitats. The mitochondrial cytochrome oxidase I (COI) region was used to identify the trapped recruits. To date, very little is known about annual reproductive peaks in this region. This dataset will provide a useful guide for identification of recruits of coral reef fishes, and will increase the number of genetic barcodes available for coral reef fishes.

PRODUCTIVITY AND SEA SURFACE TEMPERATURE CORRELATE WITH PELAGIC LARVAL DURATIONS OF DAMSELFISHES IN THE RED SEA (Abstract ID: 28911)

To date, nearly 60% of all marine studies in the Red Sea have taken place in the northernmost region, the Gulf of Aqaba. However, temperature, salinity, and nutrients gradually change from north to south, locally shaping coral reef fish communities and

populations of the Red Sea. We examined the influence of this environmental gradient in the Red Sea on the pelagic larval durations (PLDs) of three damselfishes, *Dascyllus aruanus*, *D. marginatus*, and *D. trimaculatus*. PLDs were significantly correlated with latitude, sea surface temperature (SST), and primary production (CHLA; chlorophyll *a*concentrations). Among all three species, we find a consistent decrease in PLDs with increasing SST and primary production (CHLA) towards the southern Red Sea. This trend is likely related to higher food availability and increased metabolic rates in that region. We suggest that food availability is a potentially stronger driver of variation in PLD than temperature, especially in highly oligotrophic regions. Additionally, variations in PLDs were particularly high among specimens of *D. marginatus*, suggesting a stronger response to local environmental differences for endemic species. We also report the first average PLD for this species over a broad geographic range (19.82 ± 2.92 days).

TRADE-OFFS AND VARIATION IN INSHORE CORAL HEALTH AND BIOCHEMICAL CONDITION ALONG WATER QUALITY GRADIENTS ON THE GREAT BARRIER REEF, AUSTRALIA (Abstract ID: 29353)

Biochemical attributes of corals can be used as indicators to monitor spatio-temporal changes in their health and condition. This study explores how a coral species (*Acropora tenuis*) can respond to differing water quality conditions on inshore reefs of the central Great Barrier Reef. Coral health was monitored along a strong and a weak water quality gradient, each with three reefs at increasing distances from a major river mouth. Significant differences in coral health traits were detected along the strong water quality gradient: corals grew fastest, had the least dense skeletons, highest symbiont densities, and highest tissue energetic content closest to the river mouth. Changes in coral health traits were far weaker along the second, much weaker, water quality gradient. This variation in health traits along water quality gradients illustrates that corals acclimatize and/or adapt to their surrounding environments. Our data indicate that high nutrient and particulate loads are not detrimental for the survival of this robust coral species, but the observed biochemical changes are not without potential consequence, including higher susceptibility to photo-stressors and physical damage. Our study provides insights into spatio-temporal changes of coral health indicators, the influence of water quality driving coral condition, and adds valuable data for integrated monitoring of coral reefs.

USE OF INTEGRATED LANDSCAPE INDICATORS TO EVALUATE THE CONDITION OF "RIDGE TO REEF" SYSTEMS AND PRIORITIZE WATERSHEDS FOR RESTORATION IN THE HAWAIIAN ISLANDS. (Abstract ID: 27798)

The ahupua'a concept, a linkage between the condition of watersheds and adjacent nearshore coral reef communities is an assumed paradigm in the concept of integrated coastal management. We present quantitative evidence for this "ridge to reef" relationship on a large-scale comparing the Hawai'i Watershed Health Index (HI-WHI) and Reef Health Index (HI-RHI). A significant positive relationship is shown between the health of watersheds and adjacent reef environments when all sites and depths are considered. This relationship is strongest for shallow sites facing in a southerly direction, but diminishes for north facing coasts exposed to persistent high surf that increase local wave driven currents and flush watershed-derived materials away from nearshore waters. Candidate metrics for assessing reef condition were tested against independent measures of human disturbance to define biocriteria. Prioritization of watersheds and coastal waters are being developed for protection and restoration in Hawai'i. This study facilitates an understanding of the interaction between ecological processes, spatial patterns, and human activity which can be applied to improve regional-scale conservation and resource management.

A TOOLKIT FOR MANAGING RIVER INPUTS TO CORAL REEFS (Abstract ID: 28357 | Poster ID: 443)

Recent biogeochemical studies have shown that the health of nearshore coral reefs can be directly impacted by land use practices in the adjacent terrestrial environment. Rivers often facilitate the transportation of excess nutrients, sediments, and other pollutants, resulting in both acute and chronic impacts to corals. Although the conduits of delivery are understood, establishing riverine pollutant thresholds that directly impact coral reef health, has remained elusive. This is largely due to the lack of real-time sampling connecting both environments and archival sampling that links historical land use with original stress to reefs. Here we present a progress report of our multi-tiered approach towards developing a toolkit consisting of step-wise decision tree models and a management guide. To date, we have begun to (1) quantify watershed pollutant concentrations to discern the threshold for acute stress on coral health; (2) identify point source impacts and mitigation success of existing riparian buffers; (3) link historical land use practices with marine samples; (4) develop a bibliographic library/ historical archive for Guánica related to watershed and oceanographic studies; and (5) train the next generation of resource scientists and managers.

ENHANCING THE ACQUISITION OF DATA FOR REEF SCIENCE AND MANAGEMENT: CONTRIBUTIONS FROM THE XL CATLIN SEAVIEW SURVEY (Abstract ID: 30013)

Restraining the global decline of coral reefs requires effective actions from managers, policy-makers and society as a whole. Reef scientists are challenged with the complex task of promptly providing relevant inputs for science-based decision-making. The XL Catlin Seaview Survey (CSS) is applying pioneering technologies for producing broad-scale baseline data of coral reefs worldwide. The CSS framework involves three key components: photographic surveys, image analysis and provision of information. So far, the CSS has surveyed ~650 shallow transects (10-12 m), each 1-2 km in length, using customized underwater vehicles for collecting high-definition images. Over 1000 km of reef habitats have been recorded and more than 650,000 geo-referenced images are being automatically annotated to optimise data acquisition. Validation of this approach indicates most benthic categories can be estimated with errors below 4 %. Images are in an open-access repository (www.globalreefrecord.org) and core data is progressively accessible. The CSS is making available an unprecedented source of reliable data to support spatial and structural analyses, mapping, monitoring and ecological modelling. Further, the CSS research has assessed recent disturbance events (e.g. cyclones and bleaching) and is addressing a range of ecological questions with direct implications for coral reef management. Enabling healthy reef systems is crucial for sustainability, therefore the translation of such scientific outputs into meaningful information for managers and policy-makers warrants serious attention.

EFFECT OF ABNORMAL HIGH TEMPERATURES DURING 2014-2015 ON CORAL COMMUNITIES FROM CENTRAL MEXICAN PACIFIC (Abstract ID: 27883)

Central Mexican Pacific coral communities have suffered severe bleaching events related to high temperatures with evidence of slow but constant recovery. Abnormal increases in temperature during 2014 and El Niño 2015 have severely affected to the coral com-

munities of this region, as well. Differential coral bleaching were registered at two insular National Parks, Islas Marietas and Isla Isabel, with a distance of 100 km between them. Differences on bleaching response were observed between Islands. During 2014 sea surface temperature (SST) reached a maximum of 31.9°C; mortalities were registered only at Isabel Island (~99% coral cover). During El Niño 2015 SST reached 32.7°C, impacting Islas Marietas with a bleaching of 90% of coral cover. with a high recovery rate by the end of the year and a mortality of only 2%. No recovery has been registered on coral coverage at Isla Isabel. The species that were most affected during both events were massive ones, such as Pavona and Porites , surprisingly Pocillopora has demonstrated the highest degree of tolerance. The different responses of the species distributed at the same region, demonstrate the differential acclimatization capacity acquired by the corals, product of several episodes of stress conditions, which has been different due to the location and the particular physical processes at each site. Coral community at Marietas can be considered as highly resistant to ENSO events; this acclimatization will be one of the primary characteristics that, will allow the species to maintain the coral community from this region

MICROSCOPICAL DIFFERENTIATION BETWEEN REGENERATION AND DEGENERATION OF TISSUES IN POCILLOPORA (Abstract ID: 28450)

Tissue loss is a lesion affecting many coral species and is an important cause of coral reef decline in the Western Atlantic. Causes of tissue loss may be infectious or non-infectious (trauma). As such, not all tissue loss processes are invariably fatal to coral colonies, and some colonies can recover. Tissue regeneration is a fundamental process to the normal functioning of corals. Knowing the tissue characteristics of wound repair could help differentiate degenerative from regenerative processes in coral disease. To those ends, we compared histology of wound repair in dominant Pocillopora in Mexico with experimentally induced tissue loss (trauma) to naturally occurring tissue loss of unknown origin in wild corals. Tissues in experimentally traumatized corals healed within 30 days but remained unpigmented through day 40. Histologically, completely healed tissues were evident at the edge of the lesion from Day 8 and onwards when the lesion site was microscopically indistinguishable from adjacent normal tissues. Pocillopora manifested a unique mode of regeneration involving projections of cell-covered mesoglea from the upper body wall that anastomosed to form gastrovascular canals. Samples of wild corals with tissue loss of undefined origin presented characteristics associated with degeneration such as necrosis and hypertrophy of epithelia with no microscopic evidence of tissue regeneration as seen in experimental corals thereby proving the utility of histology to aid interpretation of lesion pathogenesis in corals.

GEOMORPHIC ZONATION AND CORAL TYPE MAPS FOR THE GREAT BARRIER REEF (GBR): A MAPPING AND MODELLING APPROACH APPLIED IN THE CAPRICORN BUNKER GROUP (Abstract ID: 29071)

The Great Barrier Reef (GBR) is a globally unique and essential national resource for Australia; however no single map exists showing its geomorphic zonation and benthic community composition. These maps have not been produced for the GBR due to its large extent and the cost of mapping its extensive and mostly submerged reefs. This presentation introduces a new approach to map geomorphic and coral community zonation for the "shallow offshore reefs", and validate the results, for a large reef system of the Capricorn Bunker Group in the GBR. These "shallow offshore reefs" are visible in optical remote sensing imagery to depths of 20 m. This approach to mapping and modelling of geomorphic and coral community zones combines: field data; Landsat 8 derived reflectance and bathymetry data (15 m x 15 m pixel size); cyclone track data; slope, wave exposure; object based image analysis and models for predicting the spatial distribution of GBR coral communities. The mapping and validation methods are being developed for future application to the whole of the GBR. This larger scale approach will include existing field data collection programs (e.g. Long Time Monitoring Program), citizen science groups (e.g. Reef Check, Eye on The Reef), and, crowd sourcing of other field data and interpretations (e.g. GeoWiki). The methods and digital maps represent a significant advance in our capability to map, monitor and manage coral reefs in Australia, supporting management and science in the conservation of the Great Barrier Reef, and, are applicable to other reefs globally.

PHASE SHIFT DYNAMICS FOLLOWING CATASTROPHIC DISTURBANCE ON AN INDO-PACIFIC CORAL REEF SYSTEM (PALAU, WESTERN PACIFIC) (Abstract ID: 28857)

In December 2012, a Category 5 super typhoon passed 50 km south of Palau (Micronesia), causing a catastrophic loss of coral cover. Within weeks following the disturbance, we observed a rapid and extensive phase shift of the macroalgae Liagora sp. Comparisons between pre and post-disturbance surveys indicated that relative changes in herbivore biomass and coral cover did not significantly predict the extent of macroalgal cover. In contrast, wave exposure explained >90% of model variance, indicating that environmental conditions play an important role in post-disturbance dynamics. Settlement tiles deployed during the major spawning period (March – April 2013) following the typhoon revealed that reefs that had undergone phase shifts experienced an near complete failure of coral settlement, despite no limitation in larval supply. While the Liagora bloom had started to decline by April 2013, we observed succession to a second macroalgae (Lobophora variegata). Experimental manipulations and cage exclusion revealed that Liagora canopies acted as ecological facilitators, providing a 'nursery' exclusion zone from the impact of herbivorous fish, allowing for the establishment of understory Lobophora. While the ephemeral Liagora bloom had disappeared entirely 9 months post-typhoon, the facilitated phase shift to Lobophora has persisted for over 18 months, dominating ~40 % of the reef substrate. Collectively, these results provide novel insight into post-disturbance dynamics on Indo-Pacific reefs, and indicate that typhoons may also trigger rather than reverse phase shifts.

GEOCHEMICAL AND CRYSTALLOGRAPHIC STUDY OF *TRIDACNA MAXIMA* (MOLLUSCA: BIVALVIA) SPECIMENS AFFECTED BY THE 2010-2011 WESTERN AUSTRALIAN MARINE HEAT WAVE (Abstract ID: 29183 | Poster ID: 288)

*Tridacna maxima* shells are complex $CaCO_3$ micro-laminated structures that record physiological and environmental changes during growth as sequential chemical and crystallographic variations in the shells. The organic fraction, crucial to shell integrity, is also to be considered when studying records of environmental changes. In this study we highlight the relationships between shell proteins, chemical composition, crystal morphology and crystal orientation through geochemical and crystallographic characterisation of three specimens of *Tridacna maxima*from Ningaloo Reef, Western Australia. This multi-modal imaging and analytical approach uses X-ray diffractometry, Raman spectroscopy, electron probe micro-analysis, laser-ablation ICP-MS and stable isotopic analysis to constrain the relationships between shell microstructure and composition and physiological and environmental changes. These specimens show evidence of scaring and survived the marine heat wave off the Western Australian coast over the 2010-2011 summer. Water temperatures rose to unprecedented levels (over 3DegC above monthly average) causing lethal to sub-lethal effects with short- and long-term impacts on the ecosystem. Symbiotic organisms such as corals and *Tridacna* are known to bleach heavily under thermal stress, with coral bleaching recorded from Rottnest Island (near Perth) to Cygnet Bay (northern Kimberley region) in 2011. The nano- to micro scale effects of bleaching on *Tridacna* are also being investigated using a geochemical and crystallographic approach.

THE INFLUENCE OF STRUCTURAL COMPLEXITY ON CORAL REEF PRODUCTIVITY (Abstract ID: 28040)

In response to multiple stressors, live coral cover and habitat structural complexity are declining on coral reefs across the globe. These changes can influence trophic interactions and energy flows within the reef community and have consequences for ecosys-

tem services such as fish production. We have developed a size-based food web model for coral reefs that explicitly incorporates the influence of habitat structural complexity, benthic primary production, and detrital recycling on ecosystem dynamics. We use the model to explore how fish production might change in the future in response to ongoing and anticipated alterations to reef habitats. We show that, with all else being equal, a loss of reef structural complexity may result in a 3-fold reduction in fish production. However, as live coral cover declines, potential increases in the abundance and availability of algal turfs and mobile invertebrates may have positive effects on food web productivity. We explore this potential trade-off between refuge availability and resource availability through time, in the context of a changing reef state. We show how things may get better before they get worse, but also that the complexity of reef habitats must be maintained in the long-term to ensure that coral reefs can continue to provide enough food for our ever increasing human population.

DYNAMIC SPONGE DEFENSE SYSTEMS AGAINST PREDATOR AND PATHOGEN ATTACKS (Abstract ID: 27954)

Sponges and other sessile invertebrates are under constant attack by predators and pathogens. At the same time, they are lacking behavioural escape or defense mechanisms and rely therefore on morphological or chemical defenses. Sponges are a known source of a vast array of chemical metabolites, even though the metabolic costs of metabolite production and their ecological functions remain mostly unknown. We investigated whether tropical sponge species optimize their chemical weaponry by inducing defenses in response to artificial predation, or whether wounding triggers a activated defense. Additionally, we tested if these mechanisms are simultaneously used to boost antimicrobial activity to avoid bacterial infection. Laboratory experiments with eight pacific sponge species showed that 87% of the tested species were chemically defended. Two species, Stylissa massa and Melophlus sarasinorum, induced defenses in response to simulated predation, which was the first demonstration of induced antipredatory defenses in marine sponges. One species, M. sarasinorum, also showed activated defense in response to wounding. Interestingly, 50% of the tested sponge species demonstrated induced antimicrobial defense. Simulated predation increased the antimicrobial defenses in Aplysinella sp., Cacospongia sp., M. sarasinorum, and S. massa. Our results suggest that some sponges further increase their defensive effectiveness by induced and activated defenses and that these modifications boost antimicrobial activity. Predation seems to select for induced antimicrobial defenses to protect sponges from pathogens that could otherwise invade the sponge tissue via feeding scars.

UNRAVELLING COMPLIANCE DYNAMICS WITHIN LOCALLY MANAGED MARINE AREAS IN SOLOMON ISLANDS AND FIJI (Abstract ID: 28358)

Diverse socio-economic developments, population pressure as well as deficient legal mandates are increasingly challenging customary marine governance approaches in Melanesia. Compliance with and enforcement of local management strategies (such as temporal and spatial closures) constitute a growing hurdle for communities - impacting decisively on the success or failure of these local marine tenure practices. Understanding drivers of (non-) compliance can inform future management decisions as well as the design and implementation of local marine tenure rules. We have examined compliance dynamics within locally managed marine areas in Solomon Islands and Fiji. We find that perceptions of limited legitimacy of rules and of rule-makers, linked to questions about the recognition and justification of power, represent a major constraint for compliance. Using the concept of the 'enforcement chain' (detection, arrest/citation, prosecution and conviction) we analyze how social, institutional, financial and legal barriers (e.g. interpretation of customary fishing rights, weakening power of traditional leadership, poor enforcement structures and monitoring tools as well as limited legal mandates) impede the different links of the chain. In this paper we also discuss the interplay between customary and state law regarding compliance by assessing how existing (customary and state) rules and norms (dis-)connect or add up. Finally, we make suggestions that can strengthen enforcement and compliance with marine tenure rules, thus helping to maximize positive social-ecological outcomes.

PREDICTING REEF FUTURES VIA BIOPHYSICAL CHARACTERS OF HOLOBIONTS AND INTERACTION ZONES (Abstract ID: 27861)

Benthic holobionts (i.e., macrobe host with its associated viruses and microbes) engage in a constant war for space. Corals and CCAs holobionts win on healthy, calcifying reefs. Overfishing and nutrification, as well as thermal and other stressors, increasingly favor turf and fleshy macroalgae holobionts leading to microbialization and degradation of the reef structure. In earlier work, we showed that the relative abundance of interaction zones between corals and algae increases with reef degradation. Building on this observation, we hypothesized that coral-to-algal dominance switches are geometrically driven by an exponential decrease in coral surface area relative to a linear change in the perimeter that must be defended from encroachment. This hypothesis is being tested using a combination of metagenomics, metatranscriptomics, metabolomics, advanced imaging and modeling of the main reef holobionts and their interaction zones. Analysis of hundreds of samples from the Pacific and Caribbean are pinpointing viral, microbial, chemical and physical characters that predict and explain the health trajectory of benthic holobionts. Together these data provide both statistical and mechanical explanations for why coral reefs live and die.

THE BENEFITS OF LONG TERM COMMUNITY-BASED CATCH MONITORING PROGRAM FOR ADAPTIVE AND SUSTAINABLE FISHERIES DEVELOPMENT (Abstract ID: 28228)

The Philippines is a multi-gear, multi-fishery country that is largely dependent on fish protein for both diet and livelihood. Over the last three decades fishery laws and management strategies have been enacted and put in place at both national and local levels to attempt to develop sustainable fisheries. These laws and strategies include fisheries closure through establishment of Marine Protected Areas, closed and open seasons for commercially valuable species, fisher and boat registration, gear regulations and coastal enforcement policies. While a combination of tools are used to assess and validate the effectiveness of these policies and strategies, effectiveness is usually only assessed once and is not monitored over time. We hypothesize that local policies and management strategies would benefit from a long-term catch monitoring program to determine the effectiveness of both legislation and management strategies. Only via long-term monitoring can the variability in fisheries and behavioral change in fishers be assessed. Here, we reintroduce a long-term fish catch monitoring system in four pilot sites in the Philippines to obtain information on Catch Per Unit Effort [CPUE] and length-weight relationships of commercially valuable species. We discuss the processes in setting up a community-based catch monitoring system, the lessons learned in applying data, issues with limited assessment tools and the benefits of the results in evaluating current management strategies. We conclude that a comprehensive community-based catch monitoring program can bring fishers, fisheries experts, policy makers and managers together for participatory and adaptive management options.

REPRODUCTIVE PHENOLOGY ALTERS FUNCTIONAL CONNECTIVITY FOR CORALS IN THE EASTERN TROPICAL PACIFIC (Abstract ID: 29563)

In the Eastern Tropical Pacific (ETP), the reproductive phenology of corals remains largely undetermined. Here, we used long-term mean sea surface temperature (SST) and found four thermal regimes in the ETP: Tropical Upwelling, Thermally Stable, Equatorial Upwelling, and Seasonal regime. We conducted a meta-analysis of both the reproductive phenology (month of spawning) and dispersal-related traits. We correlated the SST with the month of spawning, and inferred the impact of reproductive strategies and dispersal traits on the region's functional connectivity. We found a correlation between the SST and the spawning occurrences. Asynchronic spawning occurred irregularly throughout the year in the Upwelling and Thermally Stable regimes. Spawning had a strong seasonal signal in the warm months in the Equatorial Upwelling and Seasonal regimes. Reproductive and dispersal-related traits strongly suggested a reliance on self-seeding for population persistence. In contrast, nearly half of the corals produced autotrophic larvae, a trait favouring LDD. Despite the diversity of reproductive strategies and dispersal traits, coral populations in the ETP are more reproductively isolated, more dependent on self-seeding, and more vulnerable to disturbance than previously considered. Furthermore, the tight coupling between spawning and sea surface temperature suggests an increased susceptibility of coral assemblages to El Niño events and ocean warming scenarios.

FUNCTIONAL CONNECTIVITY OF CORALS ACROSS THE EASTERN TROPICAL PACIFIC (Abstract ID: 29564)

Because of the reduced size and isolation of reefs in the Eastern Tropical Pacific (ETP), long-distance dispersal (LDD) is considered a key process that influences their ecologi-

cal dynamics. Here, we used a biophysical dispersal model to examine the functional connectivity of corals between regions in the Central Tropical Pacific (CTP) and the ETP. The connectivity simulation included an ocean circulation model, the coral's potential habitat, and their reproductive and larval-related traits. We simulated 470 spawning events from 1993–2012, exploring larval durations of up to a maximum of 150-days. We found a very low probability of connectivity from the CTP to the ETP (0.01). Larvae cross the eastern pacific barrier (EPB) along the North Equatorial Counter Current, using the Clipperton Atoll as a stepping-stone. The Clipperton Atoll appears to act as a potential larval source for nearly all the regions of the ETP. There also appears to be a possible east-to-west dispersal pathway from the Galapagos Islands to Marquesas and Line Islands. Crossing the EPB is not possible with larval durations less than 50 days. Our results suggest that transpacific LDD is possible, though likely infrequent, in the ecological time-scale for these corals. Lastly, the Clipperton Atoll and Cocos Islands may serve as key stepping-stones and as central nodes within the ETP reef MPA network.

CORALS AND THE U.S. ENDANGERED SPECIES ACT: BRIDGING THE GAP BETWEEN SCIENCE, MANAGEMENT, AND CONSERVATION ACTION (Abstract ID: 29786 | Poster ID: 699)

Coral reefs are among the most biodiverse ecosystems on earth and are important sources of goods and services, yet they are being increasingly degraded, in particular from ocean warming and acidification. In response to a petition citing this degradation, in 2014 the National Marine Fisheries Service (NMFS) published a final rule listing 20 coral species, 5 from the Caribbean and 15 from the Indo-Pacific, as threatened under the U.S. Endangered Species Act (ESA). In contrast to the Caribbean, very little is known about the distribution of the listed species in U.S. waters in the Pacific. Moreover, disagreement exists among taxonomic experts on the identification of some of the species, confounding efforts to better determine their distributions and the habitats critical to their survival. However, the ESA mandates that Federal agencies or applicants requiring Federal permits for activities in coral reef ecosystem waters consult with NMFS in an effort to avoid and minimize their activity's impacts on listed species. In the absence of reliable information on the distribution of listed species, maps are being developed to show the distribution of all scleractinian corals, and the location of hard substrates they may recruit to. Using the best available data, maps are being developed for the islands of American Samoa, Guam, the Northern Mariana Islands, and the U.S. Pacific Remote Islands to facilitate management of listed species. Data and methods being used for mapping, as well as challenges and limitations of this effort will be discussed. http://www.pifsc.noaa.gov/cred/ecospatial_information.php

SOCIO-ECONOMIC ASSESSMENT TOOL (SEAT): ASSESSING THE SOCIO-ECONOMIC BENEFITS OF MARINE PROTECTED AREAS (MPAS) (Abstract ID: 30003 | Poster ID: 644)

The Socio-Economic Assessment Tool (SEAT) is a set of indicators meant to measure the effectiveness of Marine Protected Areas (MPAs) in delivering socio-economic benefits to local communities in the MPA's immediate vicinity. MPAs have been scientifically proven to enhance the earth's natural capital in the marine ecosystem. SEAT attempts to validate the claim that such an enhancement directly contributes to improved human wellbeing. The ultimate goal of resource management is to strive for a balance between consuming now and leaving enough for future generations. Thus, MPAs become socially acceptable if they are able to contribute to both present and future needs. The proposed SEAT indicators strive to assess whether managers are spending enough time, effort and resources to ensure that MPAs are established and maintained using sound scientific and economic principles, at the same time communities are benefitting enough so that they support their continued existence, all in the context of local economic development. SEAT is an initial attempt at measuring how the build-up of natural capital leads to the build-up of financial, human and social capital at the local level. SEAT complements the existing MPA Effectiveness Assessment Tool (MEAT), which assesses governance effectiveness in managing Philippine MPAs. A series of Focus Group Discussions (FGDs) were conducted among 17 municipalities. Efforts to roll out the SEAT are currently being exerted by the ECOFISH project in an additional 42 coastal municipalities. Results of the FGDs are discussed in this paper.

POPULATION GENOMICS OF RESILIENCE IN THE 2015 CORAL BLEACHING EVENT (Abstract ID: 28867)

In the spring of 2015, the third major worldwide coral bleaching event in recorded history was observed across the tropics. Acroporid corals in backreef lagoons on Ofu Island in American Samoa had extremely variable responses. A few corals bleached heavily and died, while others seemed relatively unaffected by this stress. We use full genome sequencing of 150 Acropora corals to determine the genomic architecture of bleaching response during this natural bleaching event. We test whether the genomic basis of resilience to climate change is shared between congeners, and determine the spatial distribution of thermally tolerant species, subspecies, individuals and alleles across Ofu lagoon. We find that different Acropora species had broadly similar bleaching reactions, but that cryptic species within these complexes bleached differently. We show that many genetic variants are shared between species, suggesting that similar mechanisms may drive climate adaptation in different species. In particular, regulatory alleles that control gene expression for crucial loci vary much more than expected between cryptic species and may be especially responsible for bleaching resilience and microhabitat distribution. These findings suggest that adaptation to a changing climate may be accomplished through shifts in the frequencies of many regulatory polymorphisms already present in contemporary coral populations.

DARWIN'S BERMUDA PARADOX REVISITED: ATOLL OR FRINGING REEF? (Abstract ID: 29541)

Bermuda is a carbonate platform complex in a relatively high latitude on a mid-plate seamount rimmed subaerially to S and E by islands with offshore algal-vermetid reefs to seaward, and rimmed to N and W by coral reefs. Its gross topography has long been recognized as atoll-like. Darwin did not visit Bermuda, and had to rely mostly on Nelson's geological account (1837) in his effort to classify its reefs (1842). Despite its atoll form and ocean setting, Nelson's observations inhibited Darwin from assigning Bermuda to one of his three famous reef categories. Nelson had correctly inferred an aeolian origin for its islands and noted the 10s m scale of their relief. While possibly homologous with atoll cays elsewhere, their height seemed too much for a typical atoll. Also problematic were intraformational conglomerates whose clasts were "too heavy for the wind to have moved". This was inconsistent with Darwin's atoll model of ocean floor subsidence, as posthumously illustrated by David Stoddart (1995), and pointed more to Bermuda's reefs as a fringing system around older islands. In retrospect, Darwin's Bermuda paradox is understandable in the absence of a dating framework, and because Quaternary glacioeustatic events and Bermuda's own tectonic setting were both unknowable to Darwin at that time. Bermuda is really an oceanic atoll whose particular history happens to have endowed it with an interesting, if not unique, suite of unusual features.

DEVELOPING PRACTICAL MANAGEMENT STRATEGIES TO PROMOTE CORAL RECOVERY FOLLOWING A SEVERE BLEACHING EVENT IN HAWAII (Abstract ID: 28213)

Hawaii's coral reefs suffered extensive coral bleaching in 2014 and 2015 due to dramatically elevated ocean temperatures. In some species over 95 percent of colonies were bleached with total mortality exceeding 70 percent. Although it is predicted that mass bleaching will become an annual phenomenon in Hawaii by 2050, consensus on current strategies to promote coral recovery following bleaching mortality is decidedly limited. In 2016, the State of Hawaii Department of Land and Natural Resources, Division of Aquatic Resources launched an initiative to identify applicable and effective management actions to promote the recovery of the state's coral reefs. The initiative utilized the input of a global group of coral reef scientists and managers with relevant research and management experience who vetted and prioritized proposed management actions. Through this innovative process, a consensus on management actions was reached which is now being further analyzed by the Division of Aquatic Resources for application to potential administrative rulemaking. This project reflects a direct link from science to policy and is a unique instance where government proactively worked with scientific experts to actualize pragmatic management and policy actions. This study may serve as a model for other governments looking to develop a realistic plan to accelerate coral recovery and resilience following severe bleaching events.

THE EFFICACY OF NURSERY HEAD-STARTING IN THE CULTURE AND RESTORATION OF ACROPORA CERVICORNIS (Abstract ID: 28842)

Four presumed-distinct genetic lineages of Acropora cervicornis at 12m depth were collected, grown and monitored bimonthly for 12 months through 2006 and 2007 in mid-water horizontal line nurseries at 3m, 7m and 15m depths in Montego Bay, Jamaica. These corals were then re-fragmented and propagules randomly re-set to new nurseries in the same locations, wherein they were similarly monitored for a further 10 months. The second, propagative iteration's corals started at faster growth rates than the previous wild-sourced for the first 100 days, after which the difference reduced to insignificance. This result suggests that head-starting does occur, supporting a nursery period of three months or more as an interim step for restorative relocation including in salvage, and supports multi-generational approaches to propagative coral enhancement under silviculture themes. Lineage differences in growth and branching rates of the first nursery iteration persisted into the second, as did the relative resistances to fouling and bleach-causing stress of those faster-growing lineages. Apical polyps of larger corals extended more rapidly than those of smaller individuals regardless of lineage or nursery conditions including depth or light, suggesting that larger corals be maintained in working nurseries to maximize overall production whenever possible. This should not negate the use of nubbins per se, but should inform programmatic design. A trend towards hardening to bleaching stressing conditions was noted in the second iteration corals.

GROWTH AND PHYSIOLOGY OF THE CORAL TURBINARIA RENIFORMIS IN BREMER BAY, WESTERN AUSTRALIA (34.4°S): IMPLICATIONS FOR THE SUITABILITY OF HIGH-LATITUDE REFUGIA (Abstract ID: 29010)

The ongoing tropicalisation of high-latitude environments and the increasing frequency of thermal stress events on low-latitude reefs have highlighted the importance of currently marginal environments as potential future 'coral refugia'. Although temperature and light are often considered sub-optimal for coral reef accretion above 28°N and 28°S, existing high-latitude coral communities provide natural laboratories to investigate the potential for coral refugia under future climate change. We are currently measuring seasonal changes in the growth rates of Turbinaria reniformis at Bremer Bay (34.4°S) in Western Australia; a region that has warmed at rates of 0.01--0.03°C y-1 since the mid 1900's. Preliminary data show that T. reniformis increased its skeletal biomass over winter despite minimum weekly average water temperatures of just 16.5°C. Furthermore, T. reniformis grew at similar rates in winter to those reported for the same species from tropical environments grown in aquaria studies (0.06% change in mass d-1). The maximum quantum yield of chlorophyll-a fluorescence (Fv/Fm) varied seasonally with changing light levels (0.65 in June vs. 0.50 in December); results that are comparable to studies of seasonal changes in the photophysiology of tropical coral, suggesting that T. reniformis in Bremer Bay may photoacclimate seasonally to maintain net skeletal growth year-round. We anticipate that this study will provide important insights into the capacity of coral to grow in marginal environments, with implications for the future suitability of high-latitude coral refugia.

USE OF GEOGRAPHICALLY-WEIGHTED REGRESSION TO IDENTIFY SPATIAL HETEROGENEITY IN CORAL COVER RELATIVE TO SUBMARINE GROUNDWATER DISCHARGE AND HERBIVORE ABUNDANCE (Abstract ID: 29632)

Disturbances from natural and anthropogenic threats can lead to phase shifts from coral- to algal-dominated communities. The Kahekili Herbivore Fisheries Management Area (KHFMA) on Maui, Hawaii was established in 2009 to address concerns that the reef was undergoing a phase shift based on observed declines in coral cover, ephemeral macroalgal blooms, and turf algal overgrowth of corals. The KHFMA prohibits take of all herbivorous species including reef fish and urchins to support top-down control of algal growth that may be detrimental to coral populations. Here, we synthesize multiple spatially-explicit biological and environmental data sets to evaluate the relative importance of submarine groundwater discharge and herbivore abundance to the distribution of coral cover within the management area. To address the observed spatial heterogeneity in the area, a spatially explicit Geographically Weighted Regression (GWR) was compared to a non-spatial Ordinary Least Squares (OLS) model. Both main effects and interactions between SGD and herbivore abundance were related to the distribution of coral cover. The GWR improved the fit of the model and allowed for visualization of patterns in relationships between the different variables. Local models showed that the relationship between SGD and herbivore abundance varied spatially. These results suggest that a complex interaction of both top-down (herbivory) and bottom-up (SGD) effects influences coral cover. The GWR method provided a superior method to traditional regression approaches for fine scale, spatially-explicit analyses.

ULTRASTRUCTURAL FEATURES OF ZOOXANTHELLAE PROVIDE BIOMARKERS OF DISSOLVED INORGANIC NUTRIENT EXPOSURE OF REEF CORALS (Abstract ID: 28344 | Poster ID: 90)

Increasing enrichment of coastal waters with dissolved inorganic nutrients occurs as a result of a range of anthropogenic activities and constitutes a significant local pressure to coral reefs, having both direct and indirect impacts on reef corals. Hence, monitoring of the nutrient exposure of coral reefs is highly desirable to direct management efforts. Yet, due to the fast uptake and turnover of dissolved inorganic nutrients in coral reef waters, it is difficult to establish the prevailing nutrient conditions for reef monitoring purposes solely by analyzing the water chemistry. By conducting long-term experiments under controlled laboratory conditions and assessing the resulting zooxanthellae cellular morphology by transmission electron microscopy, we could establish ultrastructural features of zooxanthellae as reliable biomarkers of the amount of dissolved inorganic nutrients available to the corals. We demonstrate that zooxanthellae cell size, the quantity of storage bodies, and accumulation body integrity change in a characteristic way indicative of the exposure to different concentrations of nitrate and phosphate. These biomarkers allow for the identification of, and discrimination between different forms of nutrient stress, providing a potentially valuable tool for targeted management of coastal pollution.

SIMULATED OVERFISHING PROMOTES RAPID SPREADING OF ASCIDIANS IN AN UPWELLING-INFLUENCED CORAL REEF AT THE PACIFIC COAST OF COSTA RICA (Abstract ID: 27915)

Overfishing and nutrient enrichment are major local stressors to coral reefs worldwide, as they can alter the benthic reef community by promoting fast growing and opportunistic functional groups. Reefs in the Gulf of Papagayo at the northern Pacific coast of Costa Rica are influenced by seasonal upwelling events that naturally increase phosphate, ammonia and nitrate concentrations (3, 2 and 6-fold, respectively) between December and March. This study therefore investigated the combined effects of naturally increased nutrient concentrations and simulated overfishing on the benthic community composition and succession on settlement tiles from October 2013 until April 2014. Overfishing was simulated using exclusion cages. While crustose coralline algae, sessile invertebrates (i.e. barnacles and polychaetes) and small filamentous algae dominated the tiles under natural conditions, simulated overfishing significantly increased the development of the colonial ascidian *Didemnum sp.*, with up to 80 % tile area cover. *Didemnum sp.* thereby overgrew other sessile invertebrates and crustose coralline algae within two weeks time, particularly during the upwelling season when nutrient- and organic matter concentrations in the reef were high. These findings suggest that overfishing can facilitate the growth and rapid distribution of ascidians, which may have a strong influence on the natural benthic reef community composition and especially its early succession patterns. Eutrophication may further enhance the proliferation of ascidians as it increases the food resources for filter feeders.

DYNAMICS OF CORAL-ALGAL PHYSIOLOGY AND TEMPERATURE STRESS ASSOCIATED WITH GLOBAL CHANGE (Abstract ID: 29675)

Increasing climate variability and temperature abnormalities associated with global change are significant contributors to worldwide coral reef decline. Elevated and depressed temperatures can have profound deleterious effects on coral-algal physiology

and lead to widespread coral bleaching and mortality. In parallel experiments, we investigated the dynamics of gene expression and physiology of *Acropora yongei* to decreased (-5°C) and increased (+5°C) seawater temperature over the course of 20 days. Decreased and increased temperatures cause divergent responses on dissimilar timescales in corals and *Symbiodinium*; cold causes acute effects by day 5 but corals eventually stabilize, while heat causes bleaching by day 9 and corals continue deteriorating. Using cDNA microarrays (13,546 genes) we observed that 12.2% of hybridized genes were differentially expressed. Cold-treated corals produced more differentially expressed genes (1.8%) compared to heat-treated corals (0.6%) with little overlap between them. Temperature and time had similar effects on gene expression. Coral green fluorescent protein (GFP) concentration and green fluorescence intensity decreased with declining coral health, prior to onset of bleaching, providing evidence for use of coral fluorescence as an early noninvasive indicator of coral health. Concordantly, green fluorescence was positively correlated with*Symbiodinium* photobiology and coral growth. These experiments demonstrate that the mechanisms of response to cold and heat stressors are different and elicit distinct responses in the coral-algal symbiosis.

## AGGRESSIVE ASCIDIAN DIDEMNUM SP. OVERGROWS BENTHIC COMMUNITIES ON PROTECTED CORAL REEFS IN THE WAKATOBI MARINE NATIONAL PARK IN SOUTHEAST SULAWESI, INDONESIA (Abstract ID: 28198)

Benthic coral reef communities are threatened by invasive and cryptogenic species,which are promoted by anthropogenic influences and pollution. In particular, ascidians have life history traits that facilitate the establishment under changing environmental conditions: they grow rapidly under eutrophic conditions, quickly reach sexual maturity, can regenerate from fragments and often lack predators. Reefs in the Wakatobi are protected but have been degraded in some areas due to overfishing, sedimentation and nutrient enrichment. Therefore, this study investigated the benthic community composition of coral reefs in the Wakatobi in a baseline survey in August 2011 (4 weeks). A special focus was put on the distribution patterns of an unidentified ascidian in the genus Didemnum. The results revealed that Didemnum sp. occurred in high abundances in non-degraded (0.66%), but to an even higher degree in eutrophic water (0.75%). Furthermore, Didemnum sp. showed the ability to overgrow dead and alive hard and soft corals with fast growth rates (up to 53% and 26% over the study period in degraded and non-degraded conditions). High eutrophic conditions along with organic matter contents are likely to promote the occurrence of filter feeders such as Didemnum sp. Moreover, the close proximity of degraded and non-degraded sites could lead to the spreading of ascidians through dispersal of larvae. The high percent cover of Didemnum sp. on protected reefs in the Wakatobi indicates a potential threat to the benthic reef community via outcompeting and should therefore be investigated further.

## CORAL HOLOBIONT RESPONSE TO SALINITY CHANGES INDICATES OSMOREGULATION OF SCLERACTINIAN CORALS (Abstract ID: 27835)

Scleractinian corals are commonly assumed to be stenohaline osmoconformers. Yet, some corals are able to tolerate salinities up to 50 PSU, but we know little about the mechanisms involved. To this end, studies have exclusively addressed the coral host and/or their algal symbionts (Symbiodinium) upon salinity changes, but the microbiome was omitted. To further investigate the role of all compartments of the coral holobiont we assessed the response of the coral host, its symbiont algae (Symbiodinium), and the associated bacterial community to strongly increased salinities. In short-term incubations (4h) we measured decreases in calcification rate of the coral host and in the photosynthetic performance of Symbiodinium. In contrast, we found a major restructuring of the associated bacterial communities after a long-term (29 days) experiment, where no bleaching occurred and the photophysiology was unaffected. Based on the microbial changes we identified putative functional changes of the microbiome, namely an increased storage of the osmolyte polyhydroxybutyrate, a decreased reduction of the osmolyte and antioxidant DMSO, and changes in nitrogen cycling towards nitrogen fixing processes. Our results show a short-term reaction of coral host and Symbiodinium to strongly increased salinities. However, lack of an apparent physiological long-term response indicates an acclimation process that is accompanied by a microbiome community shift towards a microbiome that potentially supports increased osmolyte production.

## EXPLORING CLIMATE CHANGE IN THE PHOENIX ISLANDS PROTECTED AREA: RECOVERY, RESILIENCE, AND RISKS (Abstract ID: 29032)

The Kiribati Phoenix Islands are located in the central Pacific, where annual temperature fluctuations are typically narrow except during intense El Niño events. When first explored in 2000, they resembled a near-pristine state, but in 2002-03, a severe high thermal event occurred. Across all islands, coral cover declined by ~60% due to bleaching, down to ~0 at some sites. Over the next decade (2003-2015), a remarkable if variable recovery was observed, with coral cover ranging from 18-95%. Recovery on the high end of this scale is attributable, at least in part, to high fish biomass and the rapid jacketing of exposed substrata by crustose coralline algae. The observed variation among sites persisted through another (but less severe) thermal event in 2010, and in 2015, while the ongoing El Nino was beginning to strengthen. Over a 15-year period, Phoenix Islands monitoring efforts have provided insight into coral successional dynamics and resilience in a coral reef region subject to intense climate impacts, but largely innocent of local human impacts. Despite the three bleaching events, adult coral community structure still resembles that of new recruits, and is dominated by fast-growing coral genera. Yet, the important differences in resilience and recovery (and hence risk) across the 8 islands likely reflect natural environmental differences in size and positioning, coupled with remnants of historical human impact. Phoenix Islands reefs are remote, largely uninhabited, and fully protected, thus making them a good case study in natural ecosystem responses to climate. http://phoenixislands.org/

## ACCLIMATORY CAPACITY OF THE GORGONIAN *ISIS HIPPURIS*LINNAEUS 1758 TO ENVIRONMENTAL CHANGE IN SE SULAWESI, INDONESIA (Abstract ID: 28541)

Coral reefs within the Indonesian archipelago are some of the most biodiverse yet anthropogenically compromised marine ecosystems. In the Wakatobi Marine National Park, Indonesia, two distinct morphotypes of the protected zooxanthellate gorgonian octocoral Isis hippuris partition across environmental clines: long-branched bushy colonies on turbid, degraded reefs, and short-branched multi/planar colonies on healthy reefs. To test if local adaptation has lead to divergent selection through the action of environmental perturbation, a one-year reciprocal transplant experiment assessing multiple traits (45: morphological, physiological, environmental) was conducted. After one year, reduced survivorship of healthy reef morphotypes on degraded reefs implied the onset of lineage segregation through immigrant inviability. Phenotypic traits in healthy source colonies showed significant trait plasticity, whereas residents from the impacted site were insensitive to environmental change. Interestingly, photoacclimatory responses were integrated at the morphological and bio-optical levels, with host skeletal articulation maximizing the internal light field in healthy clones on degraded reefs. Variable optical responses were not, however, attributed to endosymbiont type, as all test colonies possessed a novel Symbiodinium Clade D1a. In sum, patterns of phenotypic variability within the I. hippuris holobiont likely represent incipient ecological divergence, with a high capacity for plasticity that has become fixed through on-going anthropogenic disturbance on degraded reefs.

QUANTIFYING HERBIVORY ON CORAL REEFS TO DEVELOP A METRIC FOR MANAGEMENT AND CONSERVATION OF CARIBBEAN PARROTFISHES (Abstract ID: 28510 | Poster ID: 581)

On many coral reefs, parrotfishes serve as both important fishery species that support local economies and key grazers that can facilitate settlement, growth, and survivorship of reef-building corals. Recent management priorities have recognized the importance of parrotfish in facilitating coral recovery, particularly in the US Virgin Islands. However, we lack species-level information needed to guide specific management targets. To fill this knowledge gap, we first quantified and compared the feeding behavior of the six most abundant large bodied parrotfish species in the genera Scarus and Sparisoma by conducting detailed behavioral observations of grazing rates and grazing preferences at three sites in St. Croix, US Virgin Islands. To relate these behavioral data to ecosystem status, we also quantified fish abundance and benthic community structure at our study sites. Our results show large differences in diet, preferred grazing substrates, bite rate, and distance travelled while foraging among species and between genera of parrotfishes. We will use this species- and size-specific foraging behavior data to quantify the ecological function provided by the parrotfish assemblage. The final phase of this project will be to use our grazing metrics to model the grazing potential of the parrotfish assemblage and forecast the impacts of different management strategies on the ability of the parrotfish assemblage to control algae and facilitate the protection of corals.

CLOSE ENCOUNTERS OF THE SIBLING KIND: SELF-RECRUITMENT AND KIN ASSOCIATIONS IN SOCIAL GROUPS OF A CORAL REEF CARDINALFISH (Abstract ID: 28543)

Social groups of coral reef fishes are often assumed to form from unrelated individuals that settle into the same coral habitats. However, local-scale self-recruitment and attraction between sibling larvae create the potential for kin associations within social groups and inbreeding. While there is increasing evidence that larval reef fishes may return home and kin remain associated during the larval phase, few cases of true kin group structures in marine fish have been described. Here we examined relatedness between individuals within and among reefs and within and among social groups of the pyjama cardinalfish, Sphaeramia nematoptera, in Kimbe Bay, Papua New Guinea. We quantified the pairwise relatedness and genetic distance among more than 13000 dyads from 41 social groups on 7 reefs, using 19 microsatellite markers. We found a strong negative relationship between pairwise relatedness and distance within an area less than 3km. Dyads were 1.3 times more closely related within reefs than between reefs and relatedness was higher between individuals within social groups compared with among groups on the same reef. We observed high levels of both fine-scale self-recruitment and siblings settling together, suggesting these mechanisms account for high levels of kin association within groups. However, there is some evidence of ontogenetic shifts of kin within groups suggestive of a mechanism to avoid inbreeding. Assumptions that social groups in coral reef fishes are made up of unrelated individuals may need to be re-evaluated.

A DYNAMIC MODEL OF THE INTERACTIONS BETWEEN ACROPORA CERVICORNIS AND ITS ENVIRONMENT (Abstract ID: 29404 | Poster ID: 526)

Environmental factors associated with climate change such as increasing sea surface temperature (SST) and solar radiation (SR) have negatively impacted corals throughout their geographic ranges. One such coral, which has been seriously impacted by these stressors, is the staghorn coral Acropora cervicornis. To reduce the effects such stressors, this coral utilize fluorescent proteins (FPs) and melanin. These constitutive immune components quench reactive oxygen species (ROS) produced during thermal stress and absorb or reflect potentially damaging light. The synthesis of these components are, nonetheless, energetically costly. Hence, production of these protective compounds may be traded-off against other vital functions such as growth. In this study we develop a mathematical model with a system of ordinary differential equations that simulates the growth of A. cervicornis branches under different regimes and combinations of SST and SR. The model assumes that polyps are the functional unit of the coral and that the concentration of FPs and melanin are directly proportional to SST and SR intensity, which in turn, are inversely proportional to growth. To develop the model we use empirical (birth and mortality rate of polyps and the maximum number of polyps per unit area) and theoretical parameters (concentration of FPs, melanin produced, and trade-offs with growth). The model simulates how changes in FPs and melanin due to environmental changes affect the growth capacity of A. cervicornis. The model will thus help in understanding how corals will respond to future changes in climate.

TRANSCRIPTOME CHANGES IN CORALS SUBJECT TO PROTECTIVE HEAT PULSES DURING MIDDAY LOW TIDES (Abstract ID: 28207)

Reef-building corals face many types of environmental stress. Extreme stress exposure can result in loss of endosymbionts, leaving colonies bleached. However, corals are commonly exposed to natural cycles of sub-bleaching stress, which may increase their thermal tolerance in the lead up a bleaching-inducing stress event. We monitored coral transcription daily for 17 days over a strong tidal cycle and show that sub-bleaching environmental stress triggers a strong protective transcriptional response. These data allowed us to identify a set of genes with coordinated expression that were activated only on days with strong tides, high temperature, and strong diel pH and oxygen changes. The responsive genes are enriched for gene products essential to the Unfolded Protein Response, a cellular response to endoplasmic reticulum stress. After the temporary mild environmental stress passed, expression of these genes immediately decreased suggesting that homeostasis was restored to the endoplasmic reticulum. In a laboratory temperature stress experiment we found that the expression of these environmentally responsive genes was highest in bleached corals suggesting that they may also play a role in the physiological adjustments that occur during bleaching. Our results suggest that the Unfolded Protein Response is a first line of defense that corals initiate when coping with environmental stress and enhances our understanding of coral stress physiology during a time of major concern for reefs.

CHANGING PHYTOPLANKTON ASSEMBLAGES IN RESPONSE TO INCREASING CO2 CONCENTRATION: MESOCOSM EXPERIMENT IN BARRANG LOMPO ISLAND, SOUTH SULAWESI, INDONESIA (Abstract ID: 27979 | Poster ID: 371)

We examine the effects of seawater pCO2 concentration of 280, 380, 550, 650, 750 and 1000 ppm on the changing of phytoplankton assemblage through mesocosm experiment in Barrang Lompo Island. The experiment was run for 48 and 96 hours of incubation periods without nutrient enrichment. The aim of the study was to examine the effect of increasing CO2 concentration on changing phytoplankton assemblages. The result showed that carbonate parameters (alkalinity, DIC, PIC and POC) were affected significantly with increasing CO2 for both incubation periods. Bacillariophyceae was the most important algal group accounting for 74.5% for 48 hours of incubation period. Morever, Diatomaceae was the most dominant algal group (50.9%) for 96 hours of incubation period. There was no clear trend of Shannon diversity (H') and Evenness values between CO2 concentration and incubation period. There was clear grouping of species assemblages between incubation periods based on nMDS analysis. ANOSIM result showed that there was no significant different of species assemblages among CO2 treatments. On the other hand, there was a significant different of species assemblages among incubation periods between CO2 concentration treatments. The highest dissimilarity was found at the pair of 650 ppm vs 1000 ppm, account for 83.15%. Three taxa that were the most responsible for dissimilarity were Rhizosolenia fragilissima (10.1%), Gyrosigma acuminatum (9.3%), Biddulpia sinensis (9.2%). Keywords : Phytoplankton assemblages, increasing CO2 concentration, mesocosm experiment, Barrang Lompo Island

BLACKTIP REEF SHARKS (CARCHARHINUS MELANOPTERUS) SHOW HIGH CAPACITY FOR WOUND HEALING AND RECOVERY FOLLOWING INJURY (Abstract ID: 28034 | Poster ID: 277)

Wound healing is important for sharks from the earliest life stages -- for example, as the 'umbilical scar' in viviparous species heals -- through adulthood where sharks can incur a range of injuries from natural and anthropogenic sources. Despite anecdotal accounts of rapid healing in elasmobranchs, data regarding recovery and survival from different wound or injury types has not been systematically collected. In blacktip reef sharks, we documented:

1) 'umbilical scar' healing in wild-caught neonates reared for 30d in flow-through laboratory aquaria in French Polynesia; 2) survival and recovery of free-swimming individuals in Australia and French Polynesia following a range of injuries; and 3) long-term survival following suspected shark-finning activities. Laboratory monitoring, tag-recapture records, telemetry data, and photo-identification records suggest that blacktip reef sharks have a high capacity to survive and recover from small to even large and severe wounds. Healing rates, recovery, and survival are important factors to consider when assessing impacts of habitat degradation and fishing stress on shark populations. However, individual survival may depend more on handling practices and physiological stress rather than the extent of physical injury. Our findings also contribute to discussions regarding the ethics of tagging practices used in elasmobranch research and provide baseline healing rates that may increase the accuracy in estimating reproductive timing inferred from mating scars and birth dates for neonates based on umbilical scar healing status.

EPIZOOTIOLOGY OF BLACK BAND DISEASE ON SCLERACTINIAN CORALS OF KAUAI, HAWAII, USA (Abstract ID: 28914 | Poster ID: 159)

Since its discovery in the Florida Keys in 1973, black band disease (BBD), a tissue loss disease that infects multiple coral genera in the Caribbean, Red Sea, and Indo-Pacific, has emerged as a serious threat to the reefs worldwide. BBD is a polymicrobial disease consisting of three main microorganisms: a filamentous cyanobacterium, sulfide-oxidizing bacteria, and sulfate-reducing bacteria. In 2011, the first potential outbreak of BBD was reported in the Hawaiian Archipelago off the Island of Kauai. Histology and microscopy of coral lesion samples from Kauai revealed a mixed assemblage of motile cyanobacteria and filamentous bacteria associated with cell necrosis. Laboratory infection trials demonstrated that BBD lesion material infected 94.4% of exposed coral within 4 days of inoculation (n=18). Amplification and sequencing of 16S rRNA and dsrA genes from bacteria cultured from disease lesions identified a cyanobacterium similar to *Pseudoscillatoria coralii*, a sulfide-oxidizing *Beggiatoa* sp., and several sulfate-reducing bacteria; showing that the three common BBD constituents are present in lesion material from Kauai. Surveys found BBD widespread on the north and east facing shores of Kauai with disease prevalence ranging from 0.24% to 7.9%; it was observed to infect three reef-building *Montipora* species. In other regions, BBD prevalence increases with elevated water temperatures, and this trend was observed with BBD on the reefs of Kauai. This first report of BBD in Hawaii which extends the geographic range of this disease.

SPECTRAL REFLECTANCE OF PALAUAN REEF-BUILDING CORAL WITH DIFFERENT SYMBIONTS IN RESPONSE TO ELEVATED TEMPERATURE (Abstract ID: 27958)

Spectral reflectance patterns of corals are driven largely by the pigments of photosynthetic symbionts within the host cnidarian. The warm inshore bays and cooler offshore reefs of Palau share a variety of coral species hosting different dinoflagellates (genus: Symbiodinium), with thermally resistant S. trenchii (=type D1a or D1-4) predominating under elevated temperature regimes inshore, and primarily Clade C types in the cooler reefs offshore. Spectral reflectance of two species of coral, Cyphastrea serailia and Pachyseris rugosa, from both Inshore and Offshore locations shared multiple features between sites and to global data from other studies. No clear reflectance features were evident which might serve as markers of thermally tolerant S. trenchii symbionts compared to the same coral species with different symbionts. Reflectance from Inshore C. serailia colonies had a fluorescence peak at approximately 500 nm which was absent from Offshore samples. Integrated reflectance across visible wavlengths had an inverse correlation to symbiont cell density and could be used as a relative indicator of the symbiont abundance for each type of coral. As hypothesized, coral colonies from Offshore with Clade C symbionts showed a greater response to experimental heating, manifested as decreased symbiont density and increased reflectance or "bleaching' than Inshore counterparts with S. trenchii. Although no unique spectral features were found to distinguish symbiont types, spectral differences related to symbiont abundance could prove useful in field and remote sensing studies.

PARROTFISH HERBIVORY AND POTENTIAL RECOVERY OF CORALS IN THE CARIBBEAN: USING SPECIES-LEVEL DATA TO PREDICT ASSEMBLAGE-LEVEL IMPACTS (Abstract ID: 29606)

Coral reefs have been in decline for many years throughout much of the Caribbean. While the causes are still debated, the loss of herbivores and subsequent increase in algae has likely played an important role in many locations. In recent years, there have been increasing calls for protection of key herbivores, especially parrotfishes, since increasing parrotfish abundance should reduce algal cover and algal competition with corals and/or provide additional free space for coral settlement. While protection of herbivores in general should increase herbivory, different species have different feeding and habitat preferences, and therefore should have different impacts on benthic communities. Therefore, the grazing impact of parrotfish assemblages may vary dramatically with changes in assemblage structure. We use data on species-level grazing preferences of parrotfishes in the Florida Keys and USVI combined with long-term monitoring data on parrotfish abundance to predict overall assemblage-level grazing impacts. Our results show that overall grazing impacts vary dramatically both geographically and among habitat types, suggesting that different parrotfish assemblages are likely to have very different impacts on benthic algae, and therefore also vary in the strength of indirect effects on corals. Our approach can provide concrete predictions for reef managers about how changes in parrotfish assemblages may influence grazing, algae, and corals using widely-available reef fish monitoring data, thereby providing a powerful tool to improve management coral reef ecosystems.

TWENTY YEARS OF CHANGE AND IMPACTS OF THE 2014/2015 BLEACHING EVENT ON FLORIDA KEYS REEFS (Abstract ID: 29810)

Corals in the Florida Keys have been subjected to elevated thermal stress for two consecutive years (2014 and 2015) due to a strengthening El Nino weather pattern. Moderate to severe bleaching has been documented in 2014 and 2015 with extensive bleaching persisting well into the cooler, winter months. The last mass, widespread bleaching event in the Florida Keys coincided with the 1997/1998 El Nino and reduced coral cover by up to 40% on some reefs. The Coral Reef Evaluation and Monitoring Project (CREMP) documented this mass mortality and has studied the condition of reefs in the Florida Keys since 1996. CREMP performs annual assessments at 40 sites and the data collected has provided invaluable information on how the benthic assemblages have changed on Florida Keys reefs the last 20 years. At the time of the 1997/1998 El Nino, only benthic cover estimates (e.g. change in percent cover) were available to describe the effects of bleaching. In contrast, the metrics used to evaluate the current 2014/2015 event include a robust demographic dataset that assesses the changes in density and population structure of corals (e.g. size classes and living tissue estimates), in addition to the more conventional percent cover estimates. Using a combination of traditional techniques (percent cover) coupled with more progressive population measures will allow for the most comprehensive assessment of a mass bleaching event in the Florida Keys to date. This presentation will summarize changes in coral abundance after the 2014/2015 bleaching years and place the results within the context of how Florida Keys reefs have changed the last 20 years

REEF FLAT CORES FROM THE INSHORE GREAT BARRIER REEF PRESERVE RECORDS OF HOLOCENE REEF GROWTH, TERRESTRIAL SEDIMENTATION AND TROPICAL CYCLONES (Abstract ID: 28416)

Multiple natural and anthropogenic stressors threaten inshore coral reefs of Australia's Great Barrier Reef (GBR) located in relatively turbid and shallow water. To better understand present and future reef response to various stressors, baseline long-term data on coral reef growth is required. Growth chronologies of coral reefs can provide valuable insight into past reef development and variability and can further our understanding of present reef condition. We examined the chronostratigraphy of five fringing reefs on the inner and mid-shelf regions of the central GBR that are located on a gradient of

distance from the coast and associated anthropogenic impacts. Our record is based on 41 reef cores that capture the entire Holocene reef framework and matrix sequence, terminating in pre-reefal substrates. Cores are chronologically constrained by 112 high precision U-Th ages from in situ corals in the cores and fossil microatolls. Reef initiation age, antecedent substrate, reef accretion rates and mode, and coral palaeo-ecology varied between the five sites. However, reef flat formation began in the mid-Holocene at all sites with approximately 80% of each reef structure emplaced by 2,000 yBP and little net accretion occurring since. Late Holocene sea-level fall, tropical cyclones and sedimentation influenced Holocene reef accretion at each site to varying degrees. Terrestrial sedimentation was markedly greater on inshore sites, while the physical effects of tropical cyclones on reef development and geomorphology were more pronounced at sites further from the mainland.

VIRAL OUTBREAK IN CORALS ASSOCIATED WITH AN *IN SITU* BLEACHING EVENT: ATYPICAL HERPES-LIKE VIRUSES AND A NEW MEGAVIRUS INFECTING *SYMBIODINIUM* (Abstract ID: 29652)

We conducted transmission electron microscopy imaging and virome analysis in tandem to characterize the most conspicuous viral types found within the dominant Pacific reef-building coral genus *Acropora*. Collections for this study inadvertently captured what we interpret as a natural outbreak of viral infection driven by aerial exposure of the reef flat coincident with heavy rainfall and concomitant mass bleaching. Three of the dominant VLPs identified were observed in all tissue layers and budding out from the epidermis, including viruses that were ~70 nm, ~120 nm, and ~150 nm in diameter; these VLPs all contained electron dense cores. These morphological traits are reminiscent of retroviruses, herpesviruses, and nucleocytoplasmic large DNA viruses (NCLDVs), respectively. Some 300-500 nm megavirus-like VLPs also were observed within and associated with *Symbiodinium* cells. Abundant sequence similarities to a gammaretrovirus, herpesviruses, and members of the NCLDVs, based on a virome generated from five *Acropora aspera* colonies, corroborated these morphology-based identifications. Additionally, sequence similarities to two diagnostic genes, a MutS and a DNA polymerase B gene (based on reannotation of sequences from another study), most closely resembled *Pyramimonas orientalis* virus, demonstrating the association of a cosmopolitan megavirus with *Symbiodinium*. This study suggests that viral outbreaks may be a common but previously undocumented component of natural bleaching events.

GENETIC SEASCAPE REVEALS THAT ECOLOGICAL-EVOLUTIONARY PATTERNS IN PORITES PANAMENSIS CONFORM TO RELAXED VERSION OF THE ABUNDANT CENTRAL HYPOTHESIS (Abstract ID: 28734)

The coral fauna of the Eastern Tropical Pacific (ETP) is depauperate and peripheral; therefore, it is important to understand the factors allowing its survival. Here, we use a genetic seascape approach to test genetic predictions of the relaxed version of Abundant Center Hypothesis (rel-ACH) in *Porites panamensis*, a hermatypic coral endemic to the ETP. The relative abundance patterns of *P. panamensis* in the Mexican Pacific revealed that the northern populations from the Baja California peninsula are the center of abundance while the southern continental populations along the continental margin are peripheral relative to it. Genetic patterns of diversity and structure of nuclear DNA sequences (ribosomal DNA and single copy open reading frame) and five alloenzymatic loci are in agreement with ecological niche modeling. We found higher diversity levels in the peninsular populations and a significant differentiation between peninsular and continental colonies. In addition, continental populations showed higher levels of differentiation and lower connectivity among each other than peninsular populations. The geographic patterns of abundance, genetic diversity, genetic structure, and gene flow among populations are mostly consistent with the rel-ACH.

INFLUENCE OF A TEMPORAL MACROALGAL BLOOM ON REEF FISH COMMUNITY STRUCTURE IN NORTHWEST CALUMPANG PENINSULA (Abstract ID: 28641 | Poster ID: 261)

An unusually dense benthic algal bloom occurs in Northwest, Calumpang Peninsula during the first few months of every year (February-April). We examined the impact of this event on reef fish community structure in three periods: Before the bloom (November 2015 & January 2016), During the bloom (April-May 2015), and After the bloom (July-August 2015). Benthic community surveys and fish visual census for both reef fish adults and recruits were conducted in two stations in the study site. For each station, two permanent 50x10m belt transects were laid and surveyed for both recruits and adults. Within the permanent belt transects, an additional four 50x2m belt transects were laid randomly for recruit surveys. Initial results showed three important findings: (1) adult fish community structure was highly similar during the three periods (2) highest fish species richness was recorded during the bloom, and (3) species composition of recruits was consistently different across periods. Analysis of similarities (ANOSIM) show that the presence/absence of recruits of Acanthochromis polyacanthus, Cirrhilabrus cyanopleura, Thalassoma lunare, and Pseudanthias huchtii strongly contributed to the dissimilarity in community assemblage between periods. However, the temporary increase in benthic algal cover did not cause significant negative change in the adult reef fish assemblage of the study area.

EXPORTING FIJI'S NATURAL CAPITAL: CHALLENGES FOR THE SUSTAINABLE MANAGEMENT AND INTERNATIONAL TRADE OF INSHORE RESOURCES IN THE PACIFIC (Abstract ID: 28223)

Exports of inshore fisheries products from Pacific Island nations have grown in recent decades as global demand increases. These changes and their implications for coastal communities and resources are poorly documented or understood, despite the fact that many reef-associated fishes and invertebrates are declining. Using Fiji as a representative Pacific Island Country, we investigated the export trade of Fiji's inshore fisheries resources and the challenges associated with managing this trade. We found overall that large volumes of inshore fisheries resources are exported, potentially compromising local food security and livelihoods, though various biases and shortcomings exist in available data, including: inconsistent and underreporting; misclassification in government records; lack of regular inspection of export shipments; mismatches between volumes recorded as exported by Fiji and importing countries; and inaccuracies in reporting country of origin in the case of transhipments. To improve enabling conditions to better support inshore fisheries management in Fiji and the Pacific region, we recommend: taxation of exports and/or quotas to protect local food security and increase benefits to source countries; development of a blacklist of traders with poor trade reporting and exploitation records; development of inshore fisheries management divisions to balance current resourcing for offshore fisheries management; protecting vulnerable species from domestic and export trade, and improved monitoring systems that directly feed into decision-making for management.

SEASCAPE GENETICS ALONG ENVIRONMENTAL GRADIENTS IN THE ARABIAN PENINSULA: INSIGHTS FROM DDRAD SEQUENCING OF ANEMONEFISHES (Abstract ID: 28009)

Understanding the processes that shape patterns of genetic structure across space is a central aim of landscape genetics. Here, we evaluated the genomic composition of the two-band anemonefish Amphiprion bicinctus across its entire geographic range in the Red Sea and Gulf of Aden, as well as its close relative, Amphiprion omanensis endemic to the southern coast of Oman. Both the Red Sea and the Arabian Sea are complex and environmentally heterogeneous marine systems that provide an ideal scenario to address these questions. Our findings confirm the presence of two genetic clusters previously

reported for A. bicinctus in the Red Sea. Genetic structure analyses suggest a complex seascape configuration, with evidence of both Isolation by Distance (IBD) and Isolation by Environment (IBE). In addition to IBD and IBE, genetic structure among sites was best explained when two barriers to gene flow were also accounted for. One of these coincides with a strong oligotrophic-eutrophic gradient at around 16-20˚N in the Red Sea. The other agrees with an historical bathymetric barrier at the straight of Bab al Mandab. Finally, these data support the presence of inter-specific hybrids at an intermediate suture zone at Socotra and indicate complex patterns of genomic admixture in the Gulf of Aden with evidence of introgression between species. Our findings highlight the power of recent genomic approaches to resolve subtle patterns of gene flow in marine seascapes.

CORALLINE GEOCHEMICAL SIGNATURE TO IDENTIFY ANTHROPOGENIC INFLUENCES ON INSHORE CORAL REEFS OF MAGNETIC ISLAND, GREAT BARRIER REEF (GBR) (Abstract ID: 29072 | Poster ID: 432)

Although the GBR is the best managed coral reef system in the world, its initial inshore coral cover has decreased significantly in last few decades. This has been thought to be related to poor water quality associated with massive land use changes and rapid expansion of the ports along east coast of Queensland. However, due to lack of scientific evidences it has not been possible to adequately and objectively evaluate if the degradation of corals is a natural phenomenon or caused by human induced deterioration of water quality. In order to remedy this deficiency, we have unlocked the past 30 year geochemical signals from a Porites coral cored from Magnetic Island, GBR. The Magnetic Island's fringing reefs are influenced by terrestrial influx from the Burdekin catchment and also by resuspended fine sediment plume during dredging operations undertaken at the Port of Townsville. A close association among Ross River discharge, Mn/Ca, and Y/Ca has been observed. A sharp increase in total rare earth element concentration from 2006 to present coincides with the increased flood frequency during this time window. A major goal of this current work is to disentangle the impact of natural and human induced environmental change, principally by correlating the timing of abrupt changes in high-resolution coralline geochemical signatures with the specific natural and anthropogenic drivers. This work will allow better decision making where the best balance environmental protection and economic benefit can be achieved by developing best practise strategies for coastal land use.

TAXONOMIC STUDY OF CORAL ASSOCIATED FISHESAND THEIR PARASITES OF SAINT MARTIN'S ISLAND IN THE BAY OF BENGAL (Abstract ID: 29411 | Poster ID: 254)

This paper provides a detail first time taxonomical study of coral associated fish and their parasites from St. Martin's Island of Bay of Bengal. The information be gathered which will enable the compilation of a checklist and identification guide. St. Martin's Island is the only coral island of Bangladesh. Tourism has been increased deliberately which is posing threat to the island and its biodiversity although Bangladesh Government has declared this island as Ecologically Critical Area (ECA) in 1999. Fish surveys were conducted from February, 2014 to December, 2015 in the seven visits. Fish specimens were collected from local fishermen in the fish landing zone and fish market and also from local boys who collect these fishes by using hook and line. After that specimens were preserved in cool box till transfer at -20—Among coral associated fish 40 species of 28 genera and 19 families under 3 orders (Perciformes, Beryciformes and Scorpaeniformes) were identified on the basis of morphometrics and meristics. Among three orders, Perciformes was dominant and which belongs 17 families and 37 species, whereas other two orders contain only single family of each. For parasitic observation,33 fish individuals of the10 species were studied and among them12 individuals of the 4 species were infected by parasites only. Single nematode and 122 larval cestodes were identified and their prevalence and intensity were 36.36% and 10.25 respectively. Prevalence of larval cestodes(33.33%)was greater than nematode (3.03%) and male fish(27.27%) was more infected than female (9.09%).

THE CIVIL RESOURCE VIOLATIONS SYSTEM (CRVS) UTILIZING HAWAII'S ADMINISTRATIVE CODE TO IMPROVE ENFORCEMENT AND ADJUDICATION OF MARINE RESOURCE VIOLATIONS (Abstract ID: 29045)

In Hawaii, virtually all enforcement of marine resource violations is handled through the issuance of criminal citations. This process, which requires the defendant to appear in court for a hearing, is costly and time-consuming for judges, prosecutors, defense attorneys, enforcement officers, and defendants. Additionally, overcrowded court dockets often preclude the careful deliberation necessary to understand complex natural resource issues and laws, resulting in inconsistent rulings and dismissed cases. As an alternative to criminal prosecution, Hawaii law authorizes the use of a civil administrative code, the Civil Resource Violations System (CRVS), to process marine resource violations. Under CRVS, enforcement officers can issue civil citations akin to parking tickets which are processed administratively by the Department of Land and Natural Resources (DLNR), rather than through the criminal court system. This presentation will explore the many benefits and challenges of utilizing CRVS to enforce and adjudicate marine resource violations. It also outlines additional policy changes that would further strengthen CRVS as an enforcement tool.

POPULATION GENOMICS REVEALS CRYPTIC HYBRIDIZATION IN A CORAL REEF FISH (GENUS: *DASCYLLUS* ) (Abstract ID: 28215)

Cocos (Keeling) and Christmas Islands sit at the border of the Indian and Pacific Ocean bioregions. They represent a secondary contact zone for multiple marine species and populations that were isolated during Pleistocene glaciations. They are considered a marine suture zone, where closely related species from separate biogeographic regions overlap and interbreed. To date, 15 cases of hybridization between coral reef fishes have been documented in this region, making it an interesting area for speciation studies. In this project, Restriction Site Associated DNA sequencing (RADSeq) indicates hybridization between highly differentiated Pacific and Indian Ocean genetic clades of the three-spot dascyllus, *Dascyllus trimaculatus*. Since there are only subtle differences in color between Indian and Pacific populations, hybridization in this pair had remained undetected. These analyses reveal that the pattern within the suture zone is not homogeneous: Cocos Islands have a genetically stable population that underwent hybridization in the past, whereas hybridization is ongoing at Christmas Island. Further, we examine if introgression occurs more often on genomic regions under selection, promoting (or slowing) adaptive divergence. This project exemplifies how genomic techniques are unraveling more cases of hybridization in marine suture zones, while showing that patterns of introgression can be quite different at relatively small spatial scales. This research is important for understanding how hybridization contributes to evolutionary novelty of Indo-Pacific coral reefs.

IRREGULAR PLEISTOCENE PLATFORM BENEATH HERON REEF SOUTHERN GREAT BARRIER REEF (Abstract ID: 28988)

The geological record of fossil reefs provides essential information for interpreting palaeo-climatic change during the Holocene. Environmental influences on reef-building corals, such as variations in sea-level and sea-surface temperature, may cause significant differences in reef development and evolution. However, the early development of Holocene reefs is still poorly known. New drilling in the southern Great Barrier Reef is providing insights on classic reef models and relationships between Holocene reefs and Pleistocene antecedent topography. Five new cores collected in 2014 on the windward margin of Heron Reef suggest a much more irregular underlying topography than expected. Cores were recovered to depths of 30 m with new U-series ages constraining growth between 8472±24 and 2287±16 years. One core penetrated Pleistocene basement at ~ 15.3 m with Holocene reef growth initiated by ~ 8.4 ka. However, 1.77 km west along the same margin, four cores failed to penetrate Pleistocene basement at

depths of 19.6, 19.7, 24 and 30 m respectively, suggesting that the margin at that location overlies a karst valley or alternatively, there is no local antecedent platform there. A 48 m-long margin-perpendicular transect involving three cores shows that the topographic low is filled by a prograding succession, in places at least 30 m thick, beneath the current reef margin. These findings provide new insights into relationships between antecedent topography and subsequent reef growth and Holocene carbonate production and retention rates.

PATCH-REEFS IN THE CIENAGA DE ORO FORMATION (OLIGOCENE–MIOCENE, SAN JACINTO FOLD BELT, NW COLOMBIA) (Abstract ID: 28305 | Poster ID: 391)

Coral patch-reefs occur in thin carbonate bodies (up to 20 m thick) at the top of the Ciénaga de Oro Formation, which comprises thick successions of sandstones, siltstones, and clays within the Cenozoic deposits of the San Jacinto Fold Belt in the southern Caribbean (Colombia). In the Canta Gallo quarry, 40 km east of Montería, carbonate lithofacies reflect a rapid transgression of middle-ramp branching coralline algal floatstone to rudstone over shallow-water bioclastic sandstone. Rhodolith floatstone and packstone with dispersed platy corals initiate a regressive pattern continued by coral mixstone (3 m thick) and platestone (1.5 m thick), which make up the patch-reef deposits. The top of the carbonate sequence consists of trough cross-bedded rudstone with terrigenous grains rich in sand dollars, representing shoal sediments. Strong cementation and recrystallization of coral-rich lithofacies prevent any precise identification of coral taxa. Poritids, agathiphylliids, pocilloporids (Stylophora), and mussids seem to be the main components. Sr-isotope chemostratigraphic data indicate the Ciénaga de Oro Formation is Late Oligocene to Early Miocene in age. Larger benthic foraminifers suggest an Oligocene age for the Canta Gallo carbonates. These patch-reefs extend the geographic distribution of zooxanthellate coral records of this age farther south in the Caribbean.

FLUORESCENT PATTERNS IN CORALS FUNCTION IN SOLAR ENERGY MODULATION. (Abstract ID: 30135)

The striking fluorescent colors of corals are due to green fluorescent protein (GFP) type pigments. There is an increasing experimental evidence that one of their major roles is in photobiology. However, the function of intricate patterns made by multi-colored GFPs overlying anatomical macro- and microstructures are poorly understood. Using a combination of optical microsensor, confocal microspectral and micro-PAM fluorescence techniques we investigated GFPs' cellular localization, optical properties and photoresponses of symbionts in fluorescently patterned corals and examined their distribution in relation to the underlying skeleton. GFP tissue concentration correlated with strong surface light scattering and was highest in high light corals, especially those with dense cyan and green GFP-granules in oral disc fluorochromatophores. GFP patterns correlated with sub-surface light intensity and spectral gradients and acted in concert with skeletal elements to strongly enhance light propagation into shaded deeper tissues in fleshy or in shade adapted corals. Certain GFP cell micro-structures increased light propagation by several hundred micrometers forming effective light guides that amplified symbiont photosynthesis. Light-induced polyp contraction and expansion altered light propagation properties of GFP patterned tissues forming a dynamic light modulatory system. Together these results support a conclusion that GFP patterns redistribute and channel light towards or away from photosynthetic absorption forming an efficient biophotonic system that dynamically regulates solar energy.

EXCEPTIONAL MULTI-GENERATION PEDIGREE AND KIN RELATIONSHIPS IN A NATURAL CORAL REEF FISH POPULATION (Abstract ID: 28581)

Multi-generation pedigrees can provide a unique baseline to investigate some of the major issues in evolutionary biology, including local adaptation, inbreeding depression and evolutionary responses to rapid environmental changes. Accurate pedigrees are challenging to obtain in nature and a multi-generational pedigree has never been constructed for a marine fish population. The complex life-cycle of marine fishes makes it difficult to track individuals through space and time, and to measure their contribution to the next generation. Here we present a unique study that built an accurate pedigree over five generations in a natural reef fish population, using data from a 10-year genetic survey of orange clownfish (*Amphiprion percula*) surrounding Kimbe Island (Papua New Guinea). The pedigree contains 502 founders at its base and includes 990 parent-progeny links, spread over 121 families. The pedigree reveals successful inbreeding between related individuals. The average dispersal distance from founders to their descents increases with each generation, suggesting families spread out over time. Multi-generational pedigree and quantitative genetic approaches allowed us to investigate the relative contribution of genetic and environmental factors to variation in individual local reproductive success. Investing in the development of multi-generational pedigrees will improve our understanding of fish population dynamics and short-term evolutionary responses to environmental change.

ADDRESSING UNCERTAINTY: ENABLING APPLICATION OF SCIENCE TO CORAL REEF CONSERVATION POLICY AND PRACTICE (Abstract ID: 28234)

Scientists working alongside planners and managers to achieve effective coral reef management are exposed directly to the challenge of reforming often entrenched policy and practice. This challenge is compounded by the rates of climate and other socioeconomic changes pervading the world and calls for expedited ability to respond to emerging needs. Cutting edge science and models addressing coral reef resilience in the face of change and uncertainty are advancing faster than the ability to transform conservation planning and management approaches. Examples of sociopolitical obstacles to such transformation include: uncertainty of climate change projections, impacts and responses; entrenched governance structures that make change through the political process daunting; other perceived priorities (e.g., enforcement). Growing concern for climate impacts and the need to respond provide an opportunity to change governance structures. Making these more adaptive and designing and managing MPA networks for resilience to change provide a potential solution to uncertainties facing conservation agencies.

THE SURPRISING ROLE OF TELEOSTS IN REEF SYSTEM INORGANIC CARBON CYCLING (Abstract ID: 28174 | Poster ID: 88)

Concerns regarding the future of coral reefs in the face of rising sea surface temperatures (SSTs) and ocean acidification (OA) are growing apace. Reef system responses to these pressures will, in part, depend on the carbonate chemistry of waters surrounding them. However, changes in reef system carbonate chemistry are difficult to predict because a complex series of biogeochemical alterations and feedbacks may be triggered by rising SSTs and/or OA, possibly acting to buffer against them. In addition, several key components of reefal carbon cycling are poorly understood. Resolving these issues is vital for predicting future reef health and developing effective management strategies. Here we highlight teleost fish as a poorly understood but potentially key component of inorganic carbon cycling around reefs. Marine teleosts continuously excrete CaCO3 as a waste product of osmoregulation, and global models suggest this process could account for up to 45 % of total marine CaCO3 production. Thus, fish CaCO3 may be a highly significant component of global inorganic carbon cycles. Since reefs are historically sites of high fish biomass, fish CaCO3 could be similarly important within these systems, and may become increasingly so with rising SSTs and OA, as both are predicted to promote increased production rates. However, the significance of fish CaCO3 as a control on reef system chemistry is ultimately determined by fish biomass, which is presently undergoing drastic decline in many reef systems. We examine these issues through studies from Bahamian and Australian reef systems.

LIFE ON THE EDGE: CORAL REEF FISHES EXHIBIT STRONG BIDIRECTIONAL RESPONSES TO EDGE HABITAT (Abstract ID: 29924)

Habitat edges commonly support discrete communities compared to adjoining habitat types. Coral reefs are often adjacent to other habitats, e.g. sand, but little is known about how reef-associated organisms respond to the presence of edges. Here, we explored how fish and benthic assemblages changed with distance from a coral reef-sand edge. At each site (n=25), 30 m transects were placed at five positions: one along the edge and at 5m and 10 m away from the edge into reef and sand habitats. Counts were made of 51 fish species. Benthic composition was surveyed and hard corals identified to genus level. Multivariate analyses revealed that the fish community along the edge was significantly different to the fish communities only 5 to 10 m into both the sand and reef habitats. Over half of the 51 fish species showed a clear directional response to the presence of an edge. 12 species were significantly more abundant along the edge, including the wrasse *Thalassoma lunare* which was 30 times more abundant along the edge compared to 10 m into the reef. In contrast, the damselfish *Pomacentrus moluccensis* was seven times more abundant 10 m into the reef compared to the edge. Coral genus richness did not differ between the edge and reef habitat, however coral cover was higher on the reef compared to the edge. These findings suggest that edge effects are prevalent on reefs. Future research should focus on experimental approaches to determine the mechanisms driving edge responses, as this will improve our understanding of the impacts of habitat fragmentation on coral reef assemblages.

RECONSIDERING THE ECOLOGICAL IMPACTS AND SOCIAL CONSEQUENCES OF INVASIVE LIONFISH (Abstract ID: 29702)

Globalization, climate change, and other influences have accelerated the rate at which species invade and re-shape ecosystems. However, in the ocean there are few examples of successful invasions by vertebrate predators. A conspicuous exception is found in the Western Atlantic, Caribbean, and Gulf of Mexico, where the Indo-Pacific lionfish (Pterois volitans/miles) has become firmly established with unprecedented speed. There is a near universal call to reduce the abundance of lionfish, as their ecological impacts on native populations are thought to be enormous. We propose a deeper consideration of the lionfish invasion, by (i) identifying research gaps with respect to lionfish population and community dynamics, especially in the context of the huge geographic range over which the invasion has occurred; (ii) presenting data suggesting that lionfish impacts on native prey and predators may not be that different than those of native mesopredators released from predation, perhaps due to overfishing of apex predators like sharks and large groupers; and, (iii) reviewing socio-economic arguments for encouraging dive tourism centered on lionfish, raising awareness of environmental issues through the lens of the lionfish invasion, and for providing food to tropical developing countries by facilitating sustainable lionfish fisheries. We close with a call to action to reconsider place-based management of lionfish that is best suited to local social and ecological needs.

DISENTANGLING ECOLOGICAL AND ANTHROPOGENIC DRIVERS OF CORAL REEF FISH POPULATIONS IN THE WESTERN INDIAN OCEAN (Abstract ID: 29415)

Understanding the primary drivers that determine fish species assemblages on coral reefs is vital for effective conservation planning. However, separating factors that are natural, such as habitat requirements for juveniles fishes, from anthropogenic, such as fishing and climate induced coral bleaching, is challenging. The western Indian Ocean (WIO) represents a region of highly variable coral reefs ranging from shallow fringing reefs on the east African mainland to steep volcanic reefs in Comoros to turbid low relief reefs in north-east Madagascar. The abundance and size structure of over 140 species of coral reef fishes were measured together with a range of benthic and reef structure variables at over 100 sites in four countries of the WIO to examine correlates of fish species assemblages. Reef geographic location, structure and benthic composition all play a primary role in determining reef fish populations irrespective of anthropogenic influences. Principle species driving these patterns come from the acanthurids, chaetodontids, caesionids and scarids. The value of such large scale regional analyses lies in the ability to determine broad scale patterns in reef fish assemblages that can be attributed to natural ecological processes, after which anthropogenic drivers can be examined more closely. This revealed high impact areas related to fishing, areas with low impacts from coral bleaching and areas where protection measures appear effective. Disentangling these ecological and anthropogenic drivers now enables more accurate spatial planning to maximise the conservation of reef fish populations in the WIO.

EFFECTS OF AN ATYPICAL RAINFALL SEASON IN THE ACROPORA PALMATA POPULATION OF THE SIAN KAAN BIOSPHERE RESERVE (Abstract ID: 29905 | Poster ID: 477)

Due to the ecological importance of coral Acropora palmata during 2011-2013 we did an identification and characterization of the patches found at the Sian Kaan Biosphere Reserve (SKBR) for restoration purpouses. We found 24 high density patches (more tan 50 colonies grouped) distributed along the reef crest: 5 in the North, 13 in the Center and 6 in the South. Evaluation of condition and host and zooxanthella genotype identification was done for a sample of the patches found. During this period the population of Acropora showed an apparent stability in terms of changes in density and conditions of the colonies. Living tissue was higher than 80 percent with scarce recent mortality or other impacts. However by the end of 2013, the area was affected by an atypical rainfall season. High density patches were evaluated during 2014. Results showed more tan 70 percent of the patches affected in the center section and 30 percent in the south. Average living tissue inside the patches decreased 10 percent. Recent mortality increased in all sections: seven high density patches were found with 90 percent of colonies dead only in the central section. Although high genotype diversity was found in the area, the central section showed the lower values compared with north and south. Among the patches with higher survival, different combinations of symbiont and host genotypes were found. Looking at the different climate change related events it is then important for restoration programs to maintain higher diversity avoiding selection of specific genotypes to increase resilience.

LATITUDINAL DISCONTINUITY IN CORAL SYMBIOSES HAS THE POTENTIAL TO LIMIT SPECIES MOVEMENTS UNDER CLIMATE CHANGE (Abstract ID: 28878)

Perhaps the most significant marine symbiosis is that between reef building corals and dinoflagellates of the genus Symbiodinium. The ability of corals to thrive in specific habitats depends on the combined tolerance range of both symbiotic partners. Given the emerging migration of coral species from the tropical into higher latitudes under climate change, it is surprising that little information exists on symbiont diversity at higher latitudes and the processes defining species range margins for both symbiotic partners remain largely unknown. Here, we examine species composition of coral-symbiont associations amongst nine high-latitude coral communities along the eastern Australian coast and compare these to tropical GBR symbioses. A comparative community analyses is used to detect whether biogeography or environmental factors influence species boundaries. Compared to the GBR, symbiont diversity among high latitude coral communities was relatively high. Host generalist and specialist symbionts were common, yet these were genetically distinct from tropical symbiont species. Importantly, some coral species exhibited significant latitudinal discontinuity in their associated symbionts, indicating that local adaptation and/or genetic isolation of symbionts is common at high latitude locations. While it is unknown whether the observed breaks in symbiont species assemblages are due to dispersal limitation, adaptation under natural selection, or speciation, significant genetic discontinuity of symbionts within a coral species might restrict movement outside current range margins.

ASSESSING HEALTH OF MASSIVE *PORITES* SPP. IN THAI WATERS (Abstract ID: 29409 | Poster ID: 418)

Coral diseases are associated with both anthropogenic and natural stressors such as sediment from coastal development, excess nutrients, pollution, and competition with

macroalgae and reef benthic animals. The purpose of this study was to assess coral health by detecting prevalence of coral diseases on massive *Porites* in twenty two study sites covering the Eastern, Inner, Western Gulf of Thailand and the Andaman Sea during 2010 – 2015. High incidence of all coral diseases was found at Ko Khang Khao, Ko Nok, Ko Sak, in the inner Gulf of Thailand, Ko Samet and Ko Kudi in the eastern Gulf of Thailand, Ko Thai Phlao, Ko Sam Sao in the western Gulf of Thailand, Ao Thaimuang, Ko Surin Nua, Ko Rawi, and Ko Butang in the Andaman Sea. The major patterns of coral diseases in Thai waters consisted of pigmentation responses (pink lines, pink patches, pink spots, pink borers), white syndromes (white patches, white bands, ulcerative white spots), growth anomalies, fish bites and unusual bleaching patterns. Pink borers and white patches were the most prevalent disease at Ko Thai Phlao and Ko Sam Sao in the western Gulf of Thailand. Fish bites were mostly found at Ao Thaimuang, Ko Surin Nua, Ko Rawi and Ko Butang in the Andaman Sea. Poor water quality, especially with high nutrients and organic carbon, may link to high incidence of coral diseases in the Gulf of Thailand. This study supports evidence that higher coral disease prevalence is linked to anthropogenic disturbances on coral communities in Thai waters.

STUDY OF CORAL REEF ASSOCIATED MARINE BENTHIC POLYCHAETES IN THE MARINE NATIONAL PARK IN THE GULF OF KUTCH, GUJARAT, INDIA. (Abstract ID: 28651)

This study aims at understanding the ecological values of the coral reef and marine benthic polychaetes ecosystem at the Marine National Park in the Gulf of Kutch, Gujarat State, India. Polychaetes are highly abundant and/or diverse in most marine habitats, especially such benthic communities as soft sediments, algal turfs and fouling communities. For this, research environmental study has been carried out at the Okha and Vadinar, which is the prime area of the Marine National Park. The results of the study indicate that a total of 20 species belonging to 13 families was recorded at both study station. During the post-monsoon study period-2014, Nephthys oligobranchia, Lycastis indica, Capitella sp., Diopatra neapolitana, Glycera alba, Spirographis sp., Prionospio pinnata and Maldanides were the common species recorded in the study region. The less common species like Onuphis investigatories, Glycera lancadivae, Nereis cricognatha, Amage bioculata, Magelona sp. and a very rare species from the family Pontoderidae namely Pontodora pelagica were encountered during pre-monsoon-2015 period. Magelona cincta was the common, while the Capitella sp. was the dominant species. Seasonal changes do not seem to have much impact on the benthic polychaetes faunal abundance and diversity in the Coral reef vicinity. The study reveals that Hydrological and Sediment factors are most influencing abiotic factors in species diversity in the study area of the Gulf of Kutch Gujarat, India. Key words: Coral reef, Benthic, Polychaetes, Gulf of Kutch, Gujarat.

DISEQUILIBRIUM - IMPLEMENTING REEF MANAGEMENT STRATEGIES IN A WORLD OUT OF BALANCE (Abstract ID: 30090 | Poster ID: 404)

This analysis focuses on current issues in the field of coral reef conservation from perspectives of policy-based reef management, highlighting prominent biotic, abiotic and combination interactions that have driven changes in our modern environmental equilibrium. Historical attempts at local approaches are referenced to suggest the need for updated guidelines, strategies and a proposed globally-based support system of coastal reef management, mitigation and conservation. Many current practices in this sector are either outdated, inaccurate in basis or both. Site-specific implementation of monitoring and surveillance objectives provides a non-biased approach to separately addressing local, regional and global ecological stressors. Managing these stressors at varying spatial scales must prioritize interactive effects – either synergistic, antagonistic or additive in nature. Within isolated, underdeveloped and uneducated coastal regions of the world, colloquial lifestyles and social practices lack the modern social and scientific connectivity required to create conservation connectivity frameworks. These collectives (i.e. marine protected areas and marine reserve networks) facilitate integrative data network monitoring systems and aid reef-neighboring nations by updating perspectives and knowledge of current reef spp. and Scleractinian biodiversity. Maximizing local conservation strategies will establish benefits to local, regional and global ecosystem health and coastal human populations alike.

CORAL REEF RESPONSE TO RAPID SEA-LEVEL RISE DURING THE LAST DEGLACIATION: NEW EVIDENCE FROM THE DROWNED REEF TERRACES OF WESTERN HAWAII (Abstract ID: 29160)

Fossil reefs are valuable recorders of glacio-eustatic sea-level changes, providing key constraints on last deglacial meltwater pulses (MWP). Determining the timing, magnitude, rate and meltwater source of these rapid sea-level rise events has important implications for understanding ice sheet dynamics and abrupt climatic change. Several global records span MWP-1A, but no consensus has been reached on the precise details or its impact on reef growth. The Barbados reef record initially suggested MWP-1A occurred between 14.2-13.8 ka but subsequent studies from Hawaii and Tahiti suggest it occurred ~500 years earlier at ~14.7 ka. To further investigate MWP-1A and the drowned reef terraces of Hawaii, a SCUBA diving field campaign was conducted off Kawaihae to recover samples down to -150 m. We report eight new radiocarbon ages and corresponding laser ablation inductively coupled plasma mass spectrometry U-Th ages, which are interpreted within the context of all available published dates, to better constrain the timing of reef drowning around Hawaii. Detailed sedimentological analysis and sample vetting were employed to identify key indicators of paleo-sea level, and standardized paleoenvironmental interpretations of coralgal assemblages and drowning signatures were made. These data are integrated with dive observations and mapping data, revealing that the backstepping terraces are multi-generational features with sea level acting as a primary control on their complex evolution. We conclude that the age of Hawaiian reef drowning is consistent with a ~14.75 ka onset of MWP-1A.

ARE MESOPHOTIC CORALS AND OCTOCORALS REALLY THAT DIFFERENT? AN EVOLUTIONARY PERSPECTIVE FROM CARIBBEAN REEFS (Abstract ID: 29581)

Mesophotic coral reef communities are usually below recreational SCUBA diving but too shallow for deep-sea vehicle exploration. This study aimed to provide a systematic exploration of the mesophotic zone (40-120 m) in an oceanic barrier reef complex in San Andrés Island and on banks along the Deep-sea Corals National Natural Park. Using CCR/Trimix, we wanted to determine whether the mesophotic corals and octocorals comprised unique evolutionary lineages carrying particular traits. We reconstructed molecular phylogenies for both coral (ITS2) and octocoral (mtMutS) species down to 120m and identified their symbiotic microalgae, if present. For both, we found an abrupt lineage/community replacement where zooxanthellate species disappear and azooxanthellate species dominate. We documented this replacement occurring shallower for octocorals (~60m) than corals (~90m). Some reef-building corals, notably Agaricia undata and Madracis senaria, distribute well into this zone (~80m) and are characterized by an increased presence of the endolithic algae Ostreobium, which is notable at the colony surface. Shallow coral communities are replaced by unrelated azooxanthellate cup corals also associated to Ostreobium. For octocorals, younger species lineages are replaced by older lineages characterized by phylogenetically dispersed species, which have thinner branches and smaller polyps than the shallow-water species. Our results suggest that the lower-mesophotic corals and octocorals (>60m) are old lineages related to deep-sea species, whereas upper-mesophotic (<60m) species are young species in response to deep-related ecological divergence.

THE STRUGGLE FOR EXISTENCE -- HOW COMPETITION REIGNS, ESPECIALLY WHEN PREDATION ABOUNDS (Abstract ID: 29907 | Poster ID: 2)

The seminal work of Gause and colleagues led us to consider the prominent role of competition in constraining the development of communities. When considering pairwise combinations of similar species in a closed environment, one species will exclude the other in the so-called "struggle for existence". In nature, though, we observe quite the contrary with countless species coexisting, challenging the strength of competitive dynamics in regulating community structure. Our group has been considering how complex ecological communities are organized, focusing on highly-diverse coral reef ecosystems and exploiting natural experimental conditions linked with human harvest and manipulation across replicate coral reef ecosystems (islands of the central Pacific). By including relatively untouched coral reef ecosystems as ecological end-members

into the study, we have identified the profound importance of predator-prey dynamics in structuring communities. Critically, within the context of intensive predation we find a complementary increase of competitive dynamics -- both with prey competing with prey and predators competing with predators. These observations lead us to consider a new framework in which Gause's "struggle for existence" is brought into increasing focus in well-developed ecological communities, and in which predation and competition are synergistic processes that lose their rhythm as the trophic structure of ecosystems is perturbed.

PRIMARY PRODUCTION AND NITROGEN FIXATION OF ENDOLITHIC ALGAE ASSOCIATED WITH THE MASSIVE CORAL *PORITES LUTEA*(Abstract ID: 29008 | Poster ID: 96)

The symbiotic zooxanthellae mainly contribute with photosynthetic products for the nutrition requirements of host. During bleaching event, some corals can survive from stress condition when they lose their zooxanthellae. It was suggested that the biological activity of endolithic algae living within coral skeletons might be an alternative source of energy and food during bleaching events. However, there are few studies on possible translocation of photoassmilates to coral polyps. Therefore, we wanted to investigate the contribution of endolithic algae associating with *Porites lutea* by examining primary production and nitrogen fixation by incubation experiments using $^{13}C$ and $^{15}N$ tracer techniques. We want to discuss possible translocation process between endolithic primary producers and the host. Three conditions (control, partially bleached coral and healthy coral) were used during *in situ* incubation at Sesoko beach, Okinawa, Japan. Primary production of endolithic algae was the same order of magnitude to those of coral polyps. Nitrogen fixation that occurred during the day and also during the night showed that heterocyst possessing cyanobacteria are important components of the endolithic community.

REPRODUCTIVE PLASTICITY OF THE SCLERACTINIAN CORAL ACROPORA HYACINTHUS LIVING IN DIFFERENT TEMPERATURE ENVIRONMENTS (Abstract ID: 28494 | Poster ID: 38)

Previous studies often linked the delay of coral spawning timing to decreasing seawater temperatures at higher latitudes. However, it is still not clear whether the shift in coral species' spawning timing is caused by either genetic divergence or phenotypic plasticity of corals to local temperature environments. This study focused on examining reproductive plasticity of different populations of the broadcast-spawning scleractinian coral Acropora hyacinthus, living in different temperature environments. Considering traits that are crucial determinants of fertilization success and post-settlement performance, plasticity in reproductive timing and polyp-fecundity (e.g., egg-size, testis-size, total gamete vol.) were examined during 2015–2016 through a reciprocal transplantation experiment between southern and northern coasts of an islet (Lyudao) located in southeastern Taiwan. Additionally, intraspecific variation and plasticity in polyp-fecundity were compared during 2014–2015 among populations at six latitudinal locations [Japan (32˚N), Taiwan (22–25˚N), and Indonesia (6˚S)]. We specifically expect larger egg-sizes and a delay in spawning timing at the colder-areas (higher latitude), demonstrating significant reproductive plasticity among populations living in different local temperature environments. The results of the present study will provide new insights into coral reproductive strategies and plasticity in response to different seawater temperatures.

DEVELOPING THE BIOLOGICAL CONDITION GRADIENT (BCG), AS A TOOL FOR DESCRIBING THE CONDITION OF US CORAL REEFS (Abstract ID: 28397)

Understanding effects of human activity on coral reefs requires knowing what characteristics constitute a high quality coral reef and identifying measurable criteria. The BCG is a conceptual model that describes how biological attributes of coral reefs change along a gradient of anthropogenic stress. The BCG provides a framework using qualitative and quantitative reef attributes to determine current coral reef conditions. Experts in coral reef organisms (coral, fish, sponge, gorgonian, algae) developed a BCG model for Puerto Rico. The model describes the full range of biological conditions resulting from human disturbance, including community structure, organism condition, ecosystem function and connectivity. Each condition level is defined and grounded in natural biological integrity. Levels contain a detailed narrative and process for translating specific metric scores. Reference condition is a natural fully-functioning coral reef that serves as a non-shifting baseline and established through expert consensus. BCG levels can be aligned with designated aquatic life uses specified in water quality standards and used for protection and potential restoration of coral reefs. Managers can use the BCG model to define biological integrity grounded in natural condition, assess current conditions relative to high quality coral reefs, track changes in condition as responses to management actions, and communicate environmental condition and outcomes to the public. The BCG model will be broadly applicable to Caribbean reefs, and the process is transferable to other oceanic regions.

REVEALING THE MURKY HISTORY OF THE CORAL TRIANGLE (Abstract ID: 29339)

New studies on the fossil record of Late Cenozoic corals from Eastern Borneo have revealed that the first coral assemblages that occurred in the region were mainly low-relief patch reefs. These ancient reefs developed under marginal environmental conditions of low light and high sediment inputs that we interpreted as shallow turbid habitats. Conversely, these marginal habitats hosted a high coral diversity with 100 morphospecies of 55 genera in the Oligocene and 234 morphospecies of 79 genera in the Miocene. The fauna was dominated by platy growth forms of the genera *Porites*,*Cyphastrea*, and *Leptoseris*. We found no significant faunal turnover at generic level within the studied time interval as 85 percent of genera were already present by the early Miocene. Diversity trends through time at species level appear more dynamic, but detailed taxonomic work is still required to provide a complete picture of species turnover in the region. For example, our taxonomic revision of *Acropora* fossils uncovered 31 species including 23 extant species with their first occurrence in the Neogene. Preliminary comparisons of ancient turbid reefs with analogous modern habitats of Eastern Borneo show similarities in richness and faunal composition with dominance of platy corals of the family Agariciidae, foliaceous *Porites* and abundant plate-like colonies of *Acropora elegans*. Our observations suggest that turbid reefs have played an important role during the origination and maintenance of coral diversity in the Coral Triangle.

ROLE OF THE CORAL HOLOBIONT IN NITROGEN REMINERALIZATION WITHIN DIVERSE CORAL REEF ECOSYSTEMS (Abstract ID: 28166)

Efficient nutrient recycling is thought to be a major factor in the maintenance of high productivity in coral reef ecosystems. The specific mechanisms and locations of nutrient recycling within these ecosystems, however, are poorly described. We used stable isotope tracers (15N) in coral microcosm incubations to determine rates of nitrification, the oxidation of ammonia ($NH_3$) to nitrate ($NO_3$-), associated with stony corals from the genera *Porites* and *Orbicella*. Incubations were conducted in three divergent reef ecosystems: the Micronesian archipelago; Gulf of Batabano, Cuba; and the lower Florida Keys reef tract, with 13 individual coral colonies. We detected nitrification associated with both *Porites astreoides* and *Orbicella faveolata* corals. In contrast to high nitrification rates associated with corals, rates in the waters surrounding the reefs were at or below detection limits. Molecular screening of coral tissue and mucus for the ammonia monooxygenase gene (*amoA*) indicated the presence of ammonia-oxidizing archaea, but not betaproteobacterial ammonia-oxidizing bacteria. Interestingly, several colonies showing high rates of nitrification did not screen positive for known ammonia-oxidizing organisms, suggesting the presence of novel nitrifiers not detected with current methods.

3D MAPPING OF SEABED BATHYMETRY USING TEARDROP AND SIDESCAN SONAR (Abstract ID: 29239)

The deterioration of marine ecosystem is a growing concern which calls for regular monitoring and assessment. High-resolution underwater cameras attached to towable platforms such as Teardrop (ICRS 2012) are popularly used to gather and archive underwater images, but during low visibility, hours of data gathering become useless. Nowadays, commercial sidescan sonars that can provide depth and seabed topography have become affordable. Although sidescans are not affected by underwater visibility, the lack of other visual information causes uncertainty. For example, if a protrusion is detected by the sonar, it is difficult to identify if the structure is a coral colony or a boulder. In this work, we propose a technique that combines the topographic output of a sidescan sonar and the visual output of the Teardrop imaging platform to create a 3D map of the seafloor where benthos can be identified. Visual analysis of sidescan sonars can establish a 2D to 3D relation to generate 3D maps. Algorithms to align structures seen in sonar with features seen in video were developed. Since the sonar and Teardrop outputs are geo-referenced individually, data from both units may not be simultaneously taken. This can be very valuable when weather conditions do not permit the capture of either data. Three-dimensional mapping of seabed allows faster analysis of the topography's influence to coral distribution and habitat suitability, while images from Teardrop enable diverless monitoring of coral reefs. The proposed technique is a promising tool for rapid assessment of marine habitats.

VERTICAL DISTRIBUTION OF MEIOFAUNA IN THE NEARSHORE NON-REEF INTERSTITIAL ENVIRONMENT GULF OF KACHCHH GUJARAT INDIA (Abstract ID: 29431 | Poster ID: 661)

The composition and distribution of the benthic meiofauna conglomeration of the Mundra coastal subtidal waters along the Gulf of Kachchh Sea are described in relation to abiotic variables. Sediment samples were collected seasonally from three stations chosen along the vicinity of Adani Power Limited Mundra, sea intake, outfall nearshore and control as offshore regions to observe the meiofaunal community structure, its temporal distribution and vertical fluctuation in relation to environmental conditions of the nearshore marine ecosystem. The temperature, salinity, pH, dissolved oxygen, BOD, nutrients and chlorophyll and Phaeophytin were measured at the time of collection. The water content of the sediments, total organic matters and chlorophyll -a and Phaeophytin values were determined, and sediment samples were subjected to granulometric analysis. A total of 12 meiofauna taxa were identified, with the meiofauna being primarily represented by nematodes, foraminifera harpacticoids, polycheates and ostracodes; and the meiofauna abundances ranging from 21 to 275 individuals/10 square-cm. The meiofaunal population density variation seasonally with high density during pre-monsoon, at all stations. The vertical zonation in the distribution of meiofaunal community was significantly correlated hydrography, chlorophyll a, Phaeophytin and total organic matter values. The present study indicates the existence of the well diversified meiofaunal group which can serve as food for higher trophic levels in the Gulf of Kachchh interstitial coastal environment.

SYSTEM THINKING TO SUSTAINABLE CORAL REEF MANAGEMENT FOR ACHIEVING REGULATORY COMPLIANCE: CASE STUDY OF CORAL TRIANGLE IN INDONESIA (Abstract ID: 28512 | Poster ID: 565)

Despite serious attention on conserving coral reef ecosystem in Indonesia, blast fishing is still rampant which threatens the state of this ecosystem. However coral reef ecosystem is a very complex system which involves various stakeholders with different interests and intentions therefore it needs appropriate approach to assist government in managing this environment sustainably. A system thinking approach through system dynamic modeling could be an alternative tool for communicating among stakeholders to understand the dynamic complexities and the interrelations between key variables by developing a mental model (causal loop diagram) and quantitative model (stock flow diagram) that describes positive and negative polarities, as well as balance and reinforcing loops. The model shows that compliance is not only driven by basic deterrence approach through performing certainty and severity of enforcement but also driven by moral obligation, social influence, and public perception on legitimacy of enforcement authorities. However the model needs to be simulated and tested in further research by using real data thus it can be improved and finally utilized for setting up better policy interventions and avoiding any unintended consequences.

CORAL REEF RECOVERY 2015: A DECADE AFTER AN EARTHQUAKE ON NIAS ISLAND , NORTH SUMATERA, INDONESIA (Abstract ID: 28351 | Poster ID: 210)

Nias is an island in Indian Ocean off the west coast of Sumatera. In 2005, an earthquake measuring 9 on the Richter Scale hit the island. Much of the island, particularly the coastal ecosystem like coral, seagrass and mangrove, was damaged or destroyed. The earthquake lifted the seafloor up three meters to the surface and added about 100 hectares of new land. The objective of this study is to determine the extent of the recovery of coral reefs there, a decade after the massive earthquake. Fieldwork was carried out annually from April 2004 until September 2015 in eight permanent stations. Line Intercept Transect (LIT) and Underwater Photo Transect (UPT) methods were used to collect biotic and abiotic data from each station. The observations showed that coral coverage in 2004 was 48.31% and monitoring one year after the earthquake in 2005 showed the coverage was 21.39%. Coral recovers slowly. In 2015, the coral coverage was 26,76% and it was in a fair condition. However, the coral coverage was still only 44,60% of that prior to the massive earthquake. It is not surprising that the process occurs slowly because coral reef is a vulnerable ecosystem which is easily influenced by environmental factors as well as human activities. Nevertheless, branching coral of Acropora was recovering well in several sites.

SPERMONDE ISLANDS AND CORAL REEF FLATS MORPHOLOGICAL DYNAMICS (Abstract ID: 30048)

It was necessary to understand the dynamics of the Spermonde islands in which the future growth or demise of these islands may have important impacts and influence human development of the areas. Area studied was covering more than 40 islands plus submerged coral reefs. Land-sat images of islands and including the reefs surrounding them were collected from 1978, 1990, 2001 and 2010 (NOA-free website. Evaluation of island morphology and coral reefs changes were done through correction of the land-sat images using software Arc View and analyzed to determine the area changes of the islands and reef flats over time. The ratio of island and reef flats area was analyzed using Lyzenga formula. The area of each island and its reef flats was measured, and compared over years. Spatial analysis of satellite images allowed for calculation of area changes from the most loss of 1.46 ha to the most gained of 1.07 ha. Periods of islands decline by 2010 may seems correspond with the passage of recently recorded storms in 2008 to 2010. As for the reef flats the highest lost area is occured in Bonetambung islands up to 9.38 ha, followed by Kulambing with the lost of 8.9 ha. Mass coral bleaching during the early 2009 to mid 2010 seems could contribute to abrasion and accretion processes of the islands although the impact has not yet shown. This research found some of Spermonde islands are already experiencing area lost, both the island and the reef flats, hence potential to become uninhabitable.

GULF OF KACHCHH MARINE NATIONAL PARK, INDIA, A POTENTIAL CLIMATE-CHANGE REFUGE FOR CORALS (Abstract ID: 29341)

Gulf of Kachchh, the northern most reef region of Indian ocean is the grossly and wrongly under rated reef environment, probably due to low scleractinian coral diversity, total disappearance of branching corals and turbid waters. Qualitative, quantitative and status studies carried out by Zoological Survey of India since 2001 reveal the fact that the biophysical status of Kachchh reefs is on par with other reef regions with an average live coral percentage of about 31%, 45 extant Scleractinian coral species and 800 associated species including the endangered marine mammal Dugong dugon. Scleractinian species of Kachchh are unique, hardy and adopted to harsh semi-arid, sedimented and exposive conditions. The bleaching record of Kachchh is always low to the tune of 10% on an average when compared to about 90% of bleaching reported in other reef regions. The Coral Restoration Project of ZSI under ICZM project of Ministry of Environment, Forests and Climate Change has brought out new findings enhancing the value of Kachchh reefs to the tune of identifying them as 'Climate-change refuges'. 4 species of Staghorn corals brought from Gulf of Mannar and transplanted in Kachchh survived well even in 2014, the hottest year while the mother colonies at GOMBR bleached. Branching corals, disappeared 10,000 years back are now growing well in the waters adjacent

to Mithapur, an industrialised area. The value of Kachchh in terms of its resilience, diversity, tourism potential, biophysical and bleaching status in relation to climate change is discussed in detail in this work with the listing of potential threats and strategies for the conservation of reefs and associated fauna.

RESTORATION OF EXTIRPATED SCLERACTINIAN CORALS IN TURBID ENVIRONMENT AT GULF OF KACHCHH, INDIA – A SUCCESS STORY (Abstract ID: 28656)

Gulf of Kachchh, the northern most limit of coral distribution in the Indian Ocean, inhabits temperature tolerant and most adopted residual coral species. Up-liftment of tectonic plates of the Gulf and transgression of sea levels made all branching corals to extirpate. Semi-arid conditions, large semi-diurnal tidal amplitude, coral exploitation in the past, high sedimentation, industrialization and anthropogenic activities degraded the reefs and hampering the resilience and recovery capacity of the reefs. During 2013-2015, a total 1000 sq. m. area was restored in 3 spatially distinct sites, along the Southern Gulf using jeopardized native coral species and branching coral species brought from Gulf of Mannar, about 2600 km. far. Site specific innovative and modified restoration methods and modern technologies including remote-sensing were used in each and every step of reef rehabilitation. Maximum survival rate of native coral transplants has been recorded in Pirotan (97.24%) and minimum in Narara (96.50%). Likewise maximum survival rate of branching coral species has been observed in Mithapur (85.25%) and was least in Pirotan (68.75%). Among the native transplants, Cyphastrea serailia recorded highest mean extension rate followed by Porites lichen (5.81±2.12 cm/yr and 5.42±1.25 cm/yr respectively). Among branching coral transplants, Acropora formosa and A. intermedia recorded highest mean extension rates (8.04±1.17cm/yr and 7.13±1.84 cm/yr respectively). Damming reduced sedimentation and site specific strategies are the prime reasons for restoring 10,000 years back extirpated staghorn corals successfully in the Gulf.

COMMUNITY-BASED RESILIENCE AND ADAPTATION TO CLIMATE CHANGE: USING PLA TOOLS TO FACILITATE VILLAGE CLIMATE RESILIENCY IN AMERICAN SAMOA (Abstract ID: 29506)

Coastal communities are particularly vulnerable to climate change due to their proximity to and reliance on the ocean. Fostering climate resiliency requires an approach that can inform community members about potential climate impacts, obtain community input, and work to turn community needs, priorities, and ideas into actionable items. Participatory Learning and Action (PLA) is one such approach that is well suited to community climate vulnerability assessment and adaptation planning. PLA is a bottom-up approach that aids in gathering information using a diverse range of activities and tools to facilitate participation of local people to strengthen their capacity to engage, learn, and act. Through this approach, the community has the opportunity to learn about key issues regarding their local resources and environment and subsequently implement appropriate strategies to meet those needs. Communities take ownership in the process and the implementation of actions proposed in their resiliency plans. The village of Amouli, a coastal community in American Samoa, used a participatory process in 2011, strengthened by local scientific studies, to develop a village climate resiliency plan. Through the use of PLA tools and modeled results, the village predicted climate impacts were likely to have significant implications on village livelihoods. Aunu'u and Vatia are the most recent village communities that have been engaged in community resiliency outreaches through PLA tools to ensure broad community participation and understanding on potential issues of climate change, with the ultimate goal of building community resiliency and adaptation towards climate change impacts.

A TRIAL OF IMAGING SONAR SYSTEMS IN COMBINATION WITH STEREO-VIDEO CAMERAS (Abstract ID: 29342)

In waters with varying visibility levels, such as macro-tidally affected reefs, sampling of fishes is challenging using visual-based census techniques. A number of imaging sonar systems have evolved that may be applied to sampling fishes in such waters. We evaluated the relative abundance and length measurements of fishes recorded using four imaging sonar systems in combination with Underwater stereo-Video. The imaging sonar systems trialled (Kongsberg M3, Sound Metrics DIDSON, Teledyne BlueView, and Tritech Gemini) differ in specifications including frequency, range, beam pattern and power. Laboratory comparisons of length measurements using fishes of known length were carried out at the Australian Centre for Applied Aquaculture Research in Fremantle, WA. That study showed that each imaging sonar system measured consistently, but that corrections may need to be applied to gain accurate length measurements. Field comparisons with Baited Remote Underwater stereo-Video (stereo-BRUVs) were carried out in seagrass habitat in Cockburn Sound, WA. While it was not possible to differentiate similarly sized species from the sonar footage, the relative abundance by size class estimates were similar between the imaging sonar and stereo-video recordings. Each imaging sonar system had advantages and disadvantages, with greater image resolution gained at the expense of depth of field. A combination of baited imaging sonar and stereo-BRUVs has great potential for increasing the value of the information that can be collected when sampling fishes in areas of variable visibility.

TECTONIC SUBSIDENCE PROVIDES INSIGHT INTO POSSIBLE CORAL REEF FUTURES UNDER RAPID SEA-LEVEL RISE (Abstract ID: 27803 | Poster ID: 398)

A magnitude 8.1 subduction earthquake over a relatively pristine coral reef in Solomon Islands in April 2007 caused rapid relative sea-level rise of 0.6 m, generating a unique opportunity to examine *in situ* coral reef response to relative sea-level rise of the magnitude (but not the rate) anticipated by 2100. Extent of live coral was measured from satellite imagery in four years before and after subsidence. Ecological data were obtained from microatolls and ecological surveys. The reef was sampled at 12 locations where dense live hard coral remained absent, remained present, or changed from absent to present following subsidence. To identify factors associated with coral response to relative sea-level rise, ecological data (substratum depth, live coral canopy depth, coral canopy height, substratum suitability, recruitment, diversity and *Acropora* presence) were measured at each location. Vertical and horizontal proliferation of coral occurred following subsidence. Lateral expansion of live coral, accomplished primarily by branching *Acropora spp.*, resulted in lower diversity in regions which changed composition from pavement to dense live coral following subsidence. On relatively pristine reef flats under present climatic conditions, rapid relative sea-level rise generated an opportunity for hard coral. However, the species assemblage of the existing reef was important in determining response to sea-level change, by providing previously bare substrate with a source of new coral colonies. Degraded reefs with altered species composition and slower coral growth rates may be less able to respond to climate change-induced sea-level changes. http://link.springer.com/article/10.1007/s00338-015-1365-0

SEABIRD NUTRIENTS PROMOTE GROWTH AND RESILIENCE OF CORALS: IMPLICATIONS FOR ECOSYSTEM MANAGEMENT (Abstract ID: 29014)

Marine conservation and management tends to focus on connectivity between seascapes to promote ecological connectivity processes, while often overlooking land-to-sea connectivity. Research demonstrates that seabirds are important vectors of marine nutrients to terrestrial ecosystems, but the influence of seabird-derived nutrients on marine ecosystems is less studied. Using a model island ecosystem in Fiji with a long-term marine protected area and adjacent intact watershed, we demonstrate the uptake of seabird nutrients in corals with chemical tracers. This nutrient subsidy increases coral growth and photosynthetic efficiency of a dominant reef-building coral. Complementary laboratory experiments and reciprocal transplant experiments further support our findings that seabird nutrients enhance resilience of coral reefs near seabird roosting sites when there are abundant populations of herbivorous fishes. This research highlights the need to study pristine ecosystems to understand ridge to reef connectivity and the importance of a holistic ecosystem-based approach that integrates marine and terrestrial systems in conservation planning and management.

SPATIO-TEMPORAL VARIATION OF CORAL GENE EXPRESSION ACROSS 12 LATITUDES AND 2 SEASONS IN THE RED SEA (TEMPERATURE: 21° - 33°C) (Abstract ID: 29327)

The southern Red Sea is one of the hottest coral reef regions worldwide with summer temperatures up to 33°C. This temperature is considered deadly for corals in most other biogeographic regions. Nevertheless, coral reefs are diverse and structurally complex in the southern Red Sea. This makes Red Sea corals an interesting study object in the context of global warming. By understanding underlying mechanisms of coral thermal tolerance in the Red Sea, we hope to increase our understanding on the ability of corals to adjust to ocean warming. Here, we investigated the gene expression of the coral Pocillopora verrucosa in winter and in summer at 6 stations from the northern (Gulf of Aqaba, 28.5°N, 21-27°C) to the southern Red Sea (Farasan Islands, 16.5°N, 28-33°C) using Illumina sequencing. Results are discussed in relation to coral performance, such as photosynthesis, calcification, mucus release and expression of heat shock proteins, as well as to the coral's genetic composition (host's genotype and Symbiodinium clade/type). This study seeks to elucidate the mechanisms behind the exceptional thermal tolerance of corals from this region.

INVESTIGATING THE ROLE OF EXTRACELLULAR MATRIX GENES DURING TEMPERATURE STRESS IN THE SEA ANEMONE, AIPTASIA PALLIDA (Abstract ID: 29011)

Matrix metalloproteinases remodel the extracellular matrix and play a role in regulating cell proliferation and cell death through either apoptosis or autophagy. We are investigating how increased temperature affects the expression of a MMP as well as collagen in the sea anemone Aiptasia pallida. In addition we are also using rt-qPCR to determine how increased water temperature affects the expression of two stress-sensitive genes (HSP90 and ubiquitin) relative to either the control gene NADH-dehydrogenase 5 (NDH5) or glyceraldehyde-3-phosphate dehydrogenase 1(GPD1). We temperature-shocked anemones for 0, 6, and 12 hours, isolated RNA, converted it to cDNA, and then used qPCR to measure gene expression. MMP and ubiquitin expression relative to NDH5 showed elevation at 6 and 12 hours, however when expressed relative to GPD1, MMP and ubiquitin were elevated at 6 hours, but not at 12 hours, while collagen expression was elevated at 12 hours. These results suggest that temperature is inducing changes in gene expression for MMP and collagen, but it is also affecting the control genes in a manner that was unexpected. Thus, temperature is inducing changes in expression of the control genes NDH5 and GPD1. We are investigating the relative expression of the two control genes and are also investigating whether a third control gene, actin, will resolve these discrepancies. Results from this study will help elucidate the underlying cellular mechanisms of temperature-induced Cnidarian bleaching and yield insight into which cellular pathways are affected by increased water temperature.

POST-GLACIAL CLIMATE VELOCITY PREDICTS DIVERSITY IN INDO-PACIFIC REEF-BUILDING CORALS (Abstract ID: 30083)

Resilience in the face of environmental change is determined, in part, by a species' ability to adapt to novel climatic combinations, but also in its ability to track its preferred niche across the landscape via dispersal. Examining the response of species and communities to climatic changes from paleontological to modern times may provide insight into their long-term persistence in the future. Here I examine biodiversity patterns on Indo-Pacific coral reefs as a function of modern climate and also the velocity of climate change since the peak of the last ice age 21,000 years ago. I find that the geographic range of most contemporary corals encompasses climatic combinations with no ice age analogue, and that species richness on non-analogue reefs is higher than on analogue reefs. However, the velocity of post-glacial climate change, measured in terms of dispersal distance and the overall magnitude of change, is a significant negative predictor of species richness. In other words, climatically more stable reefs harbor more species than more rapidly changing reefs, possibly as a consequence of lower rates of local extinction over evolutionary time frames. These results indicate that reef-building corals possess the capacity for climatic niche evolution over the course of tens of thousands of years, but are more susceptible to rapid change. This study provides strong evidence that Indo-Pacific coral reefs will be highly vulnerable to the rapid warming predicted to occur over the next century.

REGIONAL-SCALE EVALUATIONS OF WATER QUALITY AND CORAL REEF CONDITION IN THE INNER GREAT BARRIER REEF HIGHLIGHT CHALLENGES FOR ADAPTIVE COASTAL ZONE MANAGEMENT (Abstract ID: 29325)

A key pressure for the ecosystems of the Great Barrier Reef World Heritage Area is the exposure to runoff from broad-scale land use in the adjacent catchments. Regular assessments of the condition of the marine environment are essential to evaluate the effectiveness of management strategies put in place to address this pressure, and to support adaptive coastal zone management. A 10-yr program of monitoring the water quality and condition of inshore coral reefs clearly demonstrates the cumulative impact of multiple disturbance events, including tropical cyclones, outbreaks of crown-of-thorns seastars, coral bleaching and periods of high river discharge with associated high nutrient and sediment loads. Resultant declines in inshore water quality and coral community condition are broadly consistent over geographic regions and across various taxonomic groups. This demonstrates the importance and broad 'footprint' of runoff within the inshore Reef lagoon. Within a location, responses of coral communities are most obvious during extremes in environmental conditions. The results are examined using the DPSIR framework (driver-pressure-state-impact-response) to highlight i) the complexity of the relationships between river inputs, water quality and coral reef condition, ii) the challenges for evaluating, reporting and applying the monitoring information in a meaningful way in coastal planning and adaptive management, and iii) the expected long timeframes for measurable improvements in the inshore water quality under the current policy initiatives.

PARTICIPATORY FISHERIES MONITORING PROGRAMS TO SUPPORT LOCAL MANAGEMENT (Abstract ID: 28504 | Poster ID: 728)

With increased understanding of spatial and temporal population variability comes increased responsibility to incorporate this variability into fisheries management. This is unfeasible for many fisheries, especially data-poor ones that are typical of tropical reefs. One solution is participatory monitoring programs where local fishers, scientists, and regulating agencies work together to gather the necessary information to inform local management. These co-developed monitoring programs collect fishery data at the community scale through incorporating local knowledge along with biological surveys including gonadosomatic index (GSI) and histological assessments of reproductive state. Comparisons between community-collected GSI data and histologically accessed reproductive status produced similar results. Therefore, using basic tools such as scales and rulers, local communities can gather and interpret the necessary information to determine the reproductive biology needed for management. Result were shared with diverse resource users to support customary fishing practices through the use of moon calendars, which inform fishers as to the proper times and sizes to catch fishes specific to that location. Additional benefits included increased understanding by fishers of natural cycles in resources, which led to behavioral changes in fishing practices, resulting in greater conservation and management of these resources. Participatory programs like these build trust among groups, increase management capacity, and ultimately lead to more resilient linked social-ecological systems.

VARIATION OF SYMBIONT DENSITY OR CELL PIGMENTATION OF SYMBIODINIUM CAUSES DIFFERENT EFFECT ON HOLOBIONT PRODUCTIVITY AND ON ITS SENSITIVITY TO CORAL BLEACHING (Abstract ID: 28400)

Drastic changes in coral pigmentation occur during bleaching events but significant reductions may also occur in summer as part of the photoacclimatory response of the holobiont to the combined seasonal fluctuation in light and temperature. Those changes in coral colour result from two underlying causes, 1) the loss of symbionts and 2) the loss of Symbiodinium pigmentation per cell (Ci). As coral bleaching has been defined as a severe loss of coral colour, seasonal coral paling (optimal holobiont acclimation to summer conditions) cannot be always distinguished from bleaching (a dysfunctional symbiosis). Here we present evidence for four Caribbean coral reef-builders that similar changes in coral pigmentation respond to contrasting physiological conditions in the holobiont. Furthermore, we present an allometric analysis of the differential contribution of symbiont density and Ci to holobiont productivity (photosynthesis and calcification) and to the variation of the specific absorption coefficient (a*, m2 chla-1). Our results highlight the relevance of symbiont losses vs. changes in Symbiodinium Ci to set the "tipping point" of this ancient symbiosis, and that these physiological thresholds, which determine coral bleaching, are related to the extraordinary efficiency of Scleractinian corals as solar energy collectors. Understanding the capacity of the holobiont to maintain a minimum population of Symbiodinium under the increasing levels of light-stress that occur during events of elevated temperature, will highlight its particular sensitivity/robustness to global warming.

CORAL REEF CONNECTIVITY IN THE WIDER-CARIBBEAN: DESIGN OF MARINE PROTECTED AREA NETWORKS (Abstract ID: 27995)

We integrated coral reef connectivity data for the Caribbean and Gulf of Mexico into a conservation decision-making framework for designing a regional scale marine protected area (MPA) network that provides insight into ecological and political contexts. We used an ocean circulation model and regional coral reef data to simulate eight spawning events from 2008–2011, applying a maximum 30-day pelagic larval duration and 20% mortality rate. Coral larval dispersal patterns were analyzed between coral reefs across jurisdictional marine zones to identify spatial relationships between larval sources and destinations within countries and territories across the region. We applied our results in Marxan, a conservation planning software tool, to identify a regional coral reef MPA network design that meets conservation goals, minimizes underlying threats, and maintains coral reef connectivity. Our results suggest that approximately 77% of coral reefs identified as having a high regional connectivity value are not included in the existing MPA network. This research is unique because we quantify and report coral larval connectivity data by marine ecoregions and Exclusive Economic Zones (EZZ) and use this information to identify gaps in the current Caribbean-wide MPA network by integrating asymmetric connectivity information in Marxan to design a regional MPA network that includes important reef network connections. The identification of important reef connectivity metrics guides the selection of priority conservation areas and supports resilience at the whole system level into the future.

COMPARISON OF BACTERIAL COMMUNITIES ASSOCIATED WITH *AGARICIA LAMARCKI* FROM MESOPHOTIC AND SHALLOW WATER REEFS (Abstract ID: 30104 | Poster ID: 321)

Access to mesophotic reefs provides a unique opportunity to study the holobiont composition in corals across their bathymetric distributions. We aim at characterizing the coral-associated bacterial community profiles of the scleractinian coral *Agaricia lamarcki* in Puerto Rico and U.S. Virgin Islands. *Agaricia lamarcki* attains a wide bathymetric distribution in the Caribbean where it can be found in shallow (5-10) m and mesophotic reefs (80 m). Associations between bacterial communities and coral hosts are generally species specific, however, we hypothesize that shifts will be observed in the bacterial communities associated with shallow and mesophotic corals. We recently sequenced thousands of DNA sequences using Illumina sequencing technology from the bacterial 16S rRNA gene from over 50 samples of *A. lamarcki* tissue. Comparison of alpha and beta diversities and compositions of samples will be made using the Qiime software and differences in phylogenetic composition between depth-differentiated samples will be visualized with heat maps and network representations.

THE EFFECTS OF ENVIRONMENTAL FACTORS ON BLACKTIP REEF SHARKS, CARCHARHINUS MELANOPTERUS, ON AN INSHORE REEF (Abstract ID: 29292)

Understanding how reef sharks respond to variability in their environment is increasingly important given their vulnerability to climate change. Due to their close proximity to the mainland, sharks resident on inshore reefs are frequently exposed to fluctuating environmental conditions (e.g. high freshwater run-off/low salinity events). However, documented site attachment to coral reefs means movement in response to unfavourable environmental conditions may not be desirable for these species. Passive acoustic telemetry was used to monitor movement and space use of 18 blacktip reef sharks, Carcharhinus melanopterus, on an inshore reef off the coast of Queensland, Australia to define their response to environmental change. Activity space of sharks was modelled against all possible combinations of environmental (wind speed, barometric pressure, rain, salinity and water temperature) and biological (size, sex) factors and compared using Akaike information criterion corrected for small-sample bias. Model results indicated a relationship between shark activity space and salinity with space use increasing with decreasing salinity. Size and sex were also significant factors in the top performing models with larger sharks having larger activity spaces and males using more space than females independent of size. These results show salinity is an important environmental driver of movement and space use for C. melanopterus on an inshore reef and help define how resilient this species is to environmental disturbance and change.

ARE ALCYONACEAN SOFT CORALS THE 'GLUE" THAT HOLDS A REEF TOGETHER UNDER EXTREME CONDITIONS? (Abstract ID: 29195)

Alcyonacean soft corals are gaining increasing attention in the South West Indian Ocean (SWIO) where they are a significant component in coral communities. Surveys extending from the Chagos Archipelago towards East Africa and down the Mozambique Channel were expected to reveal a biodiversity gradient in their distribution but anomalies have emerged. While alcyonacean biodiversity in the Chagos is high, it is superseded by that at Mayotte, a regional hot spot for corals. A gradient does occur down the Mozambique Channel but another hot spot is found on South African reefs where more temperate alcyonaceans enter the picture. Anomalies are found within this range, with unexpectedly low diversities of Alcyonacea at Reunion, Geyser, Zélée and Glorieuses Island where they have nevertheless adapted to local conditions. The drivers that appear involved in this are turbulence and volcanic substrata at Reunion, greater sediment movement at Geyser and Zélée, and eutrophication with sedimentation at Glorieuses. Increasingly dynamic surf conditions on south East African reefs introduce greater turbulence and sediment movement at higher latitudes. Certain soft corals flourish under these different conditions and can play an important role in reef stability or reef recovery after disturbance. Slow-growing persistent forms provide stability while more rapid-growing species are opportunistic colonisers within the successional community. Are they 'glue' that can consolidate and stabilise reef structures under extreme conditions?

IDENTIFICATION OF MARINE PROTECTED AREAS FOR CONSERVATION, MANAGEMENT AND RESTORATION OF CORAL REEFS AND CORAL COMMUNITIES IN THE NORTHERN GULF OF MEXICO (Abstract ID: 29759)

The utilization of marine protected areas is an important strategy in the conservation and management of coral reefs and coral communities. The northern Gulf of Mexico contains a range of coral ecosystems including coral reefs, mesophotic coral communities, and deep-sea coral assemblages. In 2015, the Flower Garden Banks National Marine Sanctuary (FGBNMS) initiated a formal process to expand its current boundaries to increase protection of additional reefs, banks and other offshore features of national significance. In order to identify the most important areas of interest, a procedure was developed to systematically determine the resources of highest ecological, economic and conservation value. This study describes the methodology used to identify those areas evaluated in the expansion proposal. The design methodology was based on information derived from extensive public input, expert opinion and over 30 years of science, monitoring and resource management of the region. In 2012, the FGBNMS released a revised Management Plan, containing a recommendation to expand the boundaries of the sanctuary. Building on this recommendation, a range of alternatives was developed that encompassed new and existing biological information, high-resolution topographic data and a variety of socioeconomic factors. Designation of additional MPAs will provide significant protection to important mesophotic and deepwater coral communities and contribute to restoration efforts in the Gulf of Mexico.

RETENTION OF THERMAL TOLERANCE IN THE INVASIVE FORAMINIFERA *AMPHISTEGINA LOBIFERA* FROM THE EASTERN MEDITERRANEAN AND THE GULF OF AQABA (Abstract ID: 29314)

Observations on the high thermal tolerance of corals from the northern Red Sea have been interpreted as a result of thermal filtering of larvae thousands of years ago. We test the thermal tolerance on the common benthic foraminifera *Amphistegina lobifera* which invaded and dominates now many areas of the Mediterranean. To this end, we conducted a three-week long experiment in a replicated design exposing a "source population" from the northern Gulf of Aqaba and an "invasive population" from the Levantine Basin, to a gradient of elevated temperatures up to 36°C. Both populations and their diatom symbionts were screened genetically to confirm the invader-source relationship. The response of the populations to the temperature gradient was quantified

by monitoring survivorship, growth and photophysiolgical response. Temperature did not influence survivorship, but photochemical results showed that both populations respond in a similar way to the increased temperatures and show reduced photosynthetic dark yields at ≥34°C. Reduced light yields, occurred already between the control (24°C) and the 32°C treatment. We conclude that the invasive population retains their upper thermal tolerance of the source population. The observed tolerance to temperatures exceeding the summer peaks in the Gulf of Aqaba is consistent with observations on the bleaching resistance of local corals.

SELFING, OUTCROSSING AND SPERM DISPERSAL IN THE SCLERACTINIAN CORAL *GONIASTREA FAVULUS* (Abstract ID: 28702)

Much of what we know about reproductive relationships, such as the ability of some marine invertebrates to self-fertilise, stems from *ex situ* fertilisation experiments and relies on the assumption that laboratory trials adequately reflect processes that are occurring in natural environments. However, this has rarely been tested empirically. Using several newly developed microsatellite markers we assessed the nature of fertilisation *ex-* versus *in-situ* in the hermaphroditic broadcast-spawning coral *Goniastrea favulus* to compare estimates of selfing and outcrossing under natural and experimental conditions. In particular, we tested for the hypotheses that self-fertilisation represents an important reproductive strategy in *G. favulus*and that this species favours non-self over self-fertilisation in situations of sperm choice. In the presence of self and non-self sperm, the *ex situ*-experiments showed high levels of selfing in *G. favulus* (30%), consistent with the known ability of this species to self-fertilise. However, genotyping larvae fertilised under natural conditions revealed low levels of selfing on the reef (< 3%) and multiple paternity. Additionally, a detailed examination of larval paternity suggested sperm dispersal occurred over several meters, with few larvae being fathered by colonies in proximate distance to their maternal colony. Our results demonstrate that the occurrence of selfing in *G. favulus* may have been significantly overestimated in laboratory trials and that laboratory fertilisation experiments may fail to reflect real world conditions.

AN EXPERIMENTAL APPROACH TO ASSESSING REEF RESILIENCE: PREDICTING THE LIKELIHOOD AND REVERSIBILITY OF ABRUPT CORAL-TO-MACROALGAE STATE TRANSITIONS (Abstract ID: 27905)

Coral reefs can switch abruptly from a coral community to one where seaweeds are a major space holder. Effective means to prevent such a shift or restore the coral state can benefit by knowledge of three issues: (1) how much herbivory is needed to prevent the widespread establishment of macroalgae; (2) where ambient herbivory lies in relation to the minimum needed to retain control; and (3) whether there is hysteresis in the herbivory – macroalgae relationship that would hinder reversibility of the state shift. We developed an experimental approach to answer those questions and applied it to reefs surrounding Moorea, French Polynesia. Our design created a gradient in herbivory, which broadly mimicked the effect of variation in fishing intensity on herbivorous fishes. We found that the shape of the herbivory – macroalgae relationship was highly non-linear, with a sharp herbivory threshold below which seaweeds escaped control. Further, the intensity of ambient herbivory in relation to the tipping point varied among reefs; herbivory at some reefs was far above the threshold while at others it was not. Hysteresis also was evident in the relationship, indicating that it took more herbivory to remove seaweeds than to prevent them from becoming established. We also found that reversibility of the state shift, as indicated by the range of herbivory over which hysteresis was detected, varied among reefs. Our experimental approach can be applied to other reef systems, and as such, it can provide a powerful tool to inform resilience-based management strategies.

THERMAL TOLERANCE OF CORALS FROM THE NATURALLY EXTREME KIMBERLEY REGION IN NORTHWEST AUSTRALIA (Abstract ID: 27983)

Naturally extreme temperature environments such as the Kimberley region in northwest Australia provide ideal natural laboratories to understand what drives coral thermal tolerance. We will present findings from several lines of research assessing the capacity and limits of Kimberley corals to cope with future ocean warming. A heat stress experiment aimed at establishing bleaching thresholds for nearshore Kimberley corals showed that they were highly sensitive to temperatures exceeding their typical summer temperatures despite being adapted to a naturally extreme temperature environment. However, corals collected from the environmentally more extreme intertidal took longer to bleach and die than corals from the more moderate subtidal environment. Given that all corals harboured*Symbiodinium* clade C independent of treatment or origin, this highlights the importance of the thermal environment in shaping coral thermal tolerance. A reciprocal transplant experiment is currently in place to study over what time scales subtidal corals could acclimatize to the more extreme temperatures of the intertidal and preliminary results will be presented. Our findings have significant implications for the current global bleaching event as the Kimberley region is expected to experience significant bleaching over the next few months, which will be monitored. Overall, the evidence from the controlled tank and field experiments and bleaching surveys will significantly improve our understanding of how corals from naturally extreme environments may cope with continued climate change.

BIOERODING SPONGES ON THE CENTRAL GREAT BARRIER REEF – A LONG-TERM PERSPECTIVE (Abstract ID: 29190)

Calcifying organisms are predicted to suffer from changing environments, and bioeroder abundances and activities to at least temporarily increase, resulting in reduced reefal calcification and simultaneously in increased bioerosion. As coral reefs are already under significant pressure, this is thought to lead towards net framework erosion, to reduced biodiversity, reef structural strength and framework complexity. Nevertheless, bioerosion is routinely monitored in only a few programs, not studied over large spatial scales in a comparative way, and very few surveys have been repeated over time. Where data are available, sponge bioerosion appears to be increasing over time, largely due to deteriorating water quality or coral mortality. The community of bioeroding sponges at Orpheus Island, central Great Barrier Reef was assessed in 1997/98 before a major bleaching event, then again in 2003/04, when their total abundance had increased to 150% of the original areal cover. A further survey in 2010/11 suggested that the habitat still had not recovered. During this last survey Tropical Cyclone Yasi damaged parts of the reef, but bioeroding sponges showed no signs of being negatively affected. Lateral growth rates of one of the most dominant species, *Cliona orientalis* Thiele, 1900, were found to reach 5 cm yr-1, and its downward bioerosion of framework could amount to 1 mm yr-1. Locally, this species alone is able to erode more than 15 kg m-2 yr-1 and belongs to a species complex that is thought to include sponges that can rapidly unbalance reef carbonate budgets.

METRICS OF SUCCESS FOR ACROPORA RESTORATION IN THE CARIBBEAN (Abstract ID: 29417)

In-situ coral nurseries and coral gardening methods are increasingly used for the restoration of the threatened staghorn coral, *Acropora cervicornis*. To date, > 65,000 staghorn corals have been outplanted in Florida alone and expanding efforts are now having positive impacts at ecologically relevant scales. Here we: 1) outline key findings from regional restoration programs in Florida and Puerto Rico, and 2) propose benchmarks that can be used to evaluate the success of each step of the gardening process. Our combined data establish that the collection of fragments does not negatively impact donor colonies and that the survival of nursery fragments was >90% over the first year. Nursery corals demonstrated healthy growth (10.3-29.5 cm $yr^{-1}$) with significant variability between genotypes and platform types. Survival of outplanted corals was >80% after 2 years and strong growth was maintained. However, performance of genotypes within nurseries was not always predictive of performance on natural reefs. High survivorship and growth of corals, both within nurseries and after transplantation, demonstrates the effectiveness of nursery and outplanting programs to enhance threatened *Acropora* populations. The benchmarks of success suggested here, based on the careful tracking of thousands of corals, will ensure restoration projects are meeting acceptable goals and promote the

advancement of restoration sciences. Departures from these benchmarks should be assessed and direct the improvement of both nursery and outplanting methodologies and site selection.

PREDATION AND NUTRIENTS AFFECT THE SUCCESS AND MICROBIOME OF A FOUNDATIONAL CORAL (Abstract ID: 27792)

Elevated nutrients and altered food webs are common threats to ecosystems worldwide. On coral reefs, the impacts of nutrients and herbivory on coral-algal interactions have been extensively documented, yet the role of direct predation and nutrients on corals and their symbionts remains elusive. Here, we assess the effects of predation by a prevalent coral predator (the short coral snail, Coralliophila abbreviata) and nutrient enrichment on staghorn coral, Acropora cervicornis, and its microbiomes using a factorial experiment and high-throughput DNA sequencing. Predation significantly reduced growth, increased mortality and turf algae colonization, and altered the microbiomes of experimental corals. In contrast, nutrient enrichment most strongly affected coral microbial communities, markedly increasing the abundance of a Rickettsia-like organism (RLO) and reducing overall microbial diversity. Notably, this RLO is currently a suspected pathogen of the coral 'white band' disease, and was also found to strongly correlate with reduced growth rates in nutrient-exposed corals. These results show that predation can strongly suppress the success of small corals, while nutrient enrichment may have important, but visually imperceptible, effects on coral health by altering microbiomes. This research has novel implications for understanding the restoration or recovery of corals and the effects of top-down and bottom-up control on foundation species and their associated microbial communities.

A DECADE OF SUCCESSFUL PARTNERSHIPS THROUGH NOAA'S CORAL REEF CONSERVATION PROGRAM FISHERY LIAISONS IN THE US PACIFIC ISLANDS REGION (Abstract ID: 29016)

Lack of capacity continues to constrain coral reef conservation. For the past decade NOAA's Coral Reef Conservation Program (CRCP) and Pacific Islands Regional Office have supported Fishery Liaisons in the US Pacific. The Liaisons have significantly improved partnerships and technical capacity as they collaborate with and provide direct support to local resource agencies, NGOs, and communities, and integrate NOAA Line Offices in the matrixed CRCP, all to improve fisheries management and conserve reef habitat. Through close agency/public partnerships, Liaisons have helped reduce threats to coral reefs, enhance technical capacity, develop and implement projects, and increase compliance with mandates. The Liaisons' diverse portfolio includes field surveys, permit reviews, and community outreach, which provide unique synergistic benefits in understanding problems and developing solutions across the region. Successes include: culturally attuned village management plans in Am. Samoa; novel scientific reef resiliency studies in the CNMI; establishment of a NOAA Habitat Blueprint site in Guam; and co-coordination for the Pacific Islands Managed and Protected Area Community. The Liaisons' accomplishments highlight the value of strong collaboration and partnership in management efforts, the need for programs to engage and support community-based management, the value of using sound science to improve decisions, the need for sensitivity to and understanding of local issues and concerns, and the flexibility to capitalize on unique Liaison-strengths. Continuing into the future, Liaisons expect to expand efforts to improve reef resilience and facilitate recovery of ESA-listed corals.

MULTI-FACTOR ASSESSMENT OF RESILIENCE POTENTIAL OF CORAL REEFS IN THE MAIN HAWAIIAN ISLANDS (Abstract ID: 29754)

Declining health of coral reef ecosystems led scientists to search for factors that support reef resilience: the ability of reefs to resist and recover from environmental disturbance. Expert review of potential factors highlighted eleven that can affect reef resilience. These factors were quantifiable, and included fishing pressure, sea surface temperature variability, pollution and sedimentation from run-off from adjacent watersheds, and characteristics of coral and reef fish assemblages. These factors were used as an analytical framework to conduct a quantitative assessment of the resilience potential of reefs throughout the main Hawaiian Islands (mHI). Locations of Rapid Ecological Assessment (REA) surveys conducted by the NOAA were used to delineate study units, or 'georegions.' REA surveys provided data to quantify biological/ecological resilience factors, while external data sources were used to inform physical and environmental factors. Scores for each factor were normalized and averaged to produce a composite resilience score for each georegion. This reef resilience assessment delineated and compared 29 georegions across the mHI. Composite scores were highest for the northwest Ni'ihau and east Maui georegions, and lowest for the south O'ahu georegion. Factors such as fishing pressure, sedimentation, herbivore biomass and macroalgal cover provided the greatest differentiation among georegions. These factors can all be influenced locally, highlighting potential avenues for targeted, resilience-based management efforts.

MOLECULAR SIGNATURES OF TRANSGENERATIONAL BRAIN RESPONSE TO OCEAN ACIDIFICATION IN A REEF FISH (Abstract ID: 29226)

The impact of ocean acidification on marine ecosystems will depend on the capacity for species to adapt. Recent studies show that the behaviour of reef fishes is impaired at projected future CO2 levels; however there is also individual variation that might promote adaptation. We used a genome-wide approach to evaluate the potential heritability of this variation in CO2 sensitivity in the spiny damselfish, Acanthochromis polyacanthus. Offspring of CO2 tolerant and CO2 sensitive parents were reared at near-future CO2 (754 µatm) or present-day control levels (414 µatm). By integrating 36 brain transcriptomes and proteomes with a de novo assembled genome we investigated the molecular responses of the fish brain to increased CO2 and the expression of parental tolerance to high CO2 in the offspring molecular phenotype. Exposure to high CO2 resulted in differential regulation of 173 and 62 genes and 109 and 68 proteins in the tolerant and sensitive groups respectively. Importantly, the majority of differences between offspring of tolerant and sensitive parents occurred in high CO2 conditions. Consequently, there was a clear signature of parental sensitivity to high CO2 in the molecular phenotype of the offspring, primarily driven by circadian rhythm genes. This transgenerational molecular signature suggests that individual variation in CO2 sensitivity could facilitate adaptation of fish populations to ocean acidification.

BIOACTIVE SPONGES OUTCOMPETE SCLERACTINIAN CORALS (Abstract ID: 29803)

In recent years there has been an increasing number of reports that sponges are becoming more abundant and in some regions have become the dominating benthic organisms on coral reefs. Some locations in the Caribbean provide increasing evidence that coral reefs are shifting from coral dominated to sponge dominated reefs. For the Indo-Pacific there are also a number of reports which suggest that sponge biomass and abundance are increasingly correlating with a decline in coral cover caused by anthropogenic effects, such as overfishing, sedimentation, eutrophication as well as climate change. One possible mechanism why some sponges are successful competitors is the production of bioactive compounds. It has been well established that sponges use secondary metabolites to defend themselves against predatory fish and invertebrate predators. Studies on sponge allelopathic compounds are however largely lacking. We investigated crude extracts from 10 sponges collected from Bawe Island, Zanzibar, Tanzania to study the antipredatory effects of the sponges and tested also if sponges produced alleopathic compounds to overcome coral competitors. In addition to evaluating various reef sponges in Zanzibar, we investigated in detail the chemical ecology of a particularly dominating sponge (Pseudoceratina sp.), which we first sighted at Koh Phangan in the

Gulf of Thailand. This sponge was covering large areas of the benthic substrate and overgrew various other invertebrate species including corals. Results from both the feeding and allelopathic experiments will be presented.

SUSCESPTIBILITY OF ACROPORA PALMATA PATCHES TO THERMAL STRESS (Abstract ID: 28185)

Populations of *Acropora palmata*, a keystone reef-building coral in the Caribbean, have decreased significantly since the 1970s. Currently, its principal threat is increasing seawater temperature associated with global climate change and its relationship to bleaching and diseases. Recently, genetic diversity of the coral host, its symbiont and their combinations has been recognized as a source of functional diversity. Therefore, we selected 9 host-symbiont genotype combinations from each of three patches: La Bocana, Limones and Punta Venado in the Mexican Caribbean to study the variability in patch susceptibility to thermal stress. Coral colonies from these patches are part of one genetic population, while their symbionts belong to three local populations. After a 3 month acclimation to aquarium conditions, half of the fragments were exposed to heat stress (31°C), while the other half remained under ambient conditions (28.5°C) for 17 days. Photochemical efficiency, reflectance and survival were monitored throughout the experiment and used to calculate maximum excitation pressure and absorbance at 675 nm. At the start and end of the experiment, symbiont density, chlorophyll *a* density and skeletal weight were determined. The increased temperature induced cellular and photochemical changes associated with bleaching and reduced skeletal growth rate in all of the coral samples. Fragments from La Bocana appeared to be more susceptible to heat stress than those from the other two sites supporting the notion that genetic diversity is a source of functional diversity.

INTRACOLONIAL GENOMIC VARIABILITY IN ACROPORA HYACINTHUS (Abstract ID: 29258)

Coral reef degradation is a major economical and ecological concern. Consequently, coral reef conservation is a main goal of environmental protection. To protect reefs effectively, information about the genomic variability of corals is necessary. Population genomic data on coral species are therefore of prime scientific interest. In recent years, the new phenomenon of intracolonial genetic variability within a single coral colony has been described. This connotes that coral colonies do not necessarily consist of only a single genotype, but contain several distinct genotypes. So far only studies based on a few neutral molecular markers (e.g. microsatellites) have been used to identify heterogeneous colonies. However, it is unknown to what extent multiple genotypes within a colony vary genome wide and if they may differ in adaptively important genes. To investigate genome wide genetic variation in corals we used a new ddRADseq protocol that we optimized specifically for Acropora hyacinthus. Preliminary results show a large number of highly variable loci. Colony specific SNPs as well as allelic diversity within the same colony could be detected. Our results indicate that genomic variability in corals is much larger than expected and might influence a colonies' adaptive potential.

THE IMPACT OF BLEACHING ON REEF FISH SETTLEMENT: DOES NEMO KNOW WHEN HIS HOME IS STRESSED? (Abstract ID: 27809)

Understanding how bleaching impacts the settlement of symbiotic habitat specialists, and whether there is flexibility in settlement choices with regard to habitat quality is essential given our changing climate. We used five anemonefishes (Amphiprion clarkii, Amphiprion latezonatus, Amphiprion ocellaris, Amphiprion percula, and Premnas biaculeatus) and three host sea anemones (Entacmaea quadricolor, Heteractis crispa, and Heteractis magnifica) in paired-choice flume experiments to determine whether habitat naïve juveniles have the olfactory capabilities to distinguish between unbleached and bleached hosts and how bleaching may affect settlement decisions. All anemonefishes were able to distinguish between unbleached and bleached hosts, and only responded to chemical cues from species-specific host anemones irrespective of health status, indicating a lack of flexibility in host use. While bleached hosts were selected as habitat, this only occurred when other options were unavailable, with the exception of A. latezonatus, which showed strong preferences for H. crispa regardless of health. This study highlights the potential deleterious indirect impacts of declining habitat quality during larval settlement in habitat specialists, which is particularly important given that bleaching events are becoming increasingly common.

EFFECTS OF TEMPERATURE ON *IN SITU* BEHAVIOUR AND ACTIVITY OF CORAL TROUT, *PLECTROPOMUS LEOPARDUS*, ON THE GREAT BARRIER REEF, AUSTRALIA (Abstract ID: 28493)

Physiological performance of marine fishes is highly sensitive to changes in temperature. Spatial and temporal variation in ocean temperatures may have a marked impact on activity and behaviour of fishes thereby influencing population structure and fisheries productivity. This study examines variation in activity and behaviour of common coral trout (*Plectropomus leopardus* ) among seasons and between locations in the northern and southern sectors of the Great Barrier Reef, Australia. *In situ*observations show that routine swimming speeds of *P.leopardus* increase with increasing temperature from 36.1 $cms^{-1}$ ($\pm$ 4.3 SE) at 22°C compared to 40.8 $cms^{-1}$ ($\pm$ 6.5 SE) at 30°C. However, it is expected that high temperatures > 30°C might constrain the frequency and speed of burst swimming, impacting feeding success and energetic intake. Accelerometry data from 38 acoustically tagged *P. leopardus* will be downloaded and analysed in March 2016, providing detailed information on activity budgets of fishes exposed to maximum summer temperatures . This study explores the implications of the effects of increasing temperature on wild stocks of *P.leopardus* These results are complemented by previous tank based studies and will enable better informed predictions about how *P.leopardus* populations and coral reef fisheries generally, might be impacted by sustained and ongoing global climate change.

SPECIES DIVERSITY CHANGES SINCE 1980 ON BAHAMIAN REEFS SHOWS SHIFTS IN ECOLOGICAL STRUCTURE (Abstract ID: 29663)

Maintaining biodiversity over time is paramount to the functioning of coral reef ecosystems. Species abundance and richness change over time, but overall biodiversity is maintained to support ecosystem services. A decrease in biodiversity can detrimentally impact reefs; potentially phase shifts can fundamentally alter the dominance of stony corals along with ecosystem structure. SCUBA diver photography can form important baseline information on both species and taxa level diversity trends on less-accessible reefs over decades.This may be especially important to understand long-term trends and changes associated with climate change.An assessment of changes in reef benthos was carried out combining researcher and recreational underwater photographs from SCUBA divers beginning in 1980 to 2015. Reefs that were consistently visited in the Exuma Cays Land and Sea Park, The Bahamas were targeted for collecting photographs cataloged by date and dive site. The photography image database provided an exceptional opportunity to study key reef species from 2,963 slides collected on five dive sites from 1980-2015. Changes in reef biodiversity with a focus on cnidarians, sponges and annelids were evaluated with diversity indices and multivariate analyses. Invertebrate diversity showed a decrease in species diversity after 1984, with a slight recovery from 1994-1996, and a steep decline thereafter into 2015; This may be especially important to understand long-term trends and changes associated with climate change.

SPATIOTEMPORAL VARIABILITY IN MARINE SEDIMENTATION IN ST. JOHN, US VIRGIN ISLANDS AS A RESULT OF RAINFALL AND WATERSHED DEVELOPMENT (Abstract ID: 29055)

Terrigenous sedimentation on coral reefs from watershed development poses a threat to coral reefs. We examined how marine terrigenous sedimentation varied in eastern St. John as a function of: different rainfall parameters (mean daily rainfall, mean rainfall intensity, maximum daily rainfall), wave height, and degree of watershed development. Sediment traps (13) were deployed over ~26-day sampling periods near shore and at offshore reef sites below developed and minimally developed watersheds over five hurricane seasons. Terrigenous sedimentation was greater: during periods of high rainfall (especially high maximum daily rainfall and high 15-min mean rainfall intensity) and/or wave height and below developed watersheds. The relationship between rainfall parameters and terrigenous sedimentation were strongest when an antecedent precipitation index (a proxy of soil moisture) was considered. Terrigenous sedimentation rates at sites below developed watersheds were approximately four times greater than below minimally developed areas, and this degree of impact was generally consistent with watershed erosion models. Based on comparisons between total and silt accumulation rates with published data, corals near our sites were under stress two to four times as frequently at the developed compared to at the minimally developed locations. Our results demonstrate that sediment traps are an effective way to monitor general spatiotemporal patterns of terrigenous sedimentation and reliable in identifying locations where sedimentation may be inducing stress to corals.

MARINEGEO (THE MARINE GLOBAL EARTH OBSERVATORY) STUDY: SPONGES AND HABITAT CONNECTIVITY SUPPORT FISH COMMUNITIES IN DEGRADED REEF HABITATS (Abstract ID: 29502)

In 2015 the Smithsonian Tropical Research Institute in Panama (Bocas del Toro, Caribbean Sea) launched a MarineGEO research site (The Marine Global Earth Observatory, http://marinegeo.si.edu), as part of a global monitoring effort across coastal habitats. In the first year the habitat characteristics of the reefs, seagrass and mangrove fringes and the entire fish community (>2.5cm) of the Bocas del Toro region were assessed, also applying methods and tools of other global platforms as Reef Life Surveys (RLS) and CORALNET. Our data set pointed out how severely degraded the reefs, its associated habitats and the fish communities in Bocas del Toro are. The habitat degradation in combination with the ongoing overfishing led to a tremendous loss of fish biodiversity and biomass and a lack of omnivores, high-level carnivores and top predators. What remains is a fish community characterized by juvenile and small size fish, which are able to live in substrates with a low - medium complexity. However, we could also identify some positive drivers for the reef fish community. Sponges, the close proximity of mangroves and the mangrove fish biodiversity increase the reef fish biodiversity and biomass of such degraded systems. Also, they improved the quality of the reef fish community by increasing the trophic level and the overall vulnerability. Negative factors particularly for the reef fish biomass were identified as recently killed corals, zoanthids, rubble and the destruction of the mangrove fringe.

CORAL TRANSPLANTATION TO MITIGATE DREDGING IMPACTS ON CORAL REEFS FOR A PORT EXTENSION PROJECT (GUADELOUPE, FRENCH WEST INDIES) (Abstract ID: 29600)

The port extension project of Pointe-à-Pitre required the dredging of an access channel, including a coral reef area. Various surveys and mitigation measures were implemented: coral and seagrass transplantations, marine mammal surveys, water quality and noise surveys, sediment extracted quality surveys, and monitoring of marine communities. Other mitigative measures are being considered including the creation of artificial reefs. Public talks were also organized to present the project and its mitigation measures by the Guadeloupe Port Caraibes. Prior to the coral transplantation, several studies were performed to assess the feasibility of the project, determine the health status of the donor coral reefs, identify and characterize the best recipient sites and submit a detailed methodology to authorities for the different phases of the work. In view of all these studies, the State environmental services required a coral transplantation of a minimum of 4 150 coral colonies, taken from two impacted sites (> 3 ha). The transplantation was performed from January to March 2015. Almost 4 200 coral colonies belonging to 22 species and measuring 20 cm to 1.5 m were relocated. Monitoring of both translocated and control corals has begun and will continue over a 3-year period. The recurrent monitoring gauges the success rate of the transplantation, coral growth, signs of bleaching or necrosis, coral recruitment, coral cover, and status of associated fauna. First results indicate an overall success after almost one year post-transplantation.

THE DNA OF BIODIVERSITY – PREDICTING AND PROTECTING GENETIC DIVERSITY OF REEF COMMUNITIES (Abstract ID: 28937)

As conservation strategies increasingly call for preserving genetic diversity, moving beyond single-species approaches toward community-level trends in genetic diversity is needed. With genetic data for 47 reef species sampled across the Hawaiian Islands, we test a suite of hypotheses about drivers of genetic diversity at the species and community levels. Key species traits mediate response of species' genetic diversity to the seascape. Composite genetic diversity of all sampled species shows an emergent community-level association with metrics of habitat area and species diversity, supporting biogeographic theory and suggesting indicators and strategies for monitoring and preserving genetic resources of coral reef ecosystems. Species substitutions across islands may allow community-level genetic associations with seascape features despite high species-level variance. Correlation of composite genetic diversity to recent thermal stress may signal that genetic resilience of whole reefs is under threat by warming seas. Using highly predictive seascape models of composite genetic metrics across the Main Hawaiian Islands we developed an approach to biodiversity conservation planning that targets seascape features as a proxy for protecting genetic diversity alongside other targets of reef biodiversity conservation. We identify potential areas of high conservation benefit where additional conservation actions could effectively preserve genetic diversity, connectivity, species diversity, coral cover and/or fish biomass of the reef ecosystem.

FIRST BASELINE SURVEY OF CORAL LESIONS ON VILANGUCHALLI PATCH REEF, GULF OF MANNAR, INDIA (Abstract ID: 29317 | Poster ID: 163)

Incidence and prevalence of coral health issues are increasing globally, yet little work has been done on the coral reefs in India. We conducted the first baseline health study on Vilanguchalli patch reef within the Gulf of Mannar, India. We surveyed 12 transects laid haphazardly on the patch reef. Coral cover was measured via line intercept and all coral lesions observed within belt transects were recorded and photographed. Seven coral genera were found including Montipora, Acropora, Porites, Pocillopora, Turbinaria, Favites and Favia. Average coral cover was 60.0% with acroporids dominant (avg. 46% cover). Several types of lesions were recorded which include bleaching (avg. prevalence 2.0%), sponge overgrowth (avg. prevalence 2.4%), algal abrasion (avg. prevalence 2.5%), and fish and snail predation (avg. prevalence 2.9% and 1.2% respectively). Growth anomalies caused by overgrowth of discarded shells were found in Acropora (4.3%) and Montipora (2.1%). The most common diseases were growth anomalies found in Acropora (avg. prevalence 3.6%) and Porites (avg. prevalence 2.8%). Tissue loss consistent with disease was also found in Acropora with an average prevalence of 1.1%. The reefs in the Gulf of Mannar were severely damaged by coral mining until 2005 when this activity was halted. Reefs continue to be stressed by poor water quality and overfishing. More studies are needed to understand the health and status of these and the other reefs of India.

LOCALIZED DISPERSAL LEADING TO FAMILY GROUPS IN A WIDESPREAD CARIBBEAN GOBY (Abstract ID: 28209)

Local recruitment has been repeatedly demonstrated by empirical studies investigating the dispersal of coral reef fishes. Local recruitment ranges from rare to common, the extent of which depends on the biology of the species of interest and local oceanographic conditions influencing dispersal. Here we demonstrate an extreme example of local recruitment in a shoaling reef fish *Coryphopterus personatus* (Gobiidae). We found that despite having a larval stage, and a wide distribution across Caribbean coral reefs, *C. personatus* forms groups of highly related individuals at small spatial scales (<10 metres), living alongside full and half siblings as well as cousins. Within 9 reefs in Mesoamerica we found between 2 and 6 family groups per reef. Two mechanisms could explain this pattern: 1) larval coherence in the pelagic environment can lead to siblings from the same larval cohort living on the same reef as adults; 2) low levels of dispersal or lack of dispersal. We found that highly related individuals spanned multiple cohorts of individuals and we could not rule out the possibility of offspring and parents living on the same reef. This suggests that dispersal in the species may be highly reduced, similar to recent findings from other reef dwelling gobies.

ASSESSING TRENDS IN TARGETED MARINE FISHES IN THE BONAIRE MARINE PARK, LEEWARD ANTILLES CARIBBEAN (Abstract ID: 30074)

The Bonaire Marine Park (BMP), established in 1979 and encompassing the islands of Bonaire and Kline Bonaire, represents one of the oldest marine parks in the Caribbean. Primary human uses of the park include recreational diving and snorkeling, and subsistence fishing by local people. The BNP is comprised of a network of protected areas with differing human-use restrictions; no area in the park is currently restricted from

subsistence fishing. One of the primary goals of the park is to maintain a regionally and globally significant and successful multi-use marine protected area. It remains unclear, however, to what extent high-quality opportunities for extractive and non-extractive uses are being maintained through time. Since 1993, volunteers with Reef Environmental Education Foundation (REEF) have conducted reef fish surveys (species-specific presence/absence and relative abundance) at sites throughout the park. To date, over 21,000 surveys have been conducted, representing ~28,000 hours of collective survey effort. Using these data, we examined trends in the presence and abundance of marine fishes targeted by subsistence fishing (e.g. grouper and snapper) over the last two decades. We found an ongoing decline in many targeted species, suggesting that extractive uses are decreasing the quality of non-extractive uses such as wildlife viewing over time. Given the importance of vibrant and healthy reefs to locals and tourists alike, we suggest that BMP managers take action to reverse trends in fish populations.

ACROPORA PALMATA'S LAST STAND IN THE FLORIDA KEYS? (Abstract ID: 29728)

The decline of acroporid corals throughout the Caribbean over the last 30 years has been well-documented, with noted mortality of this primary reef-builder most evident along the Florida Reef Tract. While the framework of bank reefs created by Acropora palmata remains, the spatial extent of the population itself has dwindled so substantially that only few areas of multiple extant colonies remain across the reef tract as a whole. Data from recent monitoring at 10 sites in the Florida Keys reflect particularly alarming losses, including localized extirpation at a few sites within the Lower Keys. These losses are not equally distributed across sites, and while chronic drivers of decline (predation and disease) occurred at all sites, their relative impact is neither geographically nor temporally uniform. Recent severe bleaching events of 2014 and 2015 affected sites differently as well, notably causing near complete mortality at sites chronically impacted by coral-livorous snails as well as sites previously showing high growth and low mortality (although low genotypic diversity). The prevalence of corallivorous snail predation increased on the remaining colonies and continued to cause high mortality on the remaining tissue. Ultimately, chronically stressed corals seemed to be more susceptible to bleaching events, but even sites documented as healthy can suffer mass mortality. With an extensive El Nino event expected to continue in 2016, Florida's Acropora palmata population may become increasingly restricted to even fewer sites. Minimizing local stressors may provide some relief for A. palmata, but it will not remove the bleaching threat.

GOT BIOMARKERS? TRANSCRIPTOMICS TO RESCUE CORAL HEALTH (Abstract ID: 29629)

Water quality is both a critical component of coral health and relevant to reef management at the local scale. Following 2002-06 guidelines by the US Coral Reef Task Force, local stakeholders developed strategies to reduce land-based pollution (LBP) by 25% in priority U.S. watersheds. However, basic biological information regarding the suitability and efficacy of the proposed reductions to alleviate threats to corals is still lacking. Determining LBP response thresholds and threat reduction levels for corals is essential to effective management and conservation, including the development of best land management practices (BMPs) to promote the recovery and persistence of reef-building corals. In this study, we use RNASeq to identify key genes in the stress response of four Hawaiian corals exposed to sediment stress in the laboratory. Gene expression responses correlated to the severity of sediment exposures indicated the best biomarker candidates. Antibodies designed to target the proteins encoded by those genes were then used with Western blots and ELISA to validate the candidate biomarkers on samples from controlled sediment exposure experiments. We subsequently calculated the change in biomarker expression to evaluate the health of corals experiencing sediment stress in the field. These new biomarker tools provide reef managers and stakeholders with sensitive and accurate pre-bleaching diagnostics of the coral stress response so that BMPs can be tailored to effectively support reef sustainability.

FIRST CORAL DISEASE ASSESSMENT IN THE LAST MARINE SANCTUARIES IN THE SOUTH WESTERN INDIAN OCEAN: EPARSES ISLANDS (Abstract ID: 29352)

Coral diseases have caused a worldwide decline in the biodiversity and abundance of reef-building corals. These diseases are known to generate progressive tissue loss and affect coral growth, reproduction, recruitment, species diversity and the abundance of reef-associated organisms. While studies of coral disease have increased, no attempts have been made to identify infectious diseases on the French Eparses Islands. This study provides baseline data on coral disease prevalence on Glorieuses, which is one of the most pristine ecosystems, preserved from anthropogenic impacts due to its geographical isolation and a historically very limited human occupation. Surveys were conducted in December 2015 at seven latitudinal sites and across two reefs (reef slope and reef flat) and revealed the presence six disease conditions including Acropora white syndrome (AcrWS), Acropora BBD (AcrBBD), Porites white patch syndromes (PWPS), Pocillopora white syndrome (PocWS) and Seriatopora WS (SerWS). Unexpectedly, we recorded high levels of diseases with the highest disease prevalence seen at the sites closest to Ile du lyse which is a breeding ground for large number of seabirds. The data suggest that seabird's populations may have an impact on the susceptibility of corals to disease. Results of this study offer a baseline dataset of disease in these unique natural laboratory and indicate the need for continued monitoring.

DIVE INDUSTRY'S CHALLENGES AND OPPORTUNITIES TO COPE WITH CORAL BLEACHING IN INDONESIA. A RAPID ANALYSIS ON DIVER PERCEPTION IN BUNAKEN, BALI, AND GILI. (Abstract ID: 28650 | Poster ID: 671)

The mass coral bleaching event of 2009-2010 was documented in Indonesia, where up to 100% bleaching was recorded in shallow waters. To investigate potential impacts of mass bleaching events to dive operators, a diver perception survey elicited the expectations and experiences of 192 divers in Bunaken, Bali and Gili Matra in 2010. Results show that most divers were aware of the phenomenon of coral bleaching, and the diving experience was an important reason for their destination choice. Interestingly, less than half of the divers indicated they would have changed their holiday destination, and <25% would have changed their holiday activity, had they known, prior to booking the dive, that the coral was bleaching. In general, across all sites, divers valued dive conditions and dive operation experience over marine life and perceived reef condition. Aspects that made them most happy were customer service and friendliness. Furthermore, divers across the sites consistently preferred dive operators that actively support reef management. The divers were also willing to implement reef protection measures during bleaching for example, through site closures. This research shows that dive industries can cope with bleaching events if the service is high quality and the physical environment remains in good condition. The challenge will be to ensure that bleaching doesn't deteriorate the reef to the point that it significantly reduces divers' willingness to dive in a site.

LARGE-SCALE MOVEMENT AND HABITAT RANGE OF REEF MANTA (*MANTA ALFREDI*) IN NORTHERN RAJA AMPAT WATERS, WEST PAPUA, INDONESIA (Abstract ID: 28485)

Little is known about the habitat range and movement patterns of reef mantas in Raja Ampat, Indonesia. This study aimed for investigating the behavioural movement patterns and habitat range of reef mantas to underpin the conservation efforts and management actions of this species in Raja Ampat region. The mantas were tagged with Vemco V16 acoustic transmitters. In November 2013, Vemco VR2W acoustic receivers were deployed in eight listening stations throughout northern Raja Ampat waters, including Wayag Lagoon, Uranie, Eagle Rock, Yefnabi Kecil, Seprang, Dayan, Manta Ridge, and Wai. A total of 38 reef mantas were tagged in six locations. Tagging periods in general varied between 0 to 682 days (237±27 days). Moreover, the total number of days of visits ranged from 1 to 188 days (42±7 days). Manta Ridge was the most popular site with 565 days of cumulative number of days of visits. It was followed by Yefnabi Kecil (434 days), Eagle Rock (287 days), and Wai (202 days). In addition, several mantas were detected in five listening stations and most of them travelled to at least one listening sta-

tion. Interestingly, results indicate that manta seasonal movements occurred within four main listening stations (Manta Ridge, Wai, Yefnabi Kecil, and Eagle Rock). Furthermore, nearly 90% of manta visitations in all listening stations occurred during the day between 06:00 am to 06:00 pm. Overall, those results can be used to assist in the designation of manta conservation strategies, both spatially and temporally to ensure manta populations and manta tourism sustainability in Raja Ampat.

THE EXPRESSION OF DIFFERENT CELLULAR-STRESS BIOMARKERS TO ASSESS THE RESPONSE OF CORALS TO DISEASES (Abstract ID: 28350)

Coral diseases are increasing in both the occurrence and incidence, threatening the health of coral reefs worldwide. To date, although many diseases are ecologically well documented and efforts have been performed in the identification of the microbial communities associated, less attention has been given to the effects of the pathogen presence on coral health/physiology and about the mechanisms employed by corals to fight and resist to infection. For this reason the expression of some cellular stress biomarkers for detecting early signs of change in a coral's physiological state were analyzed in corals affected by diseases, at different distances along the advancing front of the infection. In particular, the modulation of the mitochondrial heat shock protein 60-kDa (Hsp60) was investigated in Acropora muricata colonies infected by the ciliate-related diseases Skeleton Eroding Band and Brown Band in the lagoon of Maghodhoo Island, Faafu Atoll, Maldives. At the same time, the expression profiles of Hsps, oxidative stress-inducible proteins and antioxidant enzymes, such as superoxide dismutase, were compared during the progression of the Black Band disease in colonies of Goniopora cf. columna. The results provide new insights into the immune response of corals. Furthermore, they highlight as different pathogens trigger different cellular responses and defense mechanisms in corals, suggesting as the analysis of the expression of these cellular-stress markers could be a useful tool for examining physiological variations that are not detected at the morphological level.

NUTRIENT EFFECTS ON GROWTH AND BIOMASS OF DOMINANT REEF CONSTITUENTS (Abstract ID: 29215 | Poster ID: 239)

Degradation of coral reefs has been accelerating at an alarming rate worldwide. Introduction of nitrates and phosphates stimulates algal growth allowing them to outcompete calcifying organisms such as corals in eutrophic environments. Additionally, there is evidence to suggest nutrient availability can inhibit calcification and promote bioerosion even in the absence of algal competition, further shifting the reef community towards net erosion. The complexity of assessing the effects of nutrients on coral reefs is further exacerbated by the diversity of the benthic community. While much information is available on primary production, calcification, and dissolution on reefs at a variety of nutrient conditions, the individual responses of the reef inhabitants are not widely available for multiple reef constituents. In this study, we examined the biological responses of dominant coral reef components of Kāne'ohe Bay under increased nutrient availability. Three replicates of four coral reef substrates, coral (Montipora capitata and Porites compressa), macroalgae (Gracilaria salicornia), coral rubble (naturally conditioned Porites skeletons), and sediment were exposed to three nutrient levels in a press experiment for a period of six weeks. We calculated growth rates using changes in buoyant weight (coral, coral rubble), wet weight (algae), and % organic content (sediment) to determine the biological response of each substrate to nutrient addition. Our results will provide the capacity to parse reef response to individual constituents and compare this to reef assemblage response.

TRANSFORMATIVE AGENDAS REQUIRE TRANSFORMED INSTITUTIONS: LESSONS LEARNED IN CAPACITY BUILDING FOR OCEANS GOVERNANCE (Abstract ID: 28697)

Long-term ocean and coastal sustainability depends upon good governance implemented on-the-ground and in-the-water, as is reflected in the new U.N. Sustainable Development Goals pertaining to oceans and coasts. Transformative agendas, like the SDGs for oceans and coasts, require transformed institutions. Thus, many are calling for capacity building and science and technology transfer to assist the world's governance institutions to implement. This reflects a broader call of late for capacity building – in marine protected areas, in fisheries management, in enforcement, in national ocean policies. But as broadly as capacity building is called for, very little guidance exists in peer reviewed or other literature, on capacity building for ocean and coastal management. What do we mean by capacity building? What works, what doesn't, and why? This paper will present results from learning exchanges and expert elicitation among those who have delivered and those who have received capacity building for ocean governance in Asia, the Pacific Islands, the Caribbean, and the Mediterranean. It will explore basic approaches, advancements, challenges and solutions – and recommendations for best practices by these experts.

SPATIOTEMPORAL VARIABILITY IN NET COMMUNITY CALCIFICATION OF A WESTERN PACIFIC CORAL REEF SYSTEM (Abstract ID: 29053)

Measurements of Net Community Calcification (NCC) are increasingly used to establish baseline calcification rates of modern reef systems and to project coral reef futures under 21st century ocean acidification (OA). We measured NCC of two coral reef communities in Palau in the western Pacific, one an exposed barrier reef on the northwest side of the archipelago, and the other a semi-enclosed lagoon within Palau's low pH Rock Islands. NCC rates at both locations were determined for two different years using carbonate chemistry, hydrodynamic, temperature, and salinity data collected over the full diel cycle for multiple four day deployments. Communities on both reefs maintained positive net calcification during all deployments. However, we observed spatial and temporal variability in NCC that cannot be explained by changes in reef source water pH. In 2013, lagoon and barrier reef NCC rates were comparable despite a large discrepancy in source water pH (ave barrier = 8.05 ± 0.01; ave lagoon = 7.94 ± 0.01). Yet within the lagoon, NCC rates in 2012 (17.0 – 23.7 mmol m-2 d-1) were half those in 2013 (42.0 – 48.1 mmol m-2 d-1), with little change in source water chemistry. Similarly, barrier reef NCC rates halved between 1994 and 2000, despite a relatively small change in ocean pH. NCC declines at both locations correspond with coral bleaching caused by high water temperatures linked to ENSO. Our results suggest that the impact of temperature on calcification is critically important in modulating NCC and must be taken into account when projecting coral reef futures under OA.

FISH-DERIVED NUTRIENT HOTSPOTS SHAPE CORAL REEF BENTHIC COMMUNITIES (Abstract ID: 29583)

Animal-derived nutrients play a strong role in structuring nutrient regimes within and between ecosystems. When animals undergo repetitive, aggregating behavior, they can create nutrient hotspots where rates of biogeochemical activity are higher than in the surrounding environment. We examined the potential for reef fishes from the family Haemulidae to create nutrient hotspots and the potential impact of these hotspots on reef communities. We tracked the schooling locations of diurnally migrating grunts, and their impact on benthic communities. Grunt schools showed a high degree of site fidelity, repeatedly sheltering at the same coral heads and these aggregations created nutrient hotspots around coral heads where nitrogen and phosphorus delivery was roughly 10 and 7 times respectively greater than at structurally similar sites lacking schools of these fishes. In turn, herbivore grazing rates at grunt-derived hotspots were over 3x those of non-shelter sites, and coral growth roughly 1.5x greater. This led to distinct benthic communities with more crustose coralline algae and less upright fleshy algae. Our results suggest schooling reef fish are important in mediating coral reef community structure and that overfishing may impair the development of healthy reef communities. As such, management strategies should consider protecting mesopredatory fishes in addition to

herbivores and top-tier predators. Furthermore, restoration strategies may benefit from providing structure for schooling fishes or focusing coral out-planting around existing nutrient hotspots.

MARINE BIODIVERSITY AT TAIPING ISLAND AND PROPOSAL FOR ESTABLISHING MARINE PROTECTED AREA AT THE SPRATLY ISLANDS (Abstract ID: 28557)

Taiping Island, controlled by the Taiwan government, is the largest island of Spratly in SCS. The Spratly islands are a myriad of coral reefs which support abundant biodiversity and fishery resources. Based on a 2-4 day survey in 2014 at Taiping Island, a total number of 232 species of terrestrial plants and animlas, 796 marine species were recorded. A book and a DVD entitled "A Frontier in the South China Sea " were published to document Taiping Island's rich biodiversity both on land and underwater. The result from a feasibility study in 2009 proposed to establish Taiping Island as a Marine protected area (MPA) or a Marine Peace Park (MPP). However, the authority has yet to approve either one. Due to its importance in economy and national defense, the area is the subject of overlapping territorial claims by surrounding countries. Recent large-scale dredging and filling operations will be detrimental to the marine biodiversity and fishery resource in SCS. "The South China Sea Peace Initiative," announced by President Ma of Taiwan, called on all claimants to temporarily shelve their disagreements to enable negotiations on sharing resources. But the authority only focused on making Taiping Island a low-carbon base for humanitarian aid at the moment. We hope their next step will be to establish the Island as a MPA or MPP and to prioritize conservation as the priority. Here we suggest that each disputed country should establish local marine protected areas at the sites currently under their control, and to encourage international academic collaboration among the sites. These efforts can ensure the conservation and sustainable use of all resources within the Spratly Islands.

CORAL ON A CHIP: A MICROFLUIDIC PLATFORM FOR STUDYING REEF-BUILDING CORALS AT THE MICROSCALE (Abstract ID: 27891)

Coral reefs, which form the basis to some of the most productive ecosystems on earth, are currently facing major challenges due to rapid changes to their natural habitat driven by human activities and climate change. Understanding these challenges is hampered by the lack of a robust experimental approach for studying the microscale processes governing corals' interaction with their environment and with the multitude of microorganisms living in, on and around them. To meet this challenge we developed the Coral on a Chip, a novel experimental platform that combines micropropagation and microfluidic techniques to allow microscopic observation of live coral polyps. The small size and transparency of coral micropropagates make them ideally suited for live-imaging microscopy, while the microfluidic platform facilitates long-term visualization under controlled environmental conditions. The use of micropropagation enables us to produce of a large number of clonal polyps from a small coral fragment, reducing sample variability and simplifying experimental design. We demonstrate the application of this platform by imaging coral micropropagtes at previously unattainable spatio-temporal resolutions, providing new insights into several microscale processes including coral calcification, coral-pathogen interaction and the loss of algal symbionts ('coral bleaching'). The Coral on a Chip thus provides a new and exciting method for studying coral physiological processes in-vivo at the single cell level, opening new vistas in coral biology.

INVESTIGATING THE INFLUENCE OF SYMBIODINIUM PSYGMOPHILUM DENSITY ON PROKARYOTIC COMMUNITIES IN THE CORAL ASTRANGIA POCULATA (Abstract ID: 29653)

The facultatively symbiotic coral Astrangia poculata naturally exhibits a wide range in Symbiodinium psygmophilum densities and can be used to explore the role of Symbiodinium in structuring the coral microbiome. Wild A. poculata colonies occur in two symbiotic states, "brown" and "white," based on Symbiodinium cell quantification. 16S rRNA gene amplicon sequencing suggests that microbiome composition in brown and white colonies is similar to that in tropical corals. While bulk diversity and taxonomic composition are generally similar between brown and white colonies, several key microbial taxa are differentially enriched. Endozoicomonas bacteria, detected in diverse tropical hard and soft corals, are enriched (10-fold) in brown colonies. Sulfate-reducing bacteria (Desulfobacteraceae) are also enriched in browns. In contrast, sequences from ammonia oxidizers (Thaumarchaeota) and nitrite oxidizers (Nitrospina/Nitrospira) are enriched in white colonies, suggesting a role for Symbiodinium in structuring nitrogen cycling in Astrangia. Metagenomic data from Astrangia microbiomes are being analyzed to confirm functional differences in carbon, nitrogen and sulfur cycling potential between white and brown colonies. Based on these results, we propose a conceptual model describing how S. psygmophilum alters local substrate availabilities within the host colony and exerts influence on the associated prokaryotic communities. These results can be framed within the larger context of how Symbiodinium affects the bulk functions and overall stability of the multi-partner coral holobiont.

EFFECTS OF ST. LUCIE ESTUARINE DISCHARGE WATER AND THERMAL STRESS ON *MONTASTRAEA CAVERNOSA* (Abstract ID: 28850 | Poster ID: 409)

Coral reef declines, particularly in coastal zones, have been linked to temperature stress and anthropogenic impacts on water quality. St. Lucie Reef near Stuart, Florida, USA receives increased estuarine efflux as a result of watershed changes and management policies that have substantially altered historic natural flows. This research examines the direct effects of estuarine discharge water and thermal stress on corals, and supplements existing *in-situ* monitoring on St. Lucie Reef with *ex-situ* factorial experimental design. Ambient and elevated temperatures (25°C and 30°C) and offshore water versus estuary discharge water collected from the St. Lucie Inlet were used to investigate the individual and interactive effects on*Montastraea cavernosa*, one of two dominant scleractinian species at St. Lucie Reef. Coral stress gene expression, zooxanthellae density, and chlorophyll concentration were evaluated to determine effects on the corals and their symbionts. Collaborative partnerships with the Florida Fish and Wildlife Commission, Florida Department of Environmental Protection, and the St. Lucie Inlet Preserve State Park facilitate data sharing to inform decision making for South Florida's resource management strategies. Creating effective resource management is crucial for the conservation of coastal ecosystems impacted by land-based sources of pollution both locally and globally.

THE EVOLUTION OF MARINE LARVAL DISPERSAL KERNELS IN SPATIALLY STRUCTURED HABITATS (Abstract ID: 28317)

Understanding the patterns, causes and consequences of marine larval dispersal is a major goal of marine ecology. Most research on the causes of variation in dispersal focuses on proximate causes, e.g., physical oceanography and larval behavior. Here, we investigate the ultimate, evolutionary causes of variation in dispersal. Building on Hamilton and May's (1977) classic paper "Dispersal in stable habitats", we develop a set of simple models for the evolution of larval dispersal kernels in spatially structured habitats. First, we extend Hamilton & May to understand how parents will allocate to different dispersal distance classes in a world without bound. This creates a paradox: parents allocate most to the longest dispersal distance class. Second, we investigate dispersal distance allocation in a world with bound. This resolves the first paradox, but creates its own paradox: parents allocate next to nothing beyond the shortest dispersal distance class. Third, we investigate dispersal distance allocation in a world with bound and patchiness. This produces a more realistic result: parents allocate more to longer distance classes. Finally, we investigate the evolution of the kernel in a real seascape and test the predictions of our model against an empirically derived kernel from that seascape. There is a good fit between the model's predictions and empirical data. This study provides a framework that can be used to model the evolution of dispersal kernels in other species and seascapes, which will provide new insights into variation in patterns of population connectivity.

EFFECTS OF CARBONATE CHEMISTRY ON METABOLISM OF AN EXPERIMENTAL CORAL REEF COMMUNITY (Abstract ID: 28568)

In situ studies have shown net community calcification (Gnet) to be correlated with pCO2 levels that vary naturally in space or time. However these relationships can be confounded by covariation between carbonate chemistry and other environmental parameters. Here we created experimental reef communities in flumes and exposed them to a range of pCO2 levels over multiple months. Seawater pCO2 treatments reflected those predicted under atmospheric CO2 levels of 400 (ambient), 700, 1000 and 1300 µatm. Under ambient conditions, communities had Gnet of ~90 mmol m-2 d-1, within the range

of values observed for in situ reefs. Gnet was significantly related to pCO2 and declined by 23% of the ambient rate per unit decline in aragonite saturation state. Net community production was not significantly related to carbonate chemistry. The change in Gnet from ambient to treatment was consistent over time (from days to months of exposure) for the 700 µatm treatment, but for the 1000 and 1300 µatm treatments, Gnet was lower after months of exposure, compared with the response after several days. Our results also showed short-term variability in Gnet of the ambient pCO2 (400 µatm) treatment. These results have important implications for selecting the duration of pCO2 exposure in both experimental and in situ studies that rely on temporal variation in carbonate chemistry. They also highlight the importance of long-term in situ community metabolic measurements for accurate comparisons between sites, and for detection of future change.

LOCAL BLEACHING THRESHOLDS ESTABLISHED BY REMOTE SENSING TECHNIQUES VARY AMONG REEFS WITH DEVIATING BLEACHING PATTERNS (Abstract ID: 27889)

In August / September, 2012, a severe bleaching event affected coral communities off the coast of Abu Dhabi in the Arabian Gulf. In Saadiyat and Ras Ghanada reefs ~40% of the corals showed signs of bleaching. On contrast, only 15% of the corals were affected in Delma Reef. Bleaching threshold temperatures for these sites were established using remotely sensed sea surface temperature (SST) data recorded by MODIS-Aqua. The threshold temperatures varied between locations, resulting in site-specific deviations in the numbers of days during which these thresholds were exceeded. Hence, the less severe bleaching of Delma reef can be explained by the lower relative heat stress experienced by this coral community.

CRYPTIC DIVERSITY UNPREDICTABLY AFFECTS MEASUREMENTS OF POPULATION DIFFERENTIATION IN CORALS (Abstract ID: 28246)

Cryptic diversity is commonly detected across diverse taxa with interspecies differences having the potential to significantly inflate or deflate population genetic correlates of dispersal capabilities. The widespread Pacific corals Acropora cytherea and hyacinthus together contain eight often sympatric cryptic species. Using 199 single nucleotide polymorphisms, we assessed population differentiation of these eight species across three geographic scales (between archipelagos, between reefs within archipelagos, and within reefs) and tested how unaccounted cryptic diversity may affect these estimates. At large geographic distances (>700 km), comparisons among the eight largest archipelagos always displayed significant genetic differentiation for all species. At moderate distances (2-100 km), significant genetic differentiation was detected in 10 out of 17 between reef comparisons in populations of the five most abundant species. Genetic structure was not found at the smallest scale (10s m) when examining two species within two reef sites. When A. hyacinthus species were merged as if cryptic identity was unknown, population differentiation estimates between archipelagos and reefs greatly increased or decreased depending largely on the mix of cryptic species between locations, leading to inaccurate conclusions on genetic structure. Recognizing cryptic diversity is fundamental to accurate estimates of connectivity.

COMPARING IN SITU AND SATELLITE-BASED WATER TEMPERATURE DATA OVER TROPICAL CORAL REEFS: IMPLICATIONS FOR ENVIRONMENTAL MONITORING AND ECOLOGICAL FORECASTING (Abstract ID: 29432 | Poster ID: 550)

Thermally-driven coral bleaching contributes significantly to the global decline of coral reefs on which many coastal populations and economies depend, and bleaching models can provide valuable guidance to reef managers for monitoring, mitigation, and recovery activities. These tools frequently use daily 5-50 km satellite estimates of sea surface temperature (SST) over open water as proxy for subsurface conditions in the reef zone. However, land-adjacency effects and the influence of local-scale (< 5 km) environmental conditions introduce uncertainty to satellite-based estimates of water temperatures in near-shore, shallow (< 30 m) reef zones. Particularly, localized oceanographic influences (e.g., upwelling, diurnal heating, micro-currents) that are not resolved by the satellite data may affect bleaching susceptibility and introduce error into ecological forecasts. To investigate these concerns, a series of water temperature profiles were deployed on coral reefs around Little Cayman Island to simultaneously collect surface and subsurface temperature data. Data from these profiles are analyzed to identify local-scale behaviors and are compared to 5-km satellite estimates of SST to quantify bias. We evaluate the differences between the data sources, quantify the scope of local-scale variability, and discuss steps toward data integration that can better inform ecological forecasting models for coral bleaching and recovery.

BUILDING ISLAND RESILIENCE AGAINST CLIMATE CHANGE THROUGH A COMMUNITY-BASED WATERSHED AND CORAL REEF REVIVAL INITIATIVE (Abstract ID: 29934 | Poster ID: 682)

Climate change is a clear and present threat in small tropical islands, requiring solutions at both global and local levels. This study took a community-based approach to building island resilience against climate change. The removal of local environmental stressors restores natural ecosystem functions, promoting resistance to and more rapid recovery from global climate change impacts. The Humåtak Project (humatakproject.org) was developed in Guam as a community-based initiative directed at reducing accelerated erosion, a major local environmental stressor caused by poor land-use practices. Erosion results in sedimentation on coral reefs, which smothers and kills corals, interferes with coral reproduction and recruitment, and destroys essential fish habitat. A six-part community engagement strategy was deployed and partnerships were formed with a village mayor, local and Federal government agencies, and academia. Nearly 2,000 volunteer hours were contributed to reducing erosion in the La Sa Fu'a Watershed. Tree seedlings and sediment filter socks were tested as watershed restoration tools over a 21-month period. These tools were effective in trapping 112 metric tons of sediment on land. Based on the efficiency of these tools, management recommendations were developed to bring Fouha Bay below severe-moderate sedimentation stress (>50 mg $cm^{-2}day^{-1}$). The community engagement strategy and data generated on the effectiveness of watershed restoration tools can be used in management plans to build resilience against climate change in other tropical islands.

RAYS ON REEFS: PRELIMINARY RESULTS FROM THE GLOBAL FINPRINT PROJECT IN SOUTH EAST ASIA (Abstract ID: 29138 | Poster ID: 276)

Fishing pressure on ray populations in South East Asia is high. They are caught for their meat and their skin. Currently, there is little understanding of ray diversity and abundance in coral reef ecosystems in this region limiting conservation action. The Global FinPrint Project is the first global survey of elasmobranchs in coral reef ecosystems and is sampling intensively in South East Asia. The project uses baited remote underwater video systems (BRUVS) to determine relative diversity and abundance. This PhD project is using the Global FinPrint data from South East Asia to better understand the ecology of rays in coral reef habitats. Preliminary analyses from selected South East Asia locations will be presented. Data collected will be used to inform management of ray populations by identifying areas of low diversity and abundance. It will also be used as a baseline for future studies.

DESIGNING INTERVENTIONS TO IMPROVE MARINE AREA MANAGEMENT (Abstract ID: 29638 | Poster ID: 624)

Lack of effective management of marine managed areas (MMAs) has resulted in a continuous decline in the condition of nearshore and coastal areas in the Eastern Caribbean. This issue is exacerbated by threats such as overfishing, unsustainable coastal development and climate change. Furthermore, protected area managers are concerned that MMAS are not achieving the objectives for which they were established. Under the Eastern Caribbean Marine Managed Areas Network (ECMMAN) project, the Management Effectiveness Tracking Tool (METT) was used to set a baseline for current

management status of 7 MMAs across 6 countries. The overarching ECMMAN project goal is to establish an ecologically representative, socio-economically beneficial, climate resilient, and effectively managed MMA network. Since METT is a simple and rapid site assessment system for tracking progress of management actions over time across related areas, it provided an effective assessment tool for comparisons across the ECMMAN network. Management strengthening programs were designed for all 7 MMAs and have begun implementation since 2014. METT has continually been used to monitor progress towards improving management effectiveness at these sites. There have been noticeable improvements in the overall management of these 7 sites in key areas such as implementation of management objectives; enforcement of regulations; biophysical, socio-cultural and economic research and monitoring; stakeholder awareness, concern and participation; and successes towards threat abatement.

PAST WATER ENVIRONMENT OF KABIRA BAY RECORDED BY ISOTOPES AND TRACE ELEMENTS OF CORAL SKELETON (Abstract ID: 29217 | Poster ID: 232)

Kabira bay, which locates in Ishigaki Island, Okinawa, Japan is known as one of the most beautiful coral reef in Okinawa. In recent years, local people feel that turbidity in Kabira bay is getting higher because of some environmental pollutions such as a runoff of red clay, a culture of pearl oyster and a tourism of glass boat. It is important to investigate the past water environment in the Kabira bay to distinguish recent turbidity level from the past and identify the source of the pollution and the initiation time for a future management of the bay. In this study, we analyzed the isotopes of $\delta^{18}O$ and $\delta^{13}C$ and some trace metals in coral skeleton, and reconstructed the water environment in Kabira bay past 50 years. Oxygen isotope ratio decreases in summer and increases in winter. Temperature dependence was -0.125 ‰/°C in the mouth of the bay, -0.173‰/°C in the center, -0.106 ‰/°C in the closed-off section of the bay. A result of these values is close to those reported in the literatures (e.g. Tsunoda et al., 2006). Carbon isotope ratio showed a significant decrease since 2000 at samples taken from a closed-off section of the bay. This result indicates the possible effect of some pollutants to deteriorate a light environment for coral photosynthesis. Trace metals, such as Mn, Al and Sn, increased from 1976 after the reversion of Okinawa to Japan, indicating the rapid developments on land around Kabira bay.

EGG FORMATION OF A STONY CORAL, *EUPHYLLIA ANCORA* (CNIDARIA, ANTHOZOA): A MOLECULAR PERSPECTIVE. (Abstract ID: 28130)

Sexual reproduction of stony corals has been studied in many species worldwide. Although various aspects of sexual reproduction, such as spawning, sexuality, and gametogenesis, were extensively investigated during the past three decades, the intrinsic mechanisms of sexual reproduction remain almost unknown. To gain a better understanding of coral gametogenesis at both the molecular and cellular levels, as a first step, we focused on the oogenesis of a stony coral *Euphyllia ancora*, and investigated 1) what kind of molecules are mainly accumulated in the coral eggs, and 2) how these molecules are formed in the coral body during the oogenesis. We found that the coral possesses at least 3 types of yolk proteins, namely, Vitellogenin (Vg), Egg protein (Ep), and Euphy. Analysis of tissue distribution by quantitative RT-PCR demonstrated that these yolk proteins were highly expressed in the ovarian tissues. Subsequent mRNA *in situ*hybridization demonstrated that mRNA of these 3 yolk proteins were present in ovarian somatic cells adjacent to oocytes. Immunohistochemical analyses with anti-Vg, Ep, or Euphy antibodies showed the immunoreactivities of these 3 yolk proteins in both oocytes and ovarian somatic cells. These results demonstrated that the ovarian somatic cells, but not the oocytes themselves, synthesize these 3 yolk proteins in the ovarian tissues. Thus, yolk proteins produced in the ovarian somatic cells would be transported to the oocytes. Our data provide new information that contribute to a more comprehensive understanding of coral egg formation.

ARE SUCCESSFUL REEF FISH SIMPLY BORN 'LUCKY' OR DO THEY 'PLAY THEIR CARDS WELL'? (Abstract ID: 28027)

Biology is the story of winners and losers; winners survive better, produce more offspring, and thus differentially contribute to population growth. Like any game, timing is paramount -- winners may be born at the right time. Indeed, in the face of uncertainty, parents can spread out reproductive timing, but this bet-hedging will stack the deck in favor of some offspring. Are fates set by parents, or can offspring improve upon the cards they've been dealt? Our work investigates the roles of parental investment, birth timing, and developmental progression as determinants of fitness components. We focus on the sixbar wrasse (*Thalassoma hardwicke*), a species of reef fish that spawns frequently to produce offspring that navigate a series of demographic bottlenecks with fitness consequences. We sampled settlement and survival of fish on 192 patch reefs over six months, and documented lunar periodicity in settlement (greatest during new moons) and survival (greatest for fish that settled during- or just prior to new moons). Fish also varied in their size-at-settlement, suggesting that some individuals may accelerate or delay development to target good 'settlement windows'. We evaluate the 'decisions' of settling fish in the context of density dependence, priority effects, and environmental heterogeneity, and propose an eco-evolutionary hypothesis that could account for the evolution of iteroparous life-history strategies.

THE THERMAL TOLERANCE OF CORAL-ASSOCIATED BACTERIAL COMMUNITIES ACCLIMATED TO TEMPERATURE STRESS BASED ON SEASONAL THERMAL HISTORY (Abstract ID: 28052)

Corals and their microbial symbionts could resist thermal stresses and acclimated to thermal fluctuations. However, the effects of temperature fluctuation and seasonal acclimation on coral-associated bacteria remain unclear. To investigate this question, we conducted coral incubation experiments with different temperature treatments. Coral samples were collected at Penghu Islands in Taiwan. Seawater temperature of the sampling site ranged from 12.1 to 23.1 °C in winter and 23.4 to 30.2 °C in summer. The experiment comprised six temperature treatments (i.e., from 10 to 33°C) for nubbins from the coral *Acropora muricata* in summer and winter, respectively. Moreover, the changes in coral-associated bacteria were detected at three time points for each tank. The partial 16S rRNA sequences were used to identify composition of bacterial communities using Illumina sequencing. Bacterial communities between seasons were different in compositions and dominant species. For different temperature treatments, the dominant bacteria were gradually altered during incubations. Interestingly, such the shifting occurred in the corals collected in winter required longer and lower temperature treatments than in summer. Besides, the change in *Endozoicomonas* , health-associated bacteria, showed a similar shifting pattern. In short, changes in coral-associated bacteria presented a new evidence to suggest that seasonal acclimation may increase the coral resistance to thermal fluctuation.

MODELING THE IMPACTS OF SEA-LEVEL RISE AND CHANGING WAVE CONDITIONS ON ATOLL ISLANDS: INSIGHT FROM WAKE AND MIDWAY ATOLLS, NORTHWESTERN HAWAIIAN ISLANDS (Abstract ID: 29706 | Poster ID: 403)

Low-lying atoll islands are dynamic landforms experiencing changing erosion and accretion patterns due to changes in waves and sea level. These changes can threaten infrastructure and island communities via increased run-up, flooding, and loss of inhabitable area. To enable managers to implement effective mitigation and resiliency efforts, it is critical to understand how climate change will drive alongshore variations in flooding and erosion/accretion patterns. A Delft 3D model and empirical formulations were used to investigate potential climate change effects at two atolls in the Northwestern Hawaiian Islands, Wake and Midway. Using winter and summer end-member wave conditions, different scenarios were modeled by varying sea level at intervals between 0.0 to +2.0 m, incident wave heights from –0.3 to +0.3 m, and incident wave directions from –15.0° to +15.0° relative to current conditions. The results indicate that the greatest magnitude changes are along ocean-facing shorelines, primarily where the reef flat is narrowest. However, the portions most vulnerable to sea-level rise and changing wave conditions are the alongshore (longitudinal) ends of islands and the lagoon-facing shorelines, with each displaying the greatest proportional change in erosion and wave-driven run-up, and large heterogeneity between atolls. Together, these results suggest that the ends of atoll islands and lagoon shorelines will be most impacted by projected climate change and management decisions should take these potential changes into account when planning future investments.

SOURCES OF VIBRIO CORALLIILYTICUS STRAIN OCN008 IN KANEOHE BAY, HAWAII AND THE EFFECT OF DECREASED SALINITY ON INFECTION OF THE CORAL, MONTIPORA CAPITATA (Abstract ID: 28967)

Identifying sources of coral pathogens and understanding environmental risk factors is important for predicting and mitigating coral disease outbreaks. In Hawaii, Montipora White Syndrome (MWS) is a tissue loss disease with numerous outbreaks occurring in Kaneohe Bay during the winter when heavy rain events are more common. The bacterium, Vibrio coralliilyticus strain OCN008, has been shown to cause acute tissue loss consistent with MWS. In order to identify sources of this pathogen in Kaneohe Bay, seawater, terrestrial freshwater/sediment, and marine organisms were sampled and tested for the presence of OCN008. In addition, manipulative experiments were conducted to determine if decreased salinity increased disease risk for corals by reducing the amount of bacteria needed to cause infections. OCN008 was detected in freshwater and several marine organisms, including gobies, corallivorous butterflyfish, coral-associated invertebrates, and the coral host (Montipora capitata). Manipulative experiments showed that exposure to decreased salinity did not create lesions in corals but the decreased salinity allowed OCN008 infections to occur at a lower dose (106 cell/mL vs. 108 cells/mL). OCN008 was found in multiple biotic and abiotic sources in Kaneohe Bay, suggesting that corals have many opportunities for exposure to this pathogen. We also found that adverse environmental conditions that lower salinity (e.g. heavy rainfall) could make M. capitata more susceptible to infection by V. coralliilyticus strain OCN008 and offer insight for predicting disease outbreaks in Kaneohe Bay.

MESOSCALE EDDIES INCREASE LARVAL GROWTH AND SHAPE PATTERNS OF MORTALITY AND RECRUITMENT IN CORAL REEF FISHES (Abstract ID: 29746)

Like most benthic marine organisms, coral reef fishes produce larvae that traverse open ocean waters before settling and metamorphosing into juveniles. Where larvae are transported and how they survive is a central question in marine and fisheries ecology. While there is increasing success in modeling larval trajectories, our knowledge of the physical and biological processes contributing to larval survivorship during dispersal remains relatively poor. Mesoscale eddies, ubiquitous throughout the world's oceans, can exhibit increased productivity in addition to providing a mechanism for retention, suggesting they may serve as important larval habitat. Yet there is a lack of empirical data on growth and survival of larvae associated with these features. We sampled larvae of five coral reef fishes inside and outside of mesoscale eddies and, for three species, tracked cohorts from the plankton to nearshore reefs. Otolith microstructure analysis revealed that four of five species of reef fish examined had consistently faster growth inside of eddies. Additionally, in comparisons of young and old age groups,*Thalassoma bifasciatum* exhibited trait-based selection that varied spatially and temporally. Importantly, larvae of *T. bifasciatum* and *Cryptotomus roseus* that encountered eddies, not only grew faster, but also preferentially survived to settlement. These results indicate that larvae retained in mesoscale eddies likely contribute disproportionately to population replenishment. Successful dispersal in oligotrophic waters may rely on larval encounter with such oceanographic features.

SEA SURFACE SALINITY VARIABILITY AND PALEOCLIMATE RECONSTRUCTIONS IN CUBA INFERRED FROM CORAL ARAGONITE d18O, d13C AND SR/CA (Abstract ID: 30100 | Poster ID: 7)

Coral geochemical records such as stable isotopic compositions and elemental ratios can provide high-resolution records of past climatic conditions and variability. Such records can elucidate our understanding of climate variability over timescales ranging from inter-annual to centennial, documenting variability associated with seasonality as well as phenomena such as the North Atlantic Oscillation (NAO). Coral paleoceanographic reconstructions are of particular value in the Atlantic basin because of the paucity of data currently available. In Cuba, the largest island in the Caribbean, there is limited instrumental data and limited knowledge of multi-decadal climate sensitivity. Cuba is also an interesting site to study seasonal variations in corals because the annual SST range is high and its shallow platform exhibits high salinity and density gradients. Here we present new results from a 227 year coral core collected in February 2015 from a Siderastrea siderea colony in the Golfo de Ana Maria, in the Southern Cuban coast. This core represents the first long core ever collected in Cuban waters. We present high temporal-resolution measurements of Sr/Ca and d18O that provide historical information about sea surface salinity and SST. Our results fill a void in paleoclimate reconstructions in this region and provide the potential to be integrated into a Caribbean-wide framework for greater understanding of past and future climate variability. This research also exemplifies the opportunities now available from bilateral collaborations between Cuban and American scientists.

SANTA CRUZ CABRALIA REEFS, BAHIA BRAZIL: USING DIGITAL TOOLS AND PRINTED MEDIA TO RAISE CONSERVATION AWARENESS IN K-12 EDUCATION (Abstract ID: 29121)

Brazilian coasts have the only coral reefs of the South Atlantic, and reefs are in relative good condition. Southern Bahia is home to the largest and most biodiverse reef systems and the coastal reefs of Santa Cruz Cabralia are intensely visited, but still poorly studied. Coral Vivo ("Living Coral") carried out physical mapping and partnered with the K-12 Terezinha Scaramussa State School in an environmental education activity, where students interviewed elder fishermen, many their own relatives, to learn the names of different areas on the reefs. Reef names were about to be lost, as traditional fishing loses importance. Students then christened areas not mentioned. Place names were identified over a WorldView-2 satellite image, which has a 1.85 m pixel for the 6 bands of the visible electromagnetic spectrum fused to 0.46 m resolution pixels of the pan-chromatic band. Imagery was geo-referenced in detail, and the public easily recognized sites. A bathymetry survey was conducted along an 800 km course, consisting of 175 parallel lines 4.5 km long, spaced 100 m. 3,253,013 sounding points, spaced roughly every 0.6 m, were corrected for tidal variations and interpolated into a digital bathymetry model that indicates the relief of the seabed, showing reef morphologies and depth. As a result, a printed poster depicting names, imagery, and relief, with 3-D views featuring depths represented by a color scale was created and distributed to public schools of Southern Bahia's coastal towns (also available at http://coralvivo.org.br/wp-content/uploads/arquivos/2198file-3.pdf).

IN SITU TEMPERATURE PROFILE OF SHALLOW REEF COMMUNITIES IN NEGROS AND APO ISLAND: 2013-2014 (Abstract ID: 28847 | Poster ID: 352)

Coral reefs provide a wide variety of ecosystem services and goods that benefit humankind. However, the survival and health of reefs are threatened by natural and anthropogenic factors such as climate change and pollution. Increased seawater temperature often results in bleaching of certain coral species. This study aimed at profiling in situ temperature of shallow reef communities in Apo I. and Sibulan, Negros I. from March 2013 to February 2014 using data loggers programmed to record hourly. Results for Apo showed temperature peaks in the months of May, June and July 2013. For Sibulan site, peaks were observed in May, June and September 2013. Lowest temperature for both sites was observed in February 2014. Comparison with satellite-derived sea surface temperatures (SST) for the Bohol Sea indicated Apo Island recorded lower temperatures by 0.5 to 1.5 °C except for the months of October, November and December whereas in Sibulan site, logger-derived temperature recordings were mostly higher by 0.5 °C in the months of March, May, October, November, December 2013, and February 2014. Between sites, variation may be explained by differences in coastal profiles, depths of reefs and influences of different water current systems. Variation from satellite-derived data may be due to depth differences since the latter are taken only from the surface. Continuous in situ temperature monitoring is recommended as it provides a more localized profile especially in this period of changing climate.

DIVING INTO THE DEEP-END: BAITED REMOTE UNDERWATER VIDEO STATIONS (BRUVS) TO STUDY DEEP-REEF FISH IN THE GREAT BARRIER REEF, AUSTRALIA (Abstract ID: 28024)

Underwater video has great utility to study harder to sample areas such as deeper reefs. Baited Remote Underwater Video Stations (BRUVS) and multi-beam bathymetry were

used to investigate deep-reef fish communities off the continental slope in the Great Barrier Reef, Australia. BRUVS were deployed between 50-300m and fish species richness and diversity were recorded using Australian Institute of Marine Science (AIMS) software. There were significant differences in fish assemblages across depths, with different dominant families and groups of species characterising broad depth categories. For the particular reefs studied, multi-beam habitat derivatives such as depth, rugosity and slope were correlated with higher species diversity and greater abundance. This study resulted in novel records for fish species recorded elsewhere in the Indo-Pacific at similar depths and also identified potential new species. BRUVS have proved useful as a fishery-independent method to survey fish communities, to identify potential "hot-spots" of biological diversity and new species, and to explore surprisingly diverse deep reefs.

MONITORING SEDIMENTATION AND SEDIMENT ACCUMMULATION RATES FOR PROTECTION OF CORAL REEFS IN COASTAL WATERS (Abstract ID: 28798)

Sediment accumulation rates are essential tools for the understanding of processes related to the deposition of organic and inorganic materials in aquatic environments. They are useful for paleo-environmental reconstructions of climate history or for biotic evolution as seen in the fossil record, and for the functioning of benthic organisms. The isotope method, based on analysis of changes in 210Pb activity in the sediment profile from the coastal waters of the Niger Delta was deployed and Sediment Accumulation Rates calculated using the Constant flux. The Constant Sedimentation Rate, CSR model for isotopic methods was used and age of sediment layers determined using the Constant Rate of Supply, CRS model. This model assumes a constant flux of 210Pb from decay of atmospheric 222Rn followed by adsorption on suspended particulates that carry the 210Pb to estuarine sediment at constant rate. Sedimentation rates estimated from the excess 210Pb profiles of the cores ranged from 0.04 g/cm2/yr before 1976 to 0.16 g/cm2/yr after 1976. Sediment accumulation rates showed minimal variation between 1930 and 1970 but became unstable in the region with leaps from the 1980s reflecting the heightened oil production activities. This has since been exacerbated by the disappearing mangrove. Prediction of possible reclamation of most of the littoral waters of the regions was made and its possible consequences on ecosytem coral reef health are discussed with recommendations for integrated coastal zone management. Key words: Sedimentation rate, Bonny Estuary, Ecological consequences, Paleo-environment, Constant Rate of Supply Model, Coastal Management

SCALING UP FROM ORGANISMS TO ECOSYSTEM: INDIVIDUAL AND COMBINED COMMUNITY METABOLIC RESPONSES OF FOUR DISTINCT BENTHIC ASSEMBLAGES TO NUTRIENT ADDITION (Abstract ID: 29062)

Reef metabolism experiments are useful for understanding the net ecosystem response of coral reefs to environmental change; however, relating community response to organismal response is challenging. To scale up from organisms to ecosystems, reef metabolism experiments often extrapolate a community response by adding metabolic rates together from individual incubations; an additive design that assumes that the functional relationship between each organism and the environment must be the same. Using a nutrient addition experiment, we measured the impact of elevated nitrate (N) and phosphate (P) on metabolic rates of individual taxa and combined reef communities to test if the relationship between individual and community metabolism is indeed additive. Our reef community consisted of the dominant substrate types found on coral reefs: macroalgae, coral, reef rubble, and sediment. We performed a nutrient press experiment, delivering elevated N and P at a constant rate using peristaltic pumps to three different nutrient concentrations: ambient (N = 0.12 μM, P = 0.05 μM), elevated (N = 2.21μM, P = 0.93 μM), and highly elevated (N = 5.54 μM, P = 1.89 μM). After a 6-week acclimation period, we calculated net ecosystem calcification, net community production, nutrient uptake, and pH feedbacks from the substrates as individuals and as mixed communities over two sequential 24-hour incubation periods. Our results will help us understand how reef organisms and communities respond to eutrophication as well as help to elucidate the scaling of metabolic rates from reef organisms to communities.

VIRUSES AS RESERVOIRS OF BACTERIAL VIRULENCE GENES IN CORAL REEFS (Abstract ID: 28845)

Marine viruses significantly impact microbial diversity and function through predation and gene transfer. The responses of coral reef bacterial communities to anthropogenic disturbance will be, therefore, tightly liked to viral community dynamics in these systems. Here we investigated genetic diversity of viral assemblages in the Abrolhos Bank coral reefs, the largest reef system in the South Atlantic, currently undergoing benthic phase-shifts, bleaching and disease outbreaks. Most of the bacteriophage sequences in the viromes had high similarity with phages implicated in lysogenic conversion of their hosts. One of the most abundant genes was *lom*, lambda outer membrane protein, which is known to confer pathogenicity to Enterobacteria. Analysis of assembled contigs containing the *lom* gene indicate that its high abundance is not due to dominance of one single viral strain containing the gene, instead, *lom* is found in the genomes of many different phage strains. We provide evidence that this gene is being laterally transferred and positively selected within the bacterial community. Lysogenic conversion of symbionts associated to coral reef organisms could be the cause of disease outbreaks observed in reefs around the globe, a well-known mechanism in human pathogens such as *Vibrio cholera* and recently proposed in the coral pathogen *Vibrio coralliitycus*.

LARVAL DEVELOPMENT AND RECRUITMENT IN *PTEROGORGIA GUADALUPENSIS* UNDER ACIDIFICATION CONDITIONS (Abstract ID: 29960 | Poster ID: 198)

Although we understand the effects of ocean acidification on adult populations of octocorals, little is known about its effects on the early life stages. For octocorals, there is evidence of resilience against ocean acidification under mesocosms conditions but the effects on larval development and recruitment are unknown. In this study, we grew larvae of the brooder gorgonian coral from the Caribbean *Pterogorgia guadalupensis*(Gorgonidae: Octocorallia) under laboratory conditions and bred the larvae to follow their complete development and metamorphosis through the polyp stage, under acidification conditions. We describe the life history of this octocoral, follow its development rates and survival, and finally, evaluate 1) larval recruitment under decreased pH conditions and 2) larval preferences and affinity for two settlement surfaces including coralline red algae and dead gorgonian axis. Treatments with decreased pH conditions did not affect significantly either larvae survival or the development processes, but they did affect recruitment and settlement rates. We found high preferences of the larvae for coralline red algae as settlement surface, showing that it significantly improves larval recruitment even at low pH. Our results suggest that although acidified environments reduce larvae recruitment in *P. guadalupensis*, coralline red algae can significantly aid in overcoming this effect and produce greater numbers of successful polyp recruits.

MONITORING ALGAL DIVERSITY IN THE WESTERN PACIFIC: A CASE STUDY ON *ACTINOTRICHIA* (Abstract ID: 29986 | Poster ID: 50)

Introduced algae are an important focus of resource managers because of their potential to become invasive and have devastating impacts on reef ecosystems. To assess the risk of introducing non-indigenous marine species (NIMS) and monitor those already present, an understanding of the current diversity and distribution of the flora is required. Traditional (morphological) identification can be expensive and often inaccurate, but recent genetic techniques – like DNA barcoding - provide fast and cost-effective methods for algae identification and cryptic species recognition. In this study, we use the red algal genus *Actinotrichia* Decaisne to examine algae species diversity in Micronesia and the western Pacific. Sequence analysis using the mitochondrial marker COI-5P and plastid marker rbcL indicates a high degree of cryptic diversity in *Actinotrichia*, with two new and undescribed species present in Micronesia's flora alone, and potentially many more throughout the Indo-Pacific. These results suggest the marine flora of these regions is substantially more diverse than currently recognized, and further study of this diversity will aid resource managers in monitoring NIMS and potentially harmful invasive species.

TROPHIC SPECTRUM ANALYSIS OF REEF FISHES IN TWINROCKS MARINE SANCTUARY, NORTHERN VERDE ISLAND PASSAGE, PHILIPPINES (Abstract ID: 28639 | Poster ID: 635)

Against the backdrop of increasing disturbances due to human-dominated environments, coral reef ecosystems are in constant threat. One useful method in defining the health of coral reefs is through trophic spectrum analysis of reef fish community. This method shows the distribution of reef fish assemblage to a continuum of trophic fractions, which can indicate the structure and functioning of aquatic ecosystems in a fisheries context. This study aims to identify the effects of coral reef protection to the trophic spectrum of its associated fish assemblage. In the study, Twin Rocks Marine Sanctuary of the North Calumpang Peninsula was monitored for seven months. Standard fish visual census, coupled with benthic phototransect method was conducted on established permanent transects. Overall, there was a total of 236 species under 38 families of reef fishes observed throughout the duration of the monitoring period. For each species identified, fractional trophic levels were assigned based on their classification in FishBase.org. Mean biomass of reef fishes across trophic levels was consistently higher inside the marine sanctuary. This difference was most evident for herbivores and mobile invertebrate feeders, which were mostly commercially important reef fishes in the study site. Furthermore, there were more facultative piscivores and schooling reef fishes inside the reserve compared to its adjacent outside boundary. The results showed the utility of trophic spectrum analysis in reflecting the benefits of protecting coral reef areas. http://ibs.uplb.edu.ph

FITTING A PIECE IN THE SOUTH ATLANTIC PUZZLE: SEAMOUNTS AS STEPPING-STONES BETWEEN MAINLAND AND OCEANIC ISLANDS (Abstract ID: 28468)

The puzzling pattern that arises from the disjunct distribution of tropical reef fishes in the South Atlantic indicates that stepping-stone habitats are not required for ocean-wide dispersal, but they may be important for short routes between oceanic islands and mainland. Trindade and Martin Vaz, 1,200 km off the Brazilian coast, are the only exposed peaks of a volcanic ridge, the Vitória-Trindade Chain (VTC), and show high species richness when compared to other remote islands of the Atlantic. The seamounts of the VTC, which summits today are in mesophotic depths (average 50 m), have been suggested to serve as stepping-stones between the continental shelf and the islands. A comparative phylogeographic approach was used to understand the role of seamounts for fish diversity on islands, helping solve the South Atlantic puzzle. Two reef fishes collected throughout the VTC were analyzed for both mtDNA (cytochrome b and control region) and nDNA (8-12 microsatellite loci) markers. Populations from the continental shelf and seamounts have undergone severe bottlenecks associated to habitat loss during glacial low sea level stands, while those from the islands apparently experienced more stable conditions. A clear signal of isolation by distance was found in the species with lower dispersal ability, evidencing that seamounts are important for increasing the reef fish richness on the remote islands. A biodiversity feedback, controlled by sea level fluctuations, was identified amongst islands, seamounts and mainland, showing that peripheral locations are not evolutionary graveyards.

THE ROLE OF CNIDARIAN FICOLIN-LIKE PROTEINS IN *SYMBIODINIUM* RECOGNITION AND UPTAKE (Abstract ID: 27980)

Coral reefs depend upon the functional symbiosis between a cnidarian animal host, the coral, and its intracellular photosynthetic dinoflagellate in the genus *Symbiodinium*. Understanding cnidarian-dinoflagellate symbiosis has been the effort of decade-long research, yet the molecular principles governing this association are still largely undescribed. The recent sequencing of the genome of the sea anemone *Aiptasia* revealed a highly promising set of proteins that might function through the lectin-complement pathway and contribute to the selection of "compatible" *Symbiodinium* types. These proteins share the canonical ficolin structure, containing terminal collagen- and fibrinogen-like domains, and are exceptional for the presence of central tandem immunoglobulin domains. Given the absence of these proteins in bilaterians, they have been named Cnidarian Ficolin-Like proteins (CniFLs). Interestingly, CniFLs have so far been identified only in symbiotic cnidarians and their gene expression in *Aiptasia* is differentially regulated upon symbiosis establishment, suggesting a role of CniFLs in *Symbiodinium* recognition and uptake. The present work aims to elucidate the putative CniFLs–associated complement pathway that mediates the uptake of *Symbiodinium* in *Aiptasia*. To this end, we use targeted-proteomic approaches to identify putative CniFLs-binding molecules exposed on the *Symbiodinium* surface and detailed biophysical characterization to investigate the nature of the interactions.

GLOBAL FINPRINT: THE FIRST GLOBAL SURVEY OF SHARKS AND RAYS ON CORAL REEFS (Abstract ID: 29112)

Over the past half century there has been a substantial decline in the abundance of sharks on many of the world's coral reefs. Fishing has been the main cause of this decline, with the proximity of human communities often identified as a key risk factor for these declines. The ad hoc reporting of declines and the use of a range of sampling techniques, has limited our understanding of the magnitude of the declines and the appropriate conservation responses. To provide a clear picture of the global status of sharks associated with coral reefs the Global FinPrint project was established in 2015. The project is using new and existing baited remote underwater video (BRUV) data to examine the diversity and abundance of sharks and rays at hundreds of coral reef locations in the Pacific, Indian and Atlantic Oceans. This presentation will describe the objectives, sampling design, opportunities for partners and intended outcomes of the project. An update on the first year of sampling will be provided.

SOUNDTRACK OF THE ANTHROPOCENE: IMPACTS OF GLOBAL CHANGE ON LARVAL RECRUITMENT IN THE 21ST CENTURY (Abstract ID: 28369)

In early life, the vast majority of coral reef organisms face four major tests that together determine dispersal, survival and population replenishment. Since larvae generally develop away from reef habitat, once sufficiently well developed to leave open water environments, they must locate reefs, select suitable habitat, settle at locations with sufficient shelter, and avoid the immediate attention of many voracious predators. Over the past 15 years we have discovered the importance of the natural soundscape (combined with other cues) for guiding fish, crustacean and coral larvae towards reefs while allowing them to avoid predation. Reef noise is generated by the resident community, so reefs sound characteristically different and sound indicates the composition of the community and quality of the habitat, enabling larvae to locate and settle into appropriate microhabitat. But we live in an era of global change, with overfishing and pollution compromising reef quality, rising levels of atmospheric CO2 causing ocean acidification, and the noise of motorboats, ships, offshore industry and naval operations modifying natural soundscapes. Our recent work demonstrates that ocean acidification can affect auditory behaviour of larvae, and that motorboat noise can affect orientation and settlement in larval fish, and behaviour, physiology and survival of newly-settled reef fish. Following a summary of these studies, I will conclude with discussion of ways in which we may mitigate the impacts of global change on larval recruitment in the 21st century. http://biosciences.exeter.ac.uk/staff/index.php?web_id=Stephen_Simpson

BIOGEOGRAPHY OF DINOFLAGELLATE SYMBIONTS ACROSS THE INDO-PACIFIC: AN ECOLOGICAL AND EVOLUTIONARY ANALYSIS (Abstract ID: 28508 | Poster ID: 77)

Biogeographic studies have shown that the dinoflagellate symbionts (Symbiodinium) that inhabit corals exhibit variation in distribution across both broad geographical and local scales. Moreover, modern molecular techniques revealed that Symbiodinium types within a single clade differ in traits such as host specificity, niche diversification, physiology or bleaching susceptibility. This has provoked the need for further investigations into the distribution and evolutionary patterns of Symbiodinium at fine taxonomic scales, particularly in congruence with coral host and environmental data since both are

considered equally important driving factors for Symbiodinium diversity and speciation. We assembled a database of several thousand occurrences of Symbiodinium at the sub-clade level from across the Indo-Pacific that included environmental data, symbiont sequence data, symbiont host data and host trait data. We investigated how environmental factors in combination with evolutionary processes and ecological traits structure present day Symbiodinium species assemblages and influence their distribution across the Indo-Pacific. Furthermore, we tested whether biogeographic breaks in Symbiodinium sub-clades are concordant with current understanding of Indo-Pacific coral faunal breaks, evolutionary processes and community composition, providing insight into the ecological and evolutionary patterns of these symbiotic partners.

GROUNDWATER-MEDIATED ANTHROPOGENIC NUTRIENT INPUTS TO A NEAR-SHORE REEF ON BERMUDA (Abstract ID: 30039 | Poster ID: 456)

Groundwater discharge is increasingly recognized as a source of nutrient pollution to coastal reefs around the world, but much has yet to be learned of the extent and severity of its effects on water quality and reef ecology. Most of the sewage generated by Bermuda's 65,000 residents (national population density of 1,200 people/km2, third-highest in the world) enters the groundwater through untreated cesspits. Despite extreme nutrient loading in the groundwater, the impact of groundwater discharge on Bermuda's coral reefs has been little studied. We surveyed submarine groundwater discharge on a patch reef, 0-30m from shore, in Tynes Bay, adjacent to a large groundwater lens. Temperature, salinity, pH, and alkalinity were monitored at the discharge site, on the adjacent reef, and 30m from shore. Groundwater discharge, characterized by low salinity, high alkalinity, elevated nitrogen concentrations (500µM NO3– + NO2–, 2.5µM NH4+) and an elevated 15N/14N ratio (δ15N=10.9‰) consistent with inputs of human waste, was strongly linked with rainfall and tidal cycles. On the adjacent patch reef, NO3- + NO2- averaged 5µM, 10 times higher than typical in central Tynes Bay. Despite this heavy localized nutrient loading, coral calcification rates and percent live coral cover on the patch reef are relatively high, and bioerosion rates are lower than they are on Pacific reefs with comparable nutrient concentrations. Understanding reef community functionality under these conditions is critical to the design of reef management strategies in densely populated areas.

SOCOTRA: THE NEW HYBRID HOTSPOT (Abstract ID: 28304 | Poster ID: 37)

Areas where closely related species of reef fish from different biogeographical regions come into contact and interbreed to form hybrids are known as suture zones. Here we characterise a previously unknown suture zone in the Western Indian Ocean at the Socotra Archipelago (Yemen), where fish fauna from the Red Sea, Gulf of Aden, Arabian Sea, and greater Indo-Polynesian province intersect. The rate of hybrid discovery at Socotra (based on the number of dives and areas explored per hybrid crosses detected) surpasses that recorded elsewhere in the tropical marine environment. Here we present morphological, behavioural and genetic evidence of hybridisation involving 14 species of reef fish. We suggest that a unique combination of; location at the intersection of multiple biogeographic provinces, abundant reef habitat, fluctuating environmental conditions, and differences in sister species abundance are responsible for the level of hybridisation reported in Socotra. Given our limited search time, we predict that the extent of hybridisation occurring at Socotra will ultimately be even greater than reported here, highlighting the prospect of Socotra as a producer or genetic novelty and new diversity.

DETECTION OF MOLECULAR STRESS RESPONSE IN CORALS EXPERIENCING CHRONIC CONTACT WITH INVASIVE ALGAE MATS (Abstract ID: 29794)

Increasing human development and activity around tropical coastlines exposes coral reefs to a host of local stressors (overfishing, sedimentation, nutrification), which act synergistically to decrease coral cover, health, and recruitment, while encouraging the growth and proliferation of macroalgae. Contact with macroalgae has been shown to cause coral bleaching, disease, and reduced growth and fecundity through shading, abrasion, oxidative stress, allelopathic interactions and alteration of the coral microbiome. Few studies have investigated the stress response of corals in chronic contact with algae, and none have used molecular methods to do so. This study focuses on finger coral (Porites compressa) colonies in naturally occurring, chronic contact with the invasive red carrageenophyte alga, Kappaphycus alvarezii, on patch reefs in Kaneohe Bay, Oahu, Hawaii. Shotgun proteome sequencing, targeted immunoblotting, and enzyme activity assays indicate that P. compressa corals experience oxidative stress and reduced metabolic health when in long term, chronic contact with invasive Kappaphycus sp. mats. This study demonstrates the use of molecular methods in identifying and characterizing stress in outwardly healthy corals, allowing for more proactive management of at-risk coral reef ecosystems, and lays the foundation for understanding mechanisms of acclimation and resilience to algae-induced stress. Comparison with the stress profiles of corals experimentally exposed to acute algal contact stress will provide further insight into ecologically relevant coral stress responses.

DEVELOPING A NOAA CORAL GENOMIC OBSERVATORY NETWORK (CGON): PRELIMINARY METAGENOMIC PILOT STUDIES AND CGON DEVELOPMENT PLANS (Abstract ID: 29763)

NOAA is in the early stages of developing a "Coral Genomic Observatory Network" (CGON) to complement the NOAA "Integrated Coral Observing Network" (ICON). This new CGON initiative intends to establish observatories in critical coral reef ecosystems for meta-'omic characterization of community DNA and RNA for functional and taxonomic genes of both coral and its holobiont microbiomes. CGON research seeks to better understand resilience and adaptation of corals to climate-related and anthropogenic stress, such as temperature, nutrients, and disease stressors. The early phase of this CGON initiative focuses on selected sentinel reef sites in the Florida Keys National Marine Sanctuary, in the urbanized coastal waters of SE Florida, and in "relatively pristine" waters of Little Cayman, allowing comparisons of reefs with high direct anthropogenic influence and a reef with minimal direct anthropogenic influence. A small-scale preliminary pilot study in advance of CGON was conducted (and is reported here) for 4 sentinel reef sites in the urbanized coastal waters of Miami-Dade and Broward Counties (Florida, USA). This pilot study only represents 16S bacterial taxonomic metagenomics, rather than full meta-'omic characterization, for two species of coral, as well as qPCR-based microbial source tracking of fecal indicating bacteria, for these coral reefs and for coastal inlets and wastewater outfalls impacting them. The CGON initiative is expected to enhance the genetic information for these sites and to eventually expand such characterization to other reefs around the world.

HIGH BIODIVERSITY OF MESOPHOTIC CORALS IN OKINAWA AND ITS IMPORTANCE IN A CHANGING WORLD. (Abstract ID: 29422)

In the Northwestern Pacific, the Kuroshio Current supplies warm tropical water to the Ryukyu Archipelago in Japan providing good conditions for a high diversity of coral species. However, as for most coral reefs worldwide, the biodiversity of Japanese mesophotic corals remains virtually unknown. Here we report the preliminary observations of the coral distribution and diversity at several sites along the archipelago at depths from 30 down to 100 m. The coral cover and community structure were estimated using photoquadrats, while detailed coral identification was based on morphological and molecular examination of samples. An important diversity of distinct coral communities was found throughout the archipelago combined with high coral species diversity. Coral coverage is usually low, although occasionally, coral coverage can be nearly total. However, the highest coral coverage was usually associated with low species diversity.

*Leptoseris*, the emblematic mesophotic coral genus, dominated communities mainly in protected bays of the Southern part of the archipelago. Other communities were dominated by *Pachyseris*, *Acropora*species, *Seriatopora hystrix*, and other anthozoans (e.g. corallimorphs). Except for the *Leptoseris*-dominated communities, most of the dense coral communities were found only from one location. This suggests that not only MCEs in the Ryukyu Archipelago are very diverse both at species and community level, but also that this diversity is still largely underexplored. We will discuss the significance of these findings in a conservation perspective.

THE DAWNING OF THE MESOPHOTIC REEF RESEARCH IN THE PHILIPPINES (Abstract ID: 29059 | Poster ID: 326)

The Philippines has among the largest and most biodiverse reef areas in the world. However, most of its shallow reefs outside marine protected areas have gradually declined over the decades while its mesophotic reefs at depths of 30–150 m have scarcely been studied. In this study, six sites from different parts of the Philippines were surveyed for documentation of the occurrence of coral ecosystems at the upper mesophotic depths. Multibeam and side scan sonars were used to map the sea floor and to identify sites for SCUBA dives, drop-camera and ROV surveys to identify biodiversity and ecological patterns. These provided an initial inventory of corals and fishes, information on the locations of high biodiversity, and emergent patterns on the differences between shallow and mesophotic reef communities. Here we present a synthesis of the initial results of the first nationwide mesophotic exploration in the Philippines and a framework of management of mesophotic coral reef resources.

RESPONDING TO FISH EXTIRPATIONS IN THE GLOBAL MARINE BIODIVERSITY EPICENTRE (Abstract ID: 28060)

The Philippines lie in the global marine biodiversity epicentre but the ecological footprint of their reef fishing is fourth highest among island nations. Fisheries landings are declining, yet the status of the most vulnerable species is scarcely known. Localised species extinctions have been detected at Bohol Island but wider survey effort has been lacking. This is the first multidisciplinary study of national scope to identify species at risk of extirpation, using local and scientific knowledge to accurately infer declines in this data-poor setting. Semi-structured interviews to capture fishers' knowledge and identify declining reef species were followed by well-replicated UVC in 5 marine KBAs, targeting shallow water fishery target species reported to have disappeared from catches between the 1950s and 2014. Five species suffered a decline in CPUE of 64-88%: bumphead parrotfish, humphead wrasse, African pompano, giant grouper and mangrove red snapper. They were also absent from the UVC surveys, in addition to 6 other target species. Fishing pressure was not a factor but massive coral and complexity were predictors of spatial variation in the assemblage. The dramatic declines in CPUE over several decades and the absence of 21% of the target species in UVC data indicate a substantial prior decline in target populations. Contrasting patterns in fish presence/absence between fishers' catch and UVC data underline the importance of using multiple methods to accurately assess past changes in and current status of populations.

FROM MESOCOSM EXPERIMENTS TO SATELLITES: IMPLEMENTING THE LIGHT STRESS DAMAGE PRODUCT SUITE FOR TRACKING CORAL PHOTOSYSTEM HEALTH. (Abstract ID: 29145)

The world's only global operational satellite product designed specifically to monitor coral bleaching thermal stress is the HotSpot product suite, developed by the National Oceanic and Atmospheric Administration's (NOAA) Coral Reef Watch (CRW) program. These products help coral reef managers map and monitor heat stress remotely and hence better understand and predict mass coral bleaching. Although these products perform quite well when used to describe the onset of bleaching, they provide only indicative measures of the severity, duration and associated mortality of a bleaching event. They also do not separate the different responses of various coral genera, which is increasingly important as the mix of genera on reefs continually alters due to the loss of less tolerant genera via past stress events. The HotSpot product suite is based only on sea surface temperature (SST). However, we now know that mass coral bleaching results from the combined effect of temperature and light and that bleaching response varies between genera. Here we describe a major evolution of the NOAA CRW satellite products. Called the Light Stress Damage (LSD) product suite, it combines satellite-derived SST and solar insolation data to provide improved measures of stress to coral health. The LSD is designed to provide an improved prediction of the severity and mortality associated with bleaching events and should also provide a more accurate measure of the onset and end of a coral stress event. It also will allow for measurement of different bleaching responses between genera.

BUTTERFLYFISHES EXHIBIT SPECIES-SPECIFIC RESPONSES TO CHANGES IN PACIFIC SOFT CORAL COMMUNITIES (Abstract ID: 28189)

Many butterflyfish species exhibit feeding preferences for scleractinian corals that represent a continuum from facultative to obligate strategies, and which affect their predicted responses to temporal and spatial changes in coral community structure. Less frequently studied are interactions between butterflyfishes and soft corals, even though the latter represent significant habitat and energetic resources on Indo-Pacific coral reefs. We examined changes to the benthic community structure of three disjunct back-reef communities on the leeward side of Guam over two decades. These communities include a reef that has remained stable and relatively pristine through time, a reef that was significantly impaired but has stabilized over time, and a reef that has experienced a shifting baseline in response to anthropogenic and natural disturbances during this period. Benthic community structure, including soft corals, was monitored from 1994-2014. Density and behavior of six species of butterflyfishes, including an obligate hard coral specialist, two soft coral specialists, and three generalists of varied dietary breadth, were recorded at each of the sites in 1994, 2004 and 2014. The populations of butterflyfishes varied through time and space, and there were significant changes in foraging behaviors, largely due to changes in the soft coral community. Moreover, our results indicate that

the soft coral specialists exhibited differential prey preferences that were directly attributable to their ability to handle soft coral chemical defenses.

"SUPER-QUENCHING" STATE PROTECTS SYMBIODINIUM FROM THERMAL STRESS: IMPLICATIONS FOR CORAL BLEACHING. (Abstract ID: 29338)

The global rise in sea surface temperatures causes regular exposure of corals to high temperature and high light stress, leading to worldwide disastrous coral bleaching events (loss of symbiotic dinoflagellates (Symbiodinium) from reef-building corals). Our picosecond chlorophyll fluorescence experiments on cultured Symbiodinium Clade C cells, exposed to coral bleaching conditions, uncovered the transformations of the alga's photosynthetic apparatus (PSA) that activate an extremely efficient non-photochemical "super-quenching" mechanism. Ultrastructural investigation of the thylakoid membranes under these elevated temperature conditions support a disaggregation of the formerly structured arrangement as has been found in other investigations. Thus the mechanism is associated with a transition from an initially heterogeneous photosystem II (PSII) pool to a homogeneous "spillover" pool, where nearly all excitation energy is transferred to photosystem I (PSI). There, the inherently higher stability of PSI and high quenching efficiency of P700+ allow dumping of PSII excess excitation energy into heat, which can result in almost complete cessation of photosynthetic electron transport (PET). This potentially reversible "super-quenching" mechanism protects the PSA against destruction at the cost of a loss of photosynthetic activity. We suggest that the inhibition of PET and the consequent inhibition of organic carbon production (e.g. sugars) in the symbiotic Symbiodinium provide a trigger for the symbiont expulsion, i.e. bleaching. However, other processes, such as ROS production from the Mehler reaction may also occur and cause irreversible damage to PSII

UNITED STATES CORAL REEF TASK FORCE WATERSHED PARTNERSHIP INITIATIVE (Abstract ID: 29646)

The United States Coral Reef Task Force (USCRTF) created the Watershed Partnership Initiative (Initiative) in 2009. The Initiative facilitates and enhances coordination, partnerships, and contributions of agency resources and expertise to implement geographically specific and integrated activities to reduce pollutant loads to coral reef ecosystems. The Initiative uses this approach in three selected priority watersheds (Guánica Bay/Rio Loco in southwest Puerto Rico, West Maui, Hawaii, and Faga'alu in American Samoa) with the intent for future application to other watersheds with likelihood for success. Individual federal, state, territory, and commonwealth agencies contribute through direct application of resources, authorities, technical assistance, and/or program expertise. The National Fish and Wildlife Foundation (NFWF) also provides funding assistance and coordination, develops relevant tools, and seeks to identify and fill gaps. The Initiative developed a series of goals, objectives, and actions which are implemented by the USCRTF Watershed Working Group (Working Group). The Working Group consists of staff from member agencies and jurisdictions, NFWF, and USCRTF priority and jurisdictional watershed coordinators. They meet monthly to implement a USCRTF resolution, and support watershed efforts and federal partnerships watersheds. A Metrics Subcommittee was formed to develop an approach to evaluate efforts of the Initiative and has been working collaboratively to develop tools and products to help document success at the priority watersheds.

IMPAIRED ALGAL TISSUES REGAIN LOW ARGININE LEVELS AFTER SHORT TIMECOURSE IN LOW NUTRIENT WATERS. (Abstract ID: 30035)

Tainted submarine groundwater discharge (SGD) has lead to substantial nutrient loading of polluted waters into coastal regions and sustains blooms of invasive algae in urban Maui, Hawaii. Bloom algae sequester excess nitrogen (N) with high levels of tissue N stored as amino acid arginine (ARG). Diets high in algal tissues with elevated ARG coincide with high incidence of the fibropapilloma disease. In sites with tainted SGD, protected green turtle*Chelonia mydas* graze on invasive weeds with substantial tissue N stored as ARG and are subjected to as much as 14-fold increase, leading to a metabolic promotion of the disease as ARG is a critical component in a Herpes lifecycle. However, it is clear that plants draw down excess N and mobilized it for metabolic needs when subjected to environmental N- limitations. To determine if bloom species can draw on stored tissue N and a possible time-course for that drawdown, we collected invasives from high nutrient sites and transferred them to oligotrophic reefs on Maui or held them in laboratory settings with typical low nutrient waters. Tissues were sampled periodically over two weeks. Plants grown in situ or in laboratory, with little known pollution, had substantial declines in levels of ARG in tissues in relatively short periods; tissue ARG often approached background levels. Thus, reduction in nutrient contamination of SGD to coastal waters can have substantial and rapid impacts on biological systems, even in the short term. These factors are important considerations for management of coastal resources.

THE GENOMIC BASIS FOR ADAPTATION TO THERMALLY EXTREME REEFS (Abstract ID: 28794)

Elevated sea temperatures have played a crucial role in the global decline of coral reefs and are expected to lead to further declines in the near future. Despite the threat of increased thermal stress due to climate change, corals' capacity to adapt or acclimatise to these conditions remains poorly understood. Corals in the thermally extreme Arabian Gulf currently experience temperatures that exceed those expected on reefs in the tropics within the next century and therefore represent an excellent resource to study the genomic basis for adaptation to high thermal stress environments. In this study, population genomics analyses were performed on Platygyra daedalea, using genome-wide SNPs obtained through double digest restriction site associated DNA (ddRAD) sequencing of corals from 12 reefs in the Arabian Gulf and the more benign Gulf of Oman. We use genome-wide SNPs to describe reduced gene flow between reefs experiencing different thermal regimes at both regional (Arabian Gulf and Gulf of Oman) and local scales (inshore and offshore). The analysis of the genomic distribution of population genetic parameters (e.g. Fst and LD) is used to characterise outlier loci under positive selection in high temperature reefs, identifying genes and pathways responsible for Arabian Gulf corals' thermal tolerance. Furthermore, signatures of selection will be analysed to ascertain whether this thermal tolerance emerged from standing genetic variation or from novel mutations within the Arabian Gulf, thereby providing vital insights into the capacity for corals to respond to climate change.

DEVELOPING A ZONING DESIGN FOR CONSERVATION, FISHERIES, AND BLUE ECONOMY IN SEYCHELLES. (Abstract ID: 29882)

The Seychelles is a rich, tropical marine ecosystem situated in the Western Indian Ocean. Encompassing 1.37 million square kilometres and 115 islands, Seychelles is a recognised global biodiversity hotspot and contains two UNESCO sites. Biodiversity is one of Seychelles' most important assets and drives the country's Blue Economy. Seychelles has a goal of 30 percent of their Exclusive Economic Zone for conservation and the Seychelles Marine Spatial Planning (MSP) Initiative is focused on developing a coarse-scale, multi-objective zoning design and management considerations for conservation, fisheries, and other uses. The Initiative runs from 2014-2020 and has significant input from stakeholders. To develop a draft zoning design we are using data from multiple sources including academia, government, industry and participatory mapping. Commercial catch data were compiled from the industrial tuna fishery (2003-2012) and semi-industrial and artisanal fisheries (2008-2013). We used Marxan to analyse multi-year datasets from the Vessel Monitoring System, excluding high piracy years, and spatially depict high-medium-low use areas for local fisheries. Using more than 100 conservation features, Marxan irreplaceability values developed by the UNDP-GEF-PCU were used to propose biodiversity zones and check biodiversity representation targets. The zoning design methodology considers ecological design principles for MPAs, coral reef fisheries and designing marine managed areas, policy and management, and design principles to maximise compliance, monitoring and enforcement.

OCEAN ACIDIFICATION CAUSES ABUNDANCE LOSS OF ZOOPLANKTON LIVING RESIDENTIAL TO CORAL REEFS (Abstract ID: 28486)

Several zooplankton species live completely residential to coral reefs by hiding within the substratum during the day and migrating into the water column at night. Their role in reef trophodynamics is rarely studied and yet they are critical to coral health, reef fisheries production, and nutrient cycling. Even less is known about how entire zooplankton communities living within reefs are affected by the precipitous changes caused by anthropogenic loading of carbon dioxide. Ocean acidification effects on zooplankton have been studied for single-species, mostly calcium carbonate species or dominant copepod species, but community effects are scarcely understood. Here, we examined the abundance and community composition of zooplankton living residential to coral reefs at two reefs in Papua New Guinea where underwater seeps create a natural gradient in pH. Zooplankton were observed on three separate expeditions and at two separate reefs using a variety of methods, including traditional net tows, emergence traps, and acoustical instruments. There was less zooplankton present in the reef affected by ocean acidification (pH 7.8) compared to the healthy reef (pH 8.1), and differences were consistent across reefs and expeditions. Sensitivities varied considerably across taxa, with species like the calanoid copepod *Labidocera bataviae* being more sensitive to ocean acidification than other zooplankton. Zooplankton abundance loss will likely have cascading impacts on entire reef ecosystems.

TOP-DOWN VERSUS BOTTOM-UP REGULATION OF CORALS IN THE FLORIDA KEYS (Abstract ID: 28057)

Caribbean coral reefs have drastically changed over the past 30 years with declines in coral cover and herbivore abundance. In order to regulate increasing competitive macroalgae, protecting the remaining reef herbivores has become a primary conservation goal throughout the Caribbean. However, this assumes that corals are limited primarily by the top-down indirect effect of herbivores on macroalgae. To test the predictions of this herbivore cascade hypothesis along with alterative bottom-up hypotheses, we surveyed the reef community structure (parrotfish abundance and substrate cover) of 34 reefs in the middle region of the Florida Keys National Marine Sanctuary. Reef physical structure was estimated by the first principle component composite variable (distance from shore, depth, visibility, substrate complexity). We estimated the major influences on percent coral cover using both multiple regression analysis and structural equation modelling. Both methods suggest that there are positive top-down (parrotfish), negative bottom-up (reef structure) and negative competitive (fleshy algae) influences on coral. However, the structural equation models suggest that these are not driven by strong negative interactions of parrotfish on turf or fleshy algae. Analysis of parrotfish foraging behavior suggests that diet composition is highly variable and preferences for algae change with relative abundance. These results suggest that hard corals of the middle Florida Keys may be regulated by a complex interaction of top-down and bottom-up influences independent of parrotfish herbivory.

ESA-LISTED INDO-PACIFIC CORALS: CHALLENGES AND OPPORTUNITIES (Abstract ID: 29718)

Many reef-building coral species are in decline in both the Caribbean and Indo-Pacific basins from a complex combination of global and local threats. Reef-building corals were first listed under the U.S. Endangered Species Act in the Caribbean in 2006, and in the Indo-Pacific in 2014. ESA-listed Caribbean corals make up a substantial proportion of the basin's coral biodiversity, and include the primary reef-building species. They are also well-studied, easy to identify, and widely distributed in U.S. waters. In contrast, ESA-listed Indo-Pacific corals make up a tiny fraction of the basin's coral biodiversity, and do not include any primary reef-building species. They are poorly studied, hard to identify, and barely occur in U.S. waters. These characteristics increase the challenges of implementing ESA management of the listed Indo-Pacific species. In fact, many experienced coral and coral reef managers and researchers in the U.S. Pacific Islands consider the listings to be an impediment to conservation. However, the Indo-Pacific listings can provide numerous conservation opportunities, if implementation is adapted to meet the challenges. Opportunities exist both via the formal protections applied to all listed species, as well as via the informal support of ongoing and proposed conservation programs and projects. http://www.fpir.noaa.gov/PRD/prd_coral.html

TO CULL OR NOT TO CULL AN INVASIVE PREDATOR? IT DEPENDS . . . (Abstract ID: 29783)

Culling is commonly used in conservation as a means to eradicate invasive species or to reduce their populations to levels that minimize ecological impacts. Culling can be an effective management tool but it is labor-intensive, costly and its effects are sometimes unpredictable. In the Caribbean, culling is widely used to control invasive Pacific red lionfish,*Pterois volitans* , predators that have substantially reduced native prey fish abundances on coral reefs. However, the effectiveness of these control efforts is unclear. We assessed the effectiveness of lionfish culling at varying frequencies in a 21-month-long field experiment on natural reefs in The Bahamas. Surprisingly, culling every 6 months was more effective at reducing lionfish densities than culling every 3 months, resulting in average declines in lionfish densities of 79% and 60%, respectively, relative to unculled reefs. However, these reductions in lionfish densities did not result in gains in native prey fish biomass or species richness, which remained indistinguishable from unculled reefs. Furthermore, lionfish densities were greater on culled than on unculled reefs while native prey fish biomass and species richness were lower on culled than on unculled reefs following Hurricane Irene, and these results persisted for several months following the disturbance. Density-dependent lionfish movement and natural disturbances appear to play a role in limiting the effectiveness of lionfish culling at local scales.

BLEACHING AND DEPTH REFUGES IN THE EASTERN PACIFIC DURING THE STRONG 2015-2016 EL NIÑO (Abstract ID: 29959)

The ongoing 2015-16 El Niño is third severe El Niño to impact reefs of the eastern tropical Pacific in the last 35 years. In the two previous events communities of the hydrocoral *Millepora intricata* were extirpated from shallow water but survived in deeper water (> 12 m depth), facilitating shallow water recovery between disturbances. This supported the deep reef refugia hypothesis, which posits that cooler temperatures and other physical characteristics buffer corals in deep environments. However, this evidence lacked supporting oceanographic observations, and recent evidence from Caribbean mesophotic reefs suggests that thermal tolerance is set by the mean warmest conditions, allowing bleaching even when conditions are cool relative to shallow reefs. To understand the oceanographic and biological processes that might support or inhibit a depth refuge, we are studying the response of six species of stony coral at depths of 5 – 30 m in Panama and the Galápagos. By August 2015, *M. intricata* had once again been nearly extirpated from shallow water study sites in Panama and other species showed paling, bleaching or early stages of mortality. Below 15 m depth temperatures were cooler and corals were unaffected. From the ultimate response of corals and the physical environment to be sampled during the predicted spring 2016 thermal maximum, we will be able to determine what physical factors support a bleaching refuge. These studies are critical to assessing the importance of refugia in preventing regional and global coral extinction in a warmer future.

MACROALGAE AND OCEAN ACIDIFICATION CAUSE SHIFTS IN BACTERIAL COMMUNITIES ON CCA WITH IMPLICATIONS FOR CORAL LARVAL SETTLEMENT (Abstract ID: 29547)

Coral recruitment is critical to the maintenance of healthy reefs and the natural recovery of degraded reefs. For some corals, settlement, which is an integral part of the recruitment process, appears to be dependent on the presence of chemical cues produced by biofilm bacteria. Both macroalgal presence and ocean acidification (OA) have detrimental impacts on coral settlement, but the extent to which these stressors impact bacterial communities associated with settlement substrata has been underexplored. Further, these stressors will not occur in isolation, and understanding the implications of these factors in combination is critical. We exposed the crustose coralline alga

(CCA) *Hydrolithon beorgesenii* to direct macroalgal contact and OA separately and in combination. Coral larvae responded differently to CCA surfaces that had been exposed to macroalgae and lowered pH, even when the larvae themselves were not directly exposed to the algae indicating a change in surface properties of the CCA as a result of these stressors. High-throughput sequencing of the CCA surfaces revealed significant shifts in the bacterial communities of CCA exposed to macroalgae. Given the increasing evidence that bacteria provide important settlement cues for some corals, it is likely that shifts seen in response of corals to surfaces treated with macroalgae and OA may be linked to changes in the bacterial communities on these surfaces.

ADVANCING ENVIRONMENTAL MONITORING SOLUTIONS FOR OUR WORLD'S OCEANS (Abstract ID: 29565 | Poster ID: 548)

The Earth's changing climate provides many uncertainties. What we do know is the effect it is having on the oceans. Higher acidity levels are known to slow the growth of organisms forming calcareous skeletons or shells, including corals and shellfish. Ocean acidification investigation is an application that benefits from multi-parameter measurements expressed by the necessity of measuring at least two of the four parameters of the marine carbonate system. While analytical instruments are available for the four parameters, there is only one commercial option for measuring total alkalinity (TA) autonomously – the CONTROS HydroFIA® TA. Kongsberg Maritime CONTROS GmbH recently launched HydroFIA® TA, which is being used by researchers for continuous monitoring and the determination of the total alkalinity in seawater. In October 2015 a new project revolving around seawater alkalinity started: "Tracking Ocean Alkalinity using New Carbon Measurement Technologies." The project will use four different deployment platforms to enhance ocean acidification monitoring within the North western Atlantic extending from coastal hatcheries to the Iceland, and at a reef system in La Parguera, PR. Adding the all-new TA measurement capability (i.e. HydroFIA® TA) to the regional observation network is expected to provide more accurate and reliable ocean acidification monitoring. The outcome will provide much needed knowledge for ocean acidification studies that are important for examining the growth of organisms forming calcareous skeletons or shells, including corals.

CORAL ASSOCIATED MICROBIAL PARTNERS INFLUENCE HOLOBIONT METABOLITE PROFILES (Abstract ID: 28760)

Microbial symbiotic partners, such as those associated with reef building corals, mediate biochemical transformations that influence host performance and alter the trajectory of individual survival. While evidence suggests microbial community composition partly accounts for differences in coral physiology, how these symbionts alter metabolic pathways remains underexplored. We aimed to assess functional variation between coral associated microbial partners in hospite. To this end, we collected fragments from 9 coral species and characterized associated Symbiodinium and prokaryotic communities in tandem with holobiont nuclear magnetic resonance based metabolomic profiling. Our data demonstrate Symbiodinium composition, prokaryotic communities, and metabolite profiles are species-specific. Taking this holistic approach in describing the relationships between metabolite composition and symbiont assemblages, we also show that a coral's symbiont composition significantly influences the colony's metabolite profile. Using Porites spp. as a case study, we present evidence that different sub-clades of Symbiodinium and prokaryote phylotypes distinctly influence the abundance and composition of functionally important metabolites. Our data suggests that while some microbial partners benefit the union, others are more opportunistic and possibly parasitize the host. Consequently, coral partner choice alters colony metabolite composition, likely influencing cellular metabolic activities and, therefore, colony nutritional provisioning.

THE RISE OF SLIME IN SILURIAN CORAL-SPONGE-MICROBIAL REEFS IN ALASKA'S ALEXANDER TERRANE: INSIGHTS FROM ECOLOGICAL TRANSITIONS AFFECTING MODERN CORAL REEFS (Abstract ID: 28377 | Poster ID: 233)

The Alexander terrane (AT) is a Neoproterozoic island arc that accreted to North America in the Mesozoic. Diagnostic biotas constrain the AT's Silurian paleogeography to the N. Atlantic region, where the rising Caledonide Mountains induced enormous ecological changes in reefs that are analogous to those recorded at some modern reef sites. During the Silurian, the 3000 m-thick Heceta Limestone accumulated in the AT on top of a tropical, submarine volcanic edifice. Coral-sponge reefs grew at the edge of an expanding carbonate platform before they were decimated during mid-Silurian orogenic pulses. As carbonate sedimentation resumed, megalodont bivalves formed dense concentrates associated with peri-tidal microbial communities. At the platform margin, coral reefs were replaced by a distinctive microbial-sponge community, which built extensive stromatolite reefs in the absence of diverse metazoans. After experiencing regional extinction, AT reef biotas did not recover for several million years. The microbe-dominated reefs and nearshore stromatolites record widespread cyanobacterial "blooms" fueled by orogenic activity, which generated significant terrestrial influx, reduced habitats for normal-marine metazoans, and elevated nutrient loads. These ancient reefs indicate how the rise of microbial slime was related to a sediment glut, yielding insights into the devastation that modern coral reefs are likely to experience if human activities contribute increasing amounts of nutrient-laden sediment to the marine environment.

FROM OTOLITH TO ORDINANCE: UTILIZING BIOLOGY AS BASIS FOR CLOSE SEASON POLICY FOR SIGANIDS (Abstract ID: 27933)

Translating scientific findings into policy is integral to successful resource management. Utilizing results of studies on the very small and unfamiliar part of fish known as otoliths or earbones, local policy action through passage of a town ordinance to declare close season for siganids has been achieved. The present study exemplifies a science-policy continuum for an extremely important resource, culturally and economically, in Lagonoy Gulf, northeast Philippines. Researches of Bicol University in the gulf revealed the ages at settlement of siganid juveniles (*Siganus spinus, S. canaliculatus, S. argenteus*) to be about three weeks based from analysis of the microstructure of the fish's otoliths. The highest volume of juvenile settlement occurred on and near the new moon dates in March, April and May. Adding few days for egg development of the fish, spawning has been inferred by back-calculation to occur between the first quarter and new moon. From these information, the researchers of the university sought audience and elucidated these results before the Tabaco City law-making council. After series of discussions with council executives and public hearing, the close season ordinance for siganids from February to May has been approved by the council in 2010. Under the ordinance, it is prohibited to catch juveniles, maturing and mature siganids during these months in the municipal waters. There has been very slight increase in juvenile production since 2010 in the last 5 years. Continuing challenge is monitoring compliance to the ordinance and its effectiveness.

HIGH-LATITUDE REEFS AS NOVEL ECOSYSTEMS – MODELS FOR FUTURE SPECIES CONFIGURATIONS, INTERACTIONS AND FUNCTIONS (Abstract ID: 29111)

Ecosystems are responding to global change with novel species configurations, interactions and functions. Biogeographic transition zones, where tropical, subtropical and temperate species overlap, are ideal systems in which to study the links between novel species compositions, environmental gradients and ecological processes. Here, we examine these dynamics in the tropical-to-temperate transition zone in eastern Australia, where corals occur at their range limits. Systematic variation in zoogeographic, functional and phylogenetic patterns suggests that environmental filtering shapes coral biodiversity patterns. Corals on high-latitude reefs are a non-random subset of the Great Barrier Reef species pool, as only species that tolerate marginal conditions are able to persist. While this supports the dominant role of abiotic filtering at regional scale, phylogenetic diversity patterns reveal growing influence of competition at lower latitude. Range limit determinants of corals vary among taxa, as patterns in species richness and the abundance of tropical species respond to light availability, whereas cold stress and temperature variability limit subtropical species and functional diversity. Moreover, high abundance and gradients of macroalgae, echinoderms, other invertebrates and fishes point to the important role of these taxa in shaping ecological dynamics on high-latitude reefs. Gradients in the relative importance of different processes (e.g. competition, abiotic stress, herbivory) thus provide predictive models for potential novel reef configurations under climate change.

MULTI-SCALAR INTERACTIONS OF A LOCAL ISLAND FISHERIES: SPATIAL MANAGEMENT AND GEOPOLITICAL CONSIDERATIONS (Abstract ID: 28453)

Fisheries and coral reef management is rarely contained in just one scale of governance. Shifts in international market conditions or new global agreements may affect how small-scale fisheries are managed and utilized. Similarly, fishers' strategies, through compliance and self-initiatives, can be expected to influence the governability of fishing regulations. While we know that management and conservation action is often connected to multiple scales, much research has been preoccupied with the local level, giving inadequate attention to the interactions that occur beyond the local processes. This presentation illustrates the multi-scalar nature of fisheries spatial planning and management by drawing on the Korean case of a Yeonpyeong Island fishery in the Yellow Sea. More specifically, by applying the notion of governmentality, I show that a locally-operating fisheries can be embroiled in domestic politics or international maritime boundary disputes, thereby being influenced by (as well as extending its influence to) wider governance scales. At the same time, this example highlights a case of fisheries embedded in extra-sectoral considerations (e.g., geopolitics), which are outside of the typical purview of resource conservation and management. I end the presentation by exploring what these insights might mean for coral reef conservation, with special reference to the circumstances unfolding in the South China Sea.

DONGSHA ATOLL IN SOUTH CHINA SEA, THE STATUS, THE RESEARCH, THE STATION (Abstract ID: 28595 | Poster ID: 704)

Dongsha Atoll, situated in north South China Sea, is comprised of several major habitats. The 16 km-diameter lagoon and hundreds of patch reefs therein are mostly covered by hard corals. Extensive bleaching of stony corals occurred in summer of 2015. Most seemed to survive in according to a spotted survey in January 2016. The 80 km2 seagrass beds circles the lagoon and Dongsha Island;to large patches in north and northeast part of the atoll, totaling 25 km2, died off in summer of 2014 as recorded by satellite pictures and confirmed by ground truthing by divers. They have yet to recover and added another bleached patch in summer of 2015. The reef crest is covered by hard corals and debris. The reef slope extending down to 35 m deep and more is dominated by soft corals with hard corals playing a minor role; they remain unharmed in the 2014-present period. Since 2013, ~150 researcher-visits and ~1000 on-island-days exploited the facilities of Dongsha Atoll Research Station, per year. Accommodation, bench space, boats, as well as logistic support, etc were provided to both domestic and international researchers. The researches encompass issues related to global warming, ocean acidification, internal waves, reef geology, atmosphere, biology and biodiversity of tropical seas.

CROWD-SOURCING CORAL REEF VISUALIZATION- THE ARRAS EXPERIENCE (Abstract ID: 30113 | Poster ID: 561)

The Automated Rapid Reef Assessment System (ARRAS) was a Philippine Government-funded research project which began in 2010 to develop low-cost tools and software to create permanent visual records of the sea floor at a fast rate. Four years on since we introduced an ARRAS platform so that coral reef visualization can be crowd-sourced (Teardrop ICRS 2012) we report our experience in deploying the tools as well as the feedback from local governments, schools, and regional environment and natural resources offices to whom the system was donated to. Their feedback led us to develop newer technologies such as towed platforms that can image shallow, wide or deep corals, software that can stitch high definition videos from multiple cameras, and calibration techniques to estimate coral sizes from video mosaics. Together with local partners all around the Philippines we have captured nearly 1000km of coastline around the archipelago, 1/10th of the estimated 10000km of coastline with reefs. The collected and processed data has been used for coral cover assessment, change detection, automatic classification studies and site selection.

SEXUAL REPRODUCTION IN THE CARIBBEAN CORAL GENUS ISOPHYLLIA (SCLERACTINIA: MUSSIDAE) IN PUERTO RICO (Abstract ID: 28476 | Poster ID: 178)

The sexual pattern, reproductive mode, and timing of reproduction of Isophyllia sinuosa and Isophyllia rigida, two small Caribbean Mussids, were assessed by histological analysis of specimens collected monthly during 2000-2001 and 2012. Tissue cores were fixed in Helly's Zenker formalin solution, decalcified in 10% HCl, dehydrated in 70% EtOH, embedded in Paraplast, sectioned with a rotary microtome, and stained utilizing a modified Heidenhain's Azocarmine-Aniline blue method. Results indicate that both species are simultaneous hermaphroditic brooders, with a single annual gametogenetic cycle. Spermatocytes and oocytes of different stages were found within the same mesentery indicating possible sequential maturation for extended planulation. Oocytes begin development in May in I. sinuosa and August in I. rigida, approximately 7 months prior to spermatocytes both sexes reaching maturity simultaneously over at least two months; May-June in I.rigida and March-April in I. sinuosa. Significantly higher polyp ($IR=33.16\pm4.44$, $IS=3.78\pm6.42$) (t-test, $p<0.001$) and mesenterial fecundity ($IR=2.76\pm4.44$, $IS=0.87\pm1.92$) (t-test, $p=0.046$) was found in I. rigida compared to I. sinuosa. Planulation proceeded rapidly in both species; planulae were observed in I. sinuosa during April through May and in I. rigida from June through September. Hermaphroditism and brooding have also been documented in the Mussid genera Scolymia and Mycetophyllia.

MESOPHOTIC MACROALGAE ACROSS THE HAWAIIAN ARCHIPELAGO: DECIPHERING THE DIVERSITY AND DISTRIBUTION OF DEEP LIMU (Abstract ID: 29933)

Macroalgae are a conspicuous, yet poorly described, component of mesophotic ecosystems in Hawaii, forming habitat for coral reef fish in the Northwestern Hawaiian Islands (NWHI) and vast meadows in the Main Hawaiian Islands (MHI). Over the past 10 years, we have used submersibles, ROVs, and technical diving to survey the distribution and diversity of mesophotic algae at 76 sites across the Hawaiian Archipelago. Expansive macroalgal meadows of native or invasive green algae were found around Oahu (*Avrainvillea* sp., *Udotea* sp.) and the Maui Nui Island complex (*Halimeda kanaloana*) to 90 m, with distinct distribution patterns among specific islands. In contrast, macroalgal beds of *Microdictyon* were observed at mesophotic depths in the NWHI. Numerous new records and new species of macroalgae were discovered, suggesting the mesophotic flora is distinct from shallow water. Molecular analyses revealed that mesophotic sea lettuces in Hawaiian waters form unique communities composed of four new species within the genera *Ulva* and *Umbraulva*. Similar patterns of cryptic diversity are emerging for other dominant algae, such as the brown alga *Distromium*. Overall, the mesophotic flora appears to be abundant and biogeographically diverse with a combination of temperate, subtropical, and tropical affinities. The current study contributes greatly to our understanding of marine biodiversity and biogeography in the Pacific, and has significant implications regarding the unique nature of mesophotic coral ecosystems in Hawaii.

MAUI'S CORAL REEFS; MANAGEMENT SUCCESSES AND FUTURE CHALLENGES (Abstract ID: 28469)

Maui's coral reefs are experiencing numerous anthropogenic stressors ranging from land-based sources of pollution to overfishing. Fifteen years of marine monitoring by the State of Hawaii, Division of Aquatic Resources, has highlighted examples where coral reefs appear to be degrading, as well as some instances of recovery. This information has been instrumental in guiding recent resource management efforts including changes to parrotfish and goatfish bag and size limits in 2014, and has helped evaluate past management actions including a ban on the use of lay-gillnets in 2007, and the establishment of the Kahekili Herbivore Fisheries Management Area in 2009. Here we review trends in both benthic cover and fish biomass to identify examples of resiliency in reef ecosystems, and to highlight management efforts that appear to have helped reefs recover from disturbances. Five years of herbivore management at Kahekili has resulted in biomass increases of 30% in surgeonfishes and 135% in parrotfishes, while the benthic cover of crustose coralline algae has increased from 2% to 14%. A crown of thorns outbreak in the Ahihi Kinau Natural Area Reserve resulted in a 78% reduction in coral cover, however ten years later, this reef has fully recovered. A careful evaluation of these types of reef recovery events will help managers prepare for and deal with newly emerging threats from global climate change and should help Hawaii's reefs survive into the future.

SEXUAL REPRODUCTION IN THE CARIBBEAN CORAL GENUS*COLPOPHYLLIA* IN PUERTO RICO (Abstract ID: 29692 | Poster ID: 168)

Colpophyllia natans spawns during summer months throughout the Gulf of Mexico and Caribbean. Its reproductive cycle has never been characterized until a preliminary histological study in La Parguera, Puerto Rico in 1999, which revealed most gametes to be mature in spring, with few in summer. Therefore, indicating the presence of two reproductively isolated species. The second species seems to be the cryptic C. amaranthus. In this study our objective was to characterized the reproductive cycles of the two Colpophyllia species in La Parguera. After a morphological assessment in the field, two distinct morphologies were identified. Preliminary tissue samples were collected before summer spawning to confirm species identification by presence absence of mature oocytes. Then, tissue samples from five to ten colonies were collected monthly between July 2014 and June 2015. Samples were processed and examined following common histological protocols. Results of this study indicate both C. natans and C. amaranthus are hermaphroditic broadcasters with one annual gametogenetic cycle. Oogenesis lasted ten to eleven months and began earlier than spermatogenesis in both species. Furthermore, oocytes and spermatocytes developed in the same mesentery with gametes reaching maturation simultaneously. Spawning occurred in September for C. natans and March for C. amaranthus, with an average mesenterial fecundity of $7 \pm 5$ and $6 \pm 4$ respectively. These results are similar to other Caribbean Faviinae species. A taxonomic revision of the genus will be done in the near future with these data.

INTERACTIONS OF CORAL RECRUITS AND JUVENILE CORALS WITH SEDIMENT AND ALGAE ON REEFS IN THE FLORIDA KEYS (Abstract ID: 30110 | Poster ID: 199)

Coral recruitment failure has been highlighted as a major factor contributing to coral reef decline. In the Florida Keys, past work has shown that there is a diverse and abundant supply of larvae, but this pattern is not reflected in the adult community. A possible explanation for this mismatch is that new recruits settle but are either smothered by sediment or outcompeted by neighboring organisms, particularly macroalgae. In the Florida Keys, reef rugosity (structural complexity) influences top-down control of macroalgae and accumulation of sediment. We hypothesized that the abundance of recruits and juvenile corals (<4cm) is related to rugosity, sedimentation, and macroalgal abundance. We surveyed coral reef communities at three high-rugosity and three low-rugosity sites in the Florida Keys to quantify the abundance of corals, turf and macroaglae, sponges, etc. We searched for recruits and juvenile corals, including in cryptic locations and under algae, and photographed each to analyze interactions with neighboring organisms. Juveniles and coral recruits were more abundant at the three high-rugosity sites, but had similar community size structure to the low-rugosity sites. Analysis of photos of individual recruits shows that and juvenile corals with more area in contact with macroalge tend to be smaller. Additionally, juvenile corals are less abundant in areas with high macroalgal cover.

RE-VISITING THE ECOLOGY AND MORPHOLOGY OF RECENT CORAL REEFS (Abstract ID: 28415)

In 1969, David Stoddart published a major, 66 page review entitled 'Ecology and Morphology of Recent Coral Reefs' in the Biological Reviews of the Cambridge Philosophical Society. The review closed with a 14 point summary of current knowledge, concluding that 'central to any discussion of the relationships between ecology and morphology of coral reefs must be considerations of the time and space scales involved, of rates of adjustments and importance of lag effects within the system, and of boundary fluctuations.' In this paper, we re-visit Stoddart's tour de horizon and its over-arching theme, both in the general context of developments in coral reef science over the last half century and in terms of the specific contribution of David Stoddart himself to this debate.

ASSESSING CORAL REEF HEALTH IN THE NORTH ARI ATOLL, MALDIVES USING THE FORAM INDEX. (Abstract ID: 28661)

Marine ecosystems in the Maldives are richly diverse, but are experiencing growing pressure from coastal development and tourism. Assessing the status of coral-reef communities along gradients of human pressure is necessary to evaluate recovery capacity of reefs in the face of anthropogenic threats. Islands in the North Ari Atoll, which are exposed to different human impact and management regimes (4 each community, uninhabited, and resort islands), were sampled during the International Union for Conservation of Nature (IUCN)-REGERATE Cruise in 2015. Assessments were carried out using the FORAM Index (FI), based on relative abundances of larger foraminiferal shells in reef sediments. Lower FI values in the vicinity of the community island of Rashdoo indicate likely nutrification of waters associated with disposal of domestic wastes. Somewhat higher FI values were recorded around the resort island of Velidhoo. The highest values were recorded near an unihabited island, Gaattafushi. Overall, FI values determined for the reefs in North Ari indicate that water quality should support active reef accretion by reef-building corals and larger benthic foraminifers. Note that the FI was designed to account for local changes in water-quality, and not for regional to global changes associated with temperature stress or ocean acidification. This study stems from a joint scientific expedition by IUCN-Marine Research Centre and University of Queensland to study coral reefs in North Ari. We warmly thank the Swiss National Science Foundation Projects 200021_149589 and IZK0Z2_165131.

REEF SCENT: HOW BROODED CORAL LARVAE FROM A TOUGH CORAL SMELL THEIR WAY TO A NEW HOME (Abstract ID: 28255)

Coral reefs are highly diverse marine ecosystems of ecological, economic, and cultural value. With the expected negative effects on reefs from global climate change including rising sea temperatures and ocean acidification, the identification of resilient coral species has become increasingly important. *Leptastrea purpurea* is an encrusting coral that is found throughout the Indo-Pacific and Red Sea. While most corals are broadcast spawners, releasing sperm and eggs to be fertilized in the water column, some corals brood embryos within their tissues after internal fertilization. *L. purpurea* appears to release planula larvae on a continuous basis from the parent colony as observed during two years of monitoring. The planula larvae show remarkable resilience under a wide range of stressful conditions including temperature, sediment, and chemical stressors, as well as the ability to successfully settle and metamorphose after 180 days in controlled laboratory conditions. Various smells were tested to identify a settlement cue for *L. purpurea* larvae, and our results suggest that the smell associated with other coral colonies induce larval settlement and metamorphosis. Knowledge of the settlement cues and reproductive biology of this coral is important to our understanding of coral resilience in the face of anthropogenic perturbation.

HABITAT AVAILABILITY AND DEPTH-DRIVEN POPULATION DEMOGRAPHICS REGULATE REGIONAL REPRODUCTIVE OUTPUT OF A COMMON CORAL REEF FISH (Abstract ID: 29645 | Poster ID: 189)

Coral reef organisms that span broad geographic and depth distributions experience a range of habitat quality, creating variable subpopulation demographics and dynamics. At the depth boundary of coral reefs, mesophotic coral ecosystems (30-150 m) that are buffered from anthropogenic stressors may be refuges that can seed larvae to degraded coral reefs. However, the degree of connectivity via larval production is restricted by population size and reproductive output of organisms at the periphery of their distributions. We incorporated population density, benthic habitat, and depth-stratified population demographics of a model reef fish (the damselfish *Stegastes partitus*) to assess subpopulation egg production across regions that encompass the depth distribution of the species: Florida Keys (FK: 0-35 m depths) and Pulley Ridge (PR: 60-100 m). Subpopulation densities and abundance peaked at mid-depths (10-20 m) and declined as depth increased. Egg production followed a similar pattern, but was considerably affected by differences in fish size, sex ratios, and probability and frequency of spawning across depths. Despite low population densities on mesophotic reefs, the expansive reef area at PR resulted in a subpopulation size that comprised 20% of the regional population and 14% of the total reproductive output across the study region. Our results indicate that mesophotic reefs may be important sources of larvae, and that habitat availability and depth-driven population demographics have substantial effects on reproductive output across geographic regions and depths.

ASSESSING FACTORS AFFECTING CORAL TRANSPLANTATION SUCCESS IN INNER APRA HARBOR, GUAM (Abstract ID: 27968 | Poster ID: 485)

Early results from an on-going coral transplantation experiment in Inner Apra Harbor, Guam will be discussed. Study objectives include: can corals be successfully relocated from a wharf face to an adjacent site; do the corals maintain good health and grow after relocation; and what key factors affect relocation success? In July 2015, 96 healthy coral colonies from 4 species were removed from the face of X-Ray Wharf in Inner Apra Harbor and reattached to locally sourced limestone boulders placed at comparable water depths approximately 450 m away. Corals were detached and transported under water, and attached using Portland cement. The experiment includes six replicates of 16 boulders each, with one coral attached per boulder. Reference colonies of the 4 species were selected adjacent to the relocation site. Effects of species, colony size, and orientation on survivorship will be monitored for 24 mos. Survival, tissue growth, attachment, colony health, predation, disease, algae overgrowth, and paling/bleaching will be assessed. Observations from the first 2 monitoring events indicate all relocated corals firmly attached to the substrate. Most of the relocated corals and half of the reference corals showed one or more stress conditions such as paling and tissue loss. Heavy rainfall during September/October 2015 resulted in increased sediment suspension and runoff into the harbor. Water temperatures were also slightly higher during 2015. The increased sedimentation along with elevated temperatures may have contributed to the stress conditions exhibited by the relocated corals.

A CONCEPTUAL MODEL OF OYSTER REMEDIATION FOR CORAL REEF RESTORATION IN BARBADOS (Abstract ID: 28982 | Poster ID: 462)

The viability of using bioremediation to enhance coral reef recovery in Holetown Bay, Barbados was assessed to develop a conceptual model for bioremediation, taking into account the current and historic water quality data from water column and pore water. The study investigated similar bioremediation in temperate locations, and proposes using similar oyster-facilitated water quality improvements to catalyze coral reef restoration in Barbados' degraded reefs. Different methods of oyster culture were considered, exploring the extent to which oyster culture traditionally done using the Eastern oyster (Crassostrea virginica) could be adapted to boost the population of indigenous mangrove oysters (C. gasar). Breakwaters in Holetown are highly suitable for oyster growth, and oyster settlement is apparent. However, oysters are harvested and unable to improve water quality to a level that would enhance coral regrowth. The model determines how many spat would be needed to create enough oyster settlement to sufficiently filter nutrients and particulates in order to promote coral growth, and proposes public education and surveillance to ensure oysters remain to perform their bioremediation function. Estimated costs for seeding the Bay and monitoring oyster settlement and water quality are shown to be relatively small, especially compared to the economic gains that could be made by improving water quality and promoting reef-based marine tourism. This study represents the first known conceptual model for using oysters to enhance water quality and promote coral reef restoration.

TRY WAIT! REVIVING THE PRACTICE OF KAPU TO REPLENISH MARINE LIFE AT KA'ŪPŪLEHU, HAWAI'I (Abstract ID: 29990)

Today, the practice of managing fisheries by abstaining from harvest has become controversial in Hawai'i, though it has not always been so. The traditional Hawaiian concept of natural resource management ensured a mutually beneficial balance between people and ecosystems – in part through a comprehensive system of rules (kanawai) and prohibitions (kapu) that governed interactions with people and nature. As traditional Hawaiian management practices, include the ability to strictly regulate harvest of wild-caught marine species, were replaced by new laws in the 20th Century, some areas of Hawai'i were insulated from sweeping social change by virtue of their relative isolation and maintenance of an uninterrupted connection to both land and ancestral knowledge. Termed cultural kipuka, and likened to hills with high native biodiversity surrounded by more recent lava flows, these areas maintained connections that were lost elsewhere. By utilizing scientific data from Kenya, the Philippines, Palau, and across the Main Hawaiian Islands, a compromise to rest a coral reef from fishing for 10 years to grow fish while a sustainable harvest plan is developed represents a blend of traditional and modern fishery management. . Learn more about Ka'ūpūlehu and how local knowledge and global science informed this approach that honors the culture of Hawai'i and benefits the resources upon which we all depend.

PHYLOGENETIC ANALYSIS OF NUTRIENT TRANSPORTERS IN THE CNIDARIAN-DINOFLAGELLATE SYMBIOSIS (Abstract ID: 28861)

The nutritional exchange between host and symbiont plays a critical role in maintaining the cnidarian-dinoflagellate symbiosis. Using a bioinformatics approach, we investigated the nutrient uptake mechanisms of each partner to discover membrane proteins involved in transporting sugars into cnidarian cells and nitrogen products into *Symbiodinium* cells. Five protein groups were investigated: the facilitated glucose transporters (GLUT), the sodium/glucose cotransporters (SGLT), the aquaporin channels (AQP), the ammonium transporters (AMT), and the high-affinity nitrate transporters (NRT2). Homology searches were conducted to identify cnidarian sugar transporters (GLUT, SGLT, and AQP) closely related to well-characterized proteins from other metazoans, and to identify dinoflagellate (*Symbiodinium* spp.) ammonium and nitrate transporters (AMT and NRT2) closely related to well-characterized proteins from other alveolates and plants. Protein phylogenies were constructed to estimate the evolutionary placement of newly identified cnidarian proteins among other metazoans and newly identified *Symbiodinium* proteins among other alveolates, as well as to infer characteristics from closely related homologs. Ultimately, multiple cnidarian homologs were discovered in all sugar transporter groups, as well as multiple *Symbiodinium* homologs in the ammonium and nitrate transporter groups. We present the corresponding protein phylogenies and discuss the possible role of these proteins in nutritional exchange between symbiotic partners.

RELATIONSHIPS BETWEEN FISH COMMUNITIES AND HABITAT COMPLEXITY ON CORAL REEFS IN MALAYSIA (Abstract ID: 29223)

Habitat structure is known to determine the abundance and diversity of coral reef fish communities. Areas with greater habitat complexity generally support higher numbers of fish species. We examined reef fish community structure and the influence of coral cover and habitat complexity at 3 locations on the east coast of Peninsula Malaysia: Redang, Tenggol and Tioman Islands, all in marine protected areas. There is a lack of ecological research on coral reefs in this region, which is just outside the Coral Triangle. Underwater visual surveys of reef fishes and benthic habitats were conducted to examine large and local scale variation in fish abundances and community structure, and one-minute timed swims were filmed in different habitat types to examine the effects of habitat structure on reef fish species richness at a finer spatial scale. The reef fish communities were similar among the 3 locations, however there were some differences in relative abundances of the most common species. Densities of coral-associated species correlated positively with coral cover. The timed swims on different habitat types showed that many of the fish species, particularly the damselfishes, have strong associations with particular coral morphologies or particular types of dead or non-coral substrates. For both of the most abundant and speciose fish families, the damselfishes and wrasses, species richness was higher in areas with a mixture of habitat types compared to areas with almost 100% cover of either live coral or dead/non-coral substrate. This work adds to our understanding of the importance of live coral diversity and spatial heterogeneity in structuring reef fish communities.

QUESTIONS WE NEED TO ASK! (Abstract ID: 27866)

Science and scientists develop along two distinct avenues; by either following a trend and studying what others study, or by exploring novel questions often enabled by technological advances that open new frontiers. Common to both is a level of secrecy about

what is being done, how, and by whom, a scenario that leads to significant redundant effort within the reef science community. Further, reef scientists almost never openly discuss the importance or relevance of questions being explored before the work is started, or while it is in process, and individuals working on closely related questions generally compete rather than coordinate, even though the latter would result in the greatest knowledge gain. This session focuses on basic questions and collaboration. We will explore long-standing unanswered and new questions that, if answered, could rapidly advance our understanding of corals and corals reefs. In short format talks, presenters will be asked to present unanswered questions, highlight their importance, discuss perceived obstacles, and suggest ways to potentially overcome these and advance the science in their specific area. The session will be highly interactive and the presentations used to stimulate a dynamic discussion regarding the themes raised as well as other activities and questions of importance in coral reef science. The goal is to develop a community-prioritized list of research activities and collaborations that can serve as a guide for future work and a framework for funding agencies in their calls for research

SEASCAPE MODELS REVEAL THE EFFECTS OF FISHING PRESSURE ON HABITAT USAGE OF CORAL REEF FISHES (Abstract ID: 29237)

The influence of habitat has long been understood to play a primary role in structuring fish assemblages and driving their distributions. Interactions between multiple variables across scales determine habitat suitability and quality for individuals and species. In addition to physical variables such as wave energy, a major factor structuring fish assemblages is the impact of fishing. Biomass of targeted reef fishes under low, medium, and high fishing pressure in the main Hawaiian Islands was modeled based on a suite of remotely sensed habitat variables, including structural and spatial pattern metrics, in a seascape ecology approach. A fishing pressure index based on accessibility to humans and scaled by total fishing effort by island was used to stratify reef fish survey locations. Boosted regression trees revealed that even very low fishing effort (<5 trips/ha) had implications for resource fish biomass. For all target fish combined, structural complexity emerged as the key predictor across all fishing pressure categories. Small-bodied fishery species were associated primarily with structural complexity at low levels of fishing, suggesting the influence of predation, while the distribution of large-bodied species was driven largely by wave power, which may reduce fishing pressure and mitigate land-based pollution. This novel approach reveals how human influence affects the relationship of reef fishes to their environment and has important implications for ecosystem-based management of nearshore fisheries in Hawaii.

HOW MARKETS ARE INFLUENCING GOVERNABILITY OF SMALL SCALE FISHERIES: UNDERSTANDING OPPORTUNITIES FOR MULTI-SCALE GOVERNANCE (Abstract ID: 28206)

Market systems are increasingly influencing small-scale fisheries. On one hand market interactions are considered key for economic development and poverty alleviation. On the other hand, price fluctuations, high market demand and monopolies have shown to compromise food security of the marginalized poor and threaten ecological sustainability. Small scale fisheries are complex and involve various governing institutions operating at different levels with different objectives. Multi-scale fishery market chains connect fishers, traders, managers and consumers. Considering this we question the simplistic dichotomy that commonly frames market as an influence on fisheries. We propose that closer consideration of how multiple governance systems emerge and function along a market chain yields more nuanced understanding of how governance of a small-scale fishery at the chain's supply-side is influenced. Five small-scale fisheries with varying local to global market chain lengths operating in the Coral Triangle Region are examined. Drawing from Interactive Governance theory we identify governing systems that have emerged at particular points in each market chain, and which are formed from specific arrangements of 'governance subsystems'. We recognize four governance subsystems that appear dominant in contemporary fisheries management; namely those centered on (i) government, (ii) decentralized multi-stakeholder management, (iii) private sector and pricing, and (iv) culture and social relations. This perspective highlights opportunities towards more effective multi-scale governance.

ULTRAVIOLET RADIATION AND CORAL EMBRYOS: DNA DAMAGE, SURVIVAL, AND DEVELOPMENT (Abstract ID: 29715 | Poster ID: 46)

Embryos of broadcast spawning reef corals spend 2-3 days floating near the ocean surface as they develop into mobile, ciliated planula larvae. These embryos may be exposed to high levels of ultraviolet radiation (UVR), particularly UVB (280-320 nm) that stimulates production of thymine dimers in DNA and interferes with replication and transcription, potentially increasing mortality or developmental defects or altering timing of development. In an effort to quantify the impact of UVR exposure on coral embryos and identify mechanisms that have evolved to mitigate negative effects, we measured UVR-induced DNA damage, survival, and development in the embryos of a Caribbean coral, Acropora palmata. Embryos were reared in outdoor tanks shaded by either UVR-transparent or UVR-opaque plastic. Samples for DNA damage and development were collected and survival assessed each afternoon after peak UVR exposure. DNA damage was quantified in coral embryos with an ELISA assay using a primary antibody that binds to thymine dimers, while the development time series was assessed via microscopy. We found that, over time, differential UVR exposure had little effect on DNA damage, timing of development, or survival in A. palmata embryos. Early differences in DNA damage and development timing between UVR exposure treatments disappeared by the third day after fertilization. Our findings on embryos support previous data from larval and adult life stages that A. palmata is well adapted to deal with the high UVR stress that accompanies life in shallow, clear tropical waters.

RESPONSE OF EARLY CORAL SETTLERS TO ENVIRONMENTAL CONDITION IN PELEKANE BAY, HAWAI'I (Abstract ID: 30105 | Poster ID: 454)

Larval production, early settlement and recruitment of corals are crucial biological processes for preservation of coral reef ecosystems. While coral settlement and recruitment has been known to show high natural variability in a given time and space in Hawai'i, early settlers and recruits may be especially sensitive to environmental degradation and unsuitable habitats. The distribution of coral settlement were studied in the Pelekane Bay and Kawaihae area, West Hawai'i to better understand the spatial and temporal variability of Hawaiian coral settlers, their response to human-altered environmental conditions, and to provide a baseline for long-term monitoring information that is essential to the effectiveness of corrective management effort in the South Kohala region. Settlement arrays were deployed at 37 sites along an environmental gradient established in 2010 and 2011, and replicated in 2014. On average, coral settlement is extremely low in the highly-sedimented inshore environment compared to farther offshore . There is no large statistical variation between years. Although overall variability of coral settlement has been known to be typically high in time and space, there was a considerable difference between the abundance and distribution of settlers by environmental conditions and habitat characteristics. Patterns of coral recruitment can be a useful indicator of environmental change and the potential recovery in relation to land-derived sedimentation in Hawai'i.

THE EASTERN CARIBBEAN: A LABORATORY FOR STUDYING THE RESILIENCE AND MANAGEMENT OF CORAL REEFS (Abstract ID: 28490)

"Degradation" is almost synonymous with the phrase "Caribbean coral reefs". The most commonly cited causes of decline are global warming, ocean acidification, pollution and overfishing. However, determining the relative contribution of these stressors is difficult because often all occur simultaneously. We assessed reef condition over a 736 km region of the eastern Caribbean from Anguilla to Grenada focusing on (when possible) the windward shores of low islands with little or no runoff. Islands of this archipelago are oceanographically and biologically distinct from adjacent islands due to the strong Equatorial Current and Trade Winds. We focused on coral reefs with no-take reserves (NTR) and high compliance (based on interviews and observations) compared to adjacent control reefs. We studied 55 reefs among 15 islands with 642 fish transects (n = 36,905 fish), and 217 coral/algal transects. Overall, NTR had twice the fish and parrotfish biomass, significantly less macroalgae and significantly greater abundance of adult and

juvenile corals than the adjacent fished areas. Coral cover in some reserves averaged over 35% (twice the abundance of fished reefs). In St. Croix where we documented a 30% decline in coral cover from 1982 to 1995, revisiting the same sites in 2014 revealed live coral at nearly 1982 level with expansive stands of Acropora palmata in places. We conclude that local management of reef fish and particularly herbivorous fish can have a strong positive impact on coral reefs thereby facilitating their recovery and improving resilience to a healthy state.

THE SMARTFIN: HOW SURFING COULD HELP INFORM COASTAL OCEAN SCIENCE AND CONSERVATION (Abstract ID: 30020 | Poster ID: 722)

Coastal marine ecosystems only represent a small percentage of the global ocean's surface area. However, these ecosystems are highly productive, rich in biodiversity, and are where the vast majority of human activity occurs. The complex interaction between seawater, land, and atmosphere makes coastal ecosystems some of the most dynamic in terms of seawater chemistry. In order to capture these dynamic changes in seawater chemistry across appropriate spatial and temporal scales requires a large amount of measurements. Unfortunately, it is often challenging to maintain an array of oceanographic sensors in coastal ecosystems, especially in high energy areas like the surf zone. Citizen science has the potential to increase the collection of oceanographic data from coastal systems such as coral reefs where traditional methods are more difficult or expensive to implement. This talk will highlight the Smartfin, a surfboard mounted fin that measures seawater chemical parameters, physical wave characteristics, and GPS location during an ordinary surf session. Coral reefs offer some of the most attractive and crowded surf breaks, and with an estimated 23 million surfers worldwide the Smartfin could greatly enhance vital data collection at these sites. The data from a Smartfin can be immediately uploaded to a server via Bluetooth and WiFi connection, making the data available in real time. Real time information on variables such as surface seawater temperature could help to better inform coral reef scientists, conservationists, and managers.

SEDIMENT TRAPS FOR MONITORING LAND-BASED IMPACTS ON MARINE ECOSYSTEMS: APPLICATIONS AND RESULTS IN AUSTRALIA AND CORAL TRIANGLE INITIATIVE REGION (Abstract ID: 29900 | Poster ID: 458)

Increasing interest in land-based impacts on marine ecosystems makes it necessary to monitor impacts with appropriate technology. Sediment traps are a simple but effective technology to provide tangible time-integrated samples. Much of the research on sediment traps to date relates to efficiency of instruments to collect suspended particles. However, there is limited understanding of the precision of instruments under natural environmental conditions or subsequent inference space of trap results over a range of spatial and temporal scales. Our recent studies show that well designed sediment traps have excellent precision, and that large differences in the composition and concentration of suspended sediment can occur over fine scales in what appear to be relatively homogeneous coral reef environments. We describe a methodology that may be useful for assessing the precision of sediment traps and further assist in the calculation of trap efficiency. Examples from the application of Sedisampler(TM) traps, including sampling design and initial results will be discussed from several long-term monitoring projects, including in the Coral Triangle (Kimbe Bay, Papua New Guinea), and Australia (Great Barrier Reef and Shark Bay). Our results suggest that monitoring of suspended sediment at coral reefs requires methods that can capture spatial and temporal variation at finer scales than is typically possible at present. Sediment traps are underutilized for investigating the role and fate of suspended particulate matter, and associated contaminates, in marine ecosystems.

ARE YOU MY BROTHER? RAD GENERATED SNPS REVEAL HIGHLY CONNECTED PARROTFISH POPULATIONS WITHIN THE PHILIPPINES. (Abstract ID: 28843)

Coral reefs within the Coral Triangle are home to the greatest marine diversity on the globe, but are often subjected to extreme fishing pressure. Marine protected areas (MPAs) have been proven to be effective management tools in this region, however the ability of MPAs to promote connectivity and resilience across large distances is still poorly understood. We used RADseq to discover 4,235 and 12,619 SNPs for two species of parrotfish (*Scarus niger* and *Chlorurus bleekeri*) and 16,853 SNPs a rabbitfish (*Siganus guttatus*) collected in the Philippines and Vietnam. Population analyses suggested high levels of gene flow within the Philippines (pairwise FST ranging from 0.0007 to 0.0018), weak structure between Vietnam and the Philippines (pairwise $F_{ST}$ between 0.021 and 0.025). Additionally, sibling analyses revealed 1 pair (*S. niger*) and 4 pairs (*C. bleekeri*) of putative full siblings (r = 0.773 – 0.500) and 1 pair (*S. niger*) and 6 pairs (*C. bleekeri*) of putative half siblings (r = 0.499 - 0.191) for sites separated by more than 400km. The low $F_{ST}$ values and sibling pairs across distant reefs indicate both genetic and demographic connectivity. These patterns suggest that MPAs within the central Philippines could theoretically provide an influx of larvae to overfished reefs throughout the region.

TEMPORAL VARIATIONS IN CALCIUM CARBONATE DISSOLUTION RATES UNDER AMBIENT AND ELEVATED PCO2 IN A SHALLOW CORAL REEF LAGOON (Abstract ID: 28219)

Dissolution of permeable calcium carbonate ($CaCO_3$) sand on coral reefs is likely driven by environmental dissolution (overlying bulk seawater chemistry), benthic metabolism, and bioerosion. Most studies on dissolution are confined to laboratory, mesocosm, or rare in situ studies, but none of these have considered seasonal variations. Coral reefs exhibit high natural variability of carbonate chemistry on spatial and temporal scales, driven by processes such as photosynthesis, respiration, calcification and $CaCO_3$ dissolution. This inherent variability of reef biogeochemistry complicates projections for the effects of ongoing ocean acidification on coral reef ecosystems. In order to understand future responses of coral reef ecosystems to elevated carbon dioxide ($CO_2$) it is necessary to first understand the natural variability of the carbonate chemistry and dissolution rates and the controls on these processes. This is particularly important in the context of a possible shift from net calcification to net dissolution of reefs which some models project for the end of the century. This study investigated $CaCO_3$ dissolution rates under both ambient and elevated $CO_2$ levels in relation to seasonal variations in water column physico-chemical properties and benthic metabolism.

CORAL REEFS AS CHAOS: AN ASSUMPTION-FREE, SYSTEM-STATE APPROACH TO CAUSALITY, DYNAMICS AND PREDICTIONS (Abstract ID: 30026)

Although there is a high risk of continued reef loss on a global scale, responses to widespread stressors at local and regional scales indicate that resilience to chronic stress is possible but also variable. Coral reefs are complex systems that exhibit nonlinear behavior, including chaos, feedbacks, multistabilities, cascading effects, adaptation and emergent phenomena. Using traditional models to resolve these dynamical processes that control resilience is problematic due to error from excluded variables, incorrectly identifying mirage correlations as system drivers, and untestable assumptions about relationships between variables. Alternatively, a changing coral reef can be considered a trajectory through different states, whose change over time depends on previous states and is determined by a set of rules. We present a promising new technique for understanding and forecasting ecosystems that is adapted from single-species Empirical Dynamic Modeling, using time series data to reconstruct nonlinear state-space. This reconstruction preserves the topology of its chaotic attractor manifold, which represents a trajectory of linked variables through state-space, allowing us to correctly discern shared causal drivers from interactions. Without the need for error-inducing model assumptions, this approach also outperforms all other tested models for forecasting system dynamics. We show ecosystem-scale predictions from simulated and real data that demonstrate the tremendous value of this tool for improving our understanding and management of coral reefs in a changing world.

MODELING CORAL LARVAL DISPERSAL AND INTERISLAND CONNECTIVITY TO HELP DESIGN MUTUALLY-SUPPORTING MARINE PROTECTED AREAS: INSIGHTS FROM MAUI NUI, HAWAII (Abstract ID: 28753)

Connectivity is one of the most important factors in evaluating the size, number, and spacing of individual marine protected areas to design an integrated network of marine protected areas. To provide such information for federal, state, and local managers in Hawaii, the US Geological Survey, Deltares, and the University of Hawaii worked to develop a physics-based numerical circulation model to determine the role of ocean currents in transporting coral larvae from natal reefs in Hawaii's Maui Nui complex

(Maui, Lanai, Molokai, and Kahoolawe). Spatially- and temporally-varying WRF-ARW wind, WAVEWATCH III wave, and NCOM circulation model output were used to drive a three-dimensional, physics-based Delft3D circulation model for the Maui Nui complex. The model was calibrated and validated using surface current drifters deployed during the July 2013 coral-spawning event. The Delft3D model was then used to simulate the movement of reef-building coral Montipora capitata larvae from 17 reefs during 5 spawning events in 2010-2012. These simulations allow us to investigate not only the general dispersal patterns from individual coral reefs, but also how anomalous conditions during individual spawning events can result in large deviations from those general patterns. Overall, the data suggest that many of the coral reefs in Maui Nui seed reefs on adjacent islands, demonstrating the interconnected nature of the coral reefs in Maui Nui and providing the scientific underpinning for the design of a mutually-supporting network of marine protected areas to support coral reef conservation.

RNA-SEQ AND MANIPULATIVE EXPERIMENTS IDENTIFY KEY RECEPTORS INVOLVED IN LARVAL COMPETENCY (Abstract ID: 29809 | Poster ID: 194)

Dispersal potential of a species is a major parameter used in reef-conservation management and is also a key target for evolution in response to climate change. The length of the larval competence period greatly contributes to a larva's ability to disperse to new environments. Identifying key receptors and groups of genes underlying larval settlement competency would provide insight into mechanisms underlying the ability of corals to disperse. We measured settlement competency, global gene expression and larval fluorescence throughout thirteen days post-fertilization in *Acropora millepora*. Molecular changes that strongly correlated with competency and fluorescence included upregulation of ion channels, calcium-binding proteins, and G-protein coupled receptors. A drug screen targeting these receptors confirmed that they are involved in driving larval settlement behavior and metamorphosis. This study also gives insight into the possible biological function of coral fluorescent proteins through this important life-history stage.

PHYSIOLOGICAL RESPONSES OF ACROPORA TENUIS ON A NUTRIENT AND TURBIDITY GRADIENT IN THE GREAT BARRIER REEF (Abstract ID: 29584)

Rising seawater temperatures from increasing atmospheric greenhouse gas concentrations increase rainfall variability in many tropical regions. This leads to increased terrestrial runoff and more frequent flood events, which washes sediments and nutrients from urbanized river catchments into coastal waters and increases turbidity level in inshore coral reef ecosystems. To date it remains controversial whether coastal eutrophication increases resistance / resilience of scleractinian corals to predicted environmental changes (e.g. increasing seawater temperature, cyclones, UV radiation), or if corals in nutrient-enriched or turbid waters are more vulnerable to those stressors. To assess coral health on a nutrient and turbidity gradient, the physiological performance of the branching coral Acropora tenuis was investigated at three inshore reefs (Burdekin River catchment region) of the Great Barrier Reef and in two mid-shelf reefs, which are distant from most terrestrial influences. Net photosynthesis, dark respiration and calcification rates of live corals were determined in field based light and dark incubation experiments. Coral samples were further analysed for total antioxidant capacity and programmed cell death as marker for cell protection and tissue maintenance. Acropora tenuis showed strong physiological performance and a high level of cell protection at all reefs investigated. Nevertheless, net photosynthesis and calcification decreased with reduced light intensity, which suggests reduced skeletal density and lower resilience of corals at more turbid inshore reefs.

POTENTIAL CHANGES IN THE DISTRIBUTION OF EASTERN PACIFIC REEF CORALS IN RESPONSE TO CLIMATE CHANGE (Abstract ID: 28179 | Poster ID: 366)

Climate change will modify oceanographic conditions and probably leave only limited areas with suitable conditions for reef development; one of these may be the Eastern Tropical Pacific (ETP) one of the most outlying and geographically isolated reef regions in the world. The objective of this work is to evaluate potential range shifts in 27 reef-corals currently resident in the ETP, on the basis of ecological niche models (built with the MaxEnt software) and prognostications of temperature increase from an ensamble of six different global models and under the RCP 2.6, 4.5 emission scenarios for the year 2050 and RCP 8.5 for the years 2050 and 2100. The basic data correspond to georeferenced occurrence records of the species, combined with 27 oceanographic variables. Results show that the overall average loss of habitat of the reef corals in the ETP would reach respectively 52%, 47% and 29% in scenarios 2.6, 4.5 and 8.5 in 2050 and 54% in the scenario 8.5 in 2100. In scenarios 2.6, 4.5 and 8.5, 2050, respectively, thirteen, thirteen and four species lose more than 50% of their distribution area and one its entire area. In the scenario 8.5 in 2100, fourteen species lose more than 50% and one suffer local extinction. On the other hand, between the species that would increase their geographic area, only few of them would extend their ranges to higher latitudes. Evaluating the individual contribution of environmental variables on the MaxEnt models, light attenuation was key to determine distribution in most species, and might be the factor that would limit latitudinal displacement of populations to the north in response to ocean warming.

UNDERSTANDING THE IMPACTS OF DREDGING ON SPONGES (Abstract ID: 29035 | Poster ID: 435)

Dredging operations generate three central abiotic stressors for marine organisms. Elevated total suspended solids (TSS) can cause light attenuation and result in high sediment deposition. These stressors can impact ecologically important filter feeders, including sponges. Experimental exposures using six abundant and broadly distributed sponge species revealed that stress responses were species specific. Whilst *Carteriospongia foliascens* exhibited high mortality under both elevated TSS and low light, most species exhibited sublethal responses to the three stressors. Novel sensitive methodologies were developed to characterise and quantify these sublethal stress responses. Microcomputed tomography (microCT) scanning was used to visualise and quantify sediment management strategies in 3D and revealed that *Stylissa flabelliformis* employs both active and passive mechanisms for moving sediment within sponge tissue. Customised thermistor flowmeters were additionally constructed to measure changes in sponge pumping rates. Short term exposure of *Cliona orientalis* to high TSS decreased pumping rates within one hour with complete pumping cessation after 2 hours. This research provides an improved understanding of sponge responses to dredge-related pressures and will contribute to more effective management of dredging operations in the future.

FUNCTIONAL DISTINCTIONS AMONG BROWSING HERBIVOROUS FISHES: REDUCED REDUNDANCY AND THE IMPORTANCE OF LARGE INDIVIDUALS (Abstract ID: 28466)

By identifying functional groups among coral reef fishes we can begin to understand key drivers of reef resilience. However, broad classifications of species into functionally homogenous groups may disguise important variety. In browsing herbivorous fishes, numerous studies have identified the species feeding on mature macroalgae, and how this varies spatially, temporally, and among different algal types. Remarkably bites per se have received little attention beyond being counted, although they form the essence of the herbivorous function. We quantified details of the feeding-behaviour and -morphology of the four dominant browsing species on the Great Barrier Reef. The algal material they targeted revealed two distinct groups: 'entire thallus-biters' vs. 'leaf-biters'. *Kyphosus vaigiensis* and *Naso unicornis* indiscriminately bit on the entire macroalgal thallus in 90% of bites. In contrast, *Siganus canaliculatus* and *S. doliatus* targeted leaves only, selectively avoiding stalks. Across species, differences in body size supported this functional distinction. As the smaller 'leaf-biting' species are unlikely able to compensate for a loss of the functionally dominant larger 'entire thallus-biting' species, functional redundancy within the macroalgal browsers appears not only lower than previously assumed, but also at risk through exploitation of large fishes. These findings caution against assumed homogeneity within this, and potentially other, functional groups on coral reefs, and highlight the importance of evaluating behavioural details.

NEW VIIRS SATELLITE OCEAN COLOR PRODUCTS FOR MANAGEMENT OF LAND-BASED SOURCES OF POLLUTION OVER CORAL REEFS (Abstract ID: 28389 | Poster ID: 444)

The National Oceanic and Atmospheric Administration's (NOAA) Coral Reef Watch (CRW) program has teamed with NOAA's Center for Satellite Applications and Research (STAR) Ocean Color Team to develop new satellite products designed to assist managers in monitoring the threat of land-based sources of pollution (LBSP) to coral reef ecosystems. Areas of focus include U.S. Coral Reef Task Force Priority Watershed sites and related reef areas in Puerto Rico, Hawai'i, and American Samoa. Near-real-time satellite products of turbidity (Diffuse Attenuation Coefficient at 490nm- Kd[490]), Chlorophyll-a, and sea surface temperature (SST) are being developed using ~750m resolution ocean color measurements from the Visible Infrared Imaging Radiometer Suite (VIIRS) launched in 2011. Background levels of each parameter are being derived using historical VIIRS data from 2012 to the present. Anomaly and time-series products are being constructed to give managers information as to how water quality conditions have varied through time. In collaboration with NOAA's Educational Partnership Program (EPP) and local student interns, in-situ measurements will be taken over coral reefs to validate each parameter. A pilot calibration/validation field study of the VIIRS ocean color products for coral reefs is already underway in the Guánica Bay Watershed, La Parguera, Puerto Rico with the University of Puerto Rico. Building on this pilot effort's success, the project will expand to include Hawaii's priority West Maui watersheds in 2016 and hopefully American Samoa in 2017.

COMPARING GENETIC CONNECTIVITY AND GENE EXPRESSION ACROSS SHALLOW AND MESOPHOTIC REEF CORALS IN THE GULF OF MEXICO (Abstract ID: 28954)

Mesophotic coral ecosystems (MCEs) comprise reef environments between 30-150m and in some cases have coral communities similar to those found on shallow reefs. Glynn (1996) originally proposed that deeper reefs may act as a coral refuge by providing larvae to nearby shallow reefs. Key questions underlying this theory remain unanswered including: (1) How well are MCEs connected to shallow reefs, and (2) Can corals adapt their morphology and gene expression to match changing environmental stimuli? To address these questions, an integrative approach combining assessments of genetic connectivity, gene expression, and corallite morphometrics was employed to investigate *Montastraea cavernosa*, a ubiquitous depth-generalist species in the Flower Garden Banks National Marine Sanctuary (FGBNMS) and Pulley Ridge MCEs. Microsatellite analysis suggests panmixia between FGBNMS banks and relatively high connectivity across sites in the Caribbean and SW Florida, consistent with dominant current patterns in the Gulf of Mexico. Genetic differentiation in the Pulley Ridge population indicates relative isolation of *M. cavernosa* from other sites in the Gulf. Gene expression profiling was completed using a novel RNA-Seq pipeline, resolving whole-transcriptome differences among shallow and mesophotic corals at FGBNMS. This research is designed to provide data for improved regional management of deeper coral reef ecosystems and collaborative marine research with NOAA partners through the Cooperative Institute for Ocean Exploration, Research, and Technology.

APPLICATION OF MASS SPECTROMETRY-BASED PROTEOMICS TO STUDY LARGER BENTHIC FORAMINIFERA AND THEIR RESPONSES TO ENVIRONMENTAL CHANGES (Abstract ID: 28735)

A new method for studying large benthic foraminifera (LBF) using novel proteomic techniques was developed. Foraminifera are a highly diverse group, contributing strongly to calcium carbonate production within oceans and commonly used as environmental indicators. LBF harbor photo-symbionts making them vulnerable to environmental changes, especially ocean warming. Due to their small size, genetic and traditional protein studies are challenging. Even for the cosmopolitan group Amphisteginidae, very little is known about their molecular biology. Therefore, cellular processes occurring in response to environmental changes are widely unknown. The presented method is based on the complete proteome analysis by liquid chromatography-mass spectrometry (LC-MS). This method allows differentiation between taxa by identification of tandem mass spectra via *de novo* peptide sequencing and homology searching as well as a new approach comparing unidentified mass spectra by computing the similarity between datasets. Moreover, label-free quantification of peptides detects changes in the relative abundance of certain protein-candidates in response to stress. Results from a temperature experiment on*Amphistegina gibbosa* show variations in the quantity of peptides linked to physiological stress. The presented approach gives deeper insight into the compartment specific cellular responses, induced in the foraminiferal host or photo-symbionts, offering new methods to monitor stress responses in this host-symbiont system.

STRENGTHENING THE MARITIME LOCAL GOVERNMENT NETWORK: TOWARD A SELF-RELIANT MARITIME LOCAL GOVERNMENT NETWORK TO SUPPORT CTI-CFF RPOA AND NPOA IMPLEMENTATION (Abstract ID: 28141)

Coral Triangle Initiative on Coral Reefs, Fisheries, and Food Security (CTI-CFF) is a multilateral partnership of six countries to sustain extraordinary marine and coastal resources by addressing crucial issues such as food security, climate change and marine biodiversity in the Coral Triangle, which provide significant benefits to around 363 millions people reside in the region and billions more outside. CTI-CFF Regional Plan of Action (RPOA) recognizes the strategic importance of Local Governments (LGs) and communities in coastal and marine management and protection. An ongoing effort to engage local governments in the CTI-CFF process since they share the common challenge of facing the front lines of marine and coastal management with local constituents. These critical and key stakeholders in the CTI-CFF process and achievements are expected, or mandated, to conduct community level planning, adopt and implement fisheries management strategy, establish and manage marine protected areas, and to implement climate change adaptation measures. Progresses have been made and more ahead in strengthening the network capacity; prioritizing the development of a clear communication strategy to facilitate and enable interaction among members; more participation and support from non-LGs institutions and to achieving the network self-reliant and effective. A roadmap for 2015-2018 developed to include capacity building to align the local program and CTI-CFF goals; exchanges and partnership programs; institutional framework development; active membership program; and technical supports.

DO PARROTFISH RULE MESOAMERICA? THE IMPACTS OF FISH HERBIVORY ON REEF MACROALGAL AND CORAL COVER TRAJECTORIES (Abstract ID: 28335)

Long-term phase shifts from coral to macroalgal dominated reef systems are well-documented in the Caribbean. Although the impact of coral diseases, climate change and other factors is acknowledged, major herbivore loss through disease and overfishing is often assigned a primary role. However, direct evidence for the link between herbivore abundance, macroalgal and coral cover is sparse, particularly over broad spatial scales. In this study we use a database of coral reef surveys performed at 85 sites along the Mesoamerican Reef of Mexico, Belize, Guatemala and Honduras, to examine potential ecological links by tracking site trajectories over the period 2005-2014. Despite the long-term reduction of herbivory capacity reported across the Caribbean, the Mesoamerican Reef displayed relatively low macroalgal cover at the onset of the study. Subsequently, increasing fleshy macroalgal cover was pervasive. Herbivorous fish populations were not responsible for this trend as fleshy macroalgal cover change was not correlated with initial herbivorous fish biomass or change, and the majority of sites experienced increases in macroalgae browser biomass. This contrasts the coral reef top-down herbivore control paradigm and suggests the role of external factors in making environmental conditions more favourable for algae. However, herbivorous fish, in addition to marine protection, had a positive impact on hard coral cover, which increased over the observation period, while coral cover trends were unrelated to macroalgal cover. This suggests the presence of alternative mechanisms such as reduced competitive pressure, disease prevalence, and physical damage benefiting coral communities.

LONG-TERM CORAL REEF MONITORING IN AMERICAN SAMOA (Abstract ID: 29575 | Poster ID: 553)

American Samoa is the only U.S. territory in the South Pacific and forms the easterly part of an archipelago shared with the independent country of Samoa. Both countries share a traditional culture with historically a strong reliance on the natural environment as a source of food, in particular from the ocean. The American Samoa Coral Reef Monitoring Program has been collecting benthic and fish population data since 2006. The key goal is to monitor the status and trends in the distribution and abundance of biota on nearshore coral reefs. Using various data analyses and mapping tools the current status of coral reefs at specific sites was assessed with the aim of detecting potential temporal and spatial trends in fish and benthic community composition. Additionally, a coral reef health index was adapted and tested to assist with identifying more resilient coral reef communities in relation to watershed condition, varying levels of protection from fishing activities, and natural disturbance events such as crown of thorn starfish outbreaks, coral bleaching, hurricanes and the 2009 tsunami. Case studies are presented to highlight specific areas where the data suggest the need for further investigation and management actions to improve the health of the ecosystem.

EVIDENCE FOR A SIGNAL TRANSDUCTION PATHWAY ASSOCIATED TO GLYCEROL SYNTHESIS IN SYMBIODINIUM (Abstract ID: 28427 | Poster ID: 115)

One of the most important aspects in the mutualistic symbioses between cnidaria and Symbiodinium, is the translocation of reduced organic carbon from the algal partner (e.g. glycerol, glucose, lipids). Host nitrogen assimilation, growth rates and calcification, are all associated to this translocated carbon. However, we do not have a clear understanding of the mechanisms involved in the stimulation and regulation of this transfer. We focused our attention to glycerol, since it represents a simple, diffusible source of carbon for the metabolism of the host, and has been considered an important translocated photosynthate. We explored the existence of a signal transduction pathway that could potentially regulate the synthesis of glycerol, with conserved elements from yeast to humans: histidine kinases for sensing, MAP kinase cascade for signal transduction and homologous transcriptional factors for gene modulation. The pathway, known as the high osmolarity glycerol (HOG) pathway in yeast, can be stimulated by osmotic or oxidative stress. We identified elements of this pathway in S. minutum through bioinformatic analysis. To validate its existence, we used (1) immunological detection of a predicted transcription factor homologous to p38 (humans) and Hog1p (yeast), (2) specific inhibition of p38 and its effect on glycerol production, (3) immunological detection of a predicted type-2 phosphatase that regulates Hog1p (anti-Ptc2), and (4) induction of glycerol synthesis in Symbiodinium under stress. We conclude that this signaling pathway may be related to glycerol synthesis in Symbiodinium.

PHOTOPHYSIOLOGICAL TRAITS ARE GLOBALLY DIAGNOSTIC OF REEF CORAL SUSCEPTIBILITY TO THERMALLY INDUCED BLEACHING (Abstract ID: 28471)

Coral symbiont (Symbiodinium spp.) diversity is a major factor regulating coral susceptibility to thermally-induced bleaching. However, the key functional traits that broadly underpin, and thus are potentially diagnostic of, thermal sensitivity amongst Symbiodinium's immense phylogeny remain unresolved. Using Symbiodinium isolates (n=18) covering broad ITS2 type diversity from clades that associate with reef corals (A-D, F), we show that active fluorescence-derived photophysiological traits under ambient growth (non-stress steady state) are highly variable amongst ITS2 types; this variability of trait expression (notably dynamic nonphotochemical energy dissipation) did not generally reflect differences in phylogeny, but was empirically related to differences in heat stress tolerance. To examine whether this relationship of steady state trait expression and thermal sensitivity was conserved for Symbiodinium in hospite, we further mined fluorescence data from corals in Australia, Brazil, Indonesia, Palau, Red Sea and Seychelles (n= 86 with >40 identified coral species-ITS2 type combinations). Consistent with our laboratory data, ~50% of variance of heat stress sensitivity could be explained by that of photophysiogical trait expression under ambient growth, thus providing the first evidence for a global diagnostic of coral thermal sensitivity independent of Symbiodinium phylogenetic identity. Our relatively simple assessment of traits expressed under ambient growth but conferring probable vulnerability to thermal events provides a new anticipative management platform.

CORAL REEF RECOVERY AND RESILIENCE ON PATCH REEFS IN KANEOHE BAY, OAHU (Abstract ID: 28254)

The resilience of coral reef ecosystems has been discussed in the literature for over four decades but has been limited due to the small number of long-term studies that span decades. Increasing frequent and severe disturbances such as major weather events, fresh water kills, and increase in nutrients and sedimentation from surface runoff are causing increased stress to the Kaneohe Bay marine ecosystem. Two events initiated the recovery of coral on patch reefs; the diversion of sewage and associated nutrients outside of the Bay and the disappearance of the native invasive macroalga Dictyosphaeria cavernosa. The resilience, or the recovery of the community, may depend on the ability of remaining corals to vegetatively grow and outcompete macroalgae that once dominated. At the same time, the composition of the macroalgal and herbivore communities that occupy the reefs are critical to the outcome. In the 45 year period from the mid-1960's to 2011, mean coral cover has increased at annual rates of 1 to 4 percent in the intervals following release from competition, comparable to the published rates of recovery observed at other sites following acute disturbances. Five years after the disappearance of D. cavernosa, the two historically dominant reef building corals showed the maximum gains in percent cover. Although the presence and diversity of the other former coral species have decreased over time, the resilience of these remaining species on reef flats and reef slopes throughout the Bay may be key in the future as impacts from global climate change increase.

PHYSIOLOGICAL RESPONSE OF SIDERASTREA RADIANS TO LOW LIGHT ENVIRONMENTS AND THERMAL STRESS. (Abstract ID: 30122 | Poster ID: 133)

The goal of this study was to describe the physiological response of the common Caribbean coral Siderastrea radians to changes in water temperature and light intensities. We conducted controlled laboratory experiments where coral fragments were exposed to treatments that combined Low (27.5°C) and High (31.5°C) temperature with Low

(200 µmol m-2 s-1) and High (400 µmol m-2 s-1) light intensities. To determine whether S. radians is affected by variations in these parameters we quantified the densities of the endosymbiotic Symbiodinium as well as protein and chlorophyll concentration. Results indicate that changes in temperature, rather than variations in light conditions, had the largest effect in the density of Symbiodinium. On the other hand, no significant differences were found when comparing proteins and chlorophylls concentration among treatment groups. The fact that, reductions in light intensities did not buffer the negative effect that high temperature has on the abundance of Symbiodinium suggest that for S. radians, turbid waters may not necessarily serve as climate-change refuges as has been proposed for other coral species.

FROM SEA LOVING PEOPLE TO CITIZENS SCIENTISTS COMMUNITY: A CASE OF OVER TWO DECADES OF SUCCESSFUL EVOLUTION IN THE BENEFITS OF THE CORAL REEFS IN PUERTO RICO (Abstract ID: 29896 | Poster ID: 723)

Current conditions of coral reefs are in a great state of decline due to an increased demand and misuse of resources, losing their ability to self-sustain. It is critical to improve the understanding, participation and management capacity of stakeholders to protect and rehabilitate coral reefs ecosystem resilience, functions and sustainability. Non-Governmental Organization (NGO) Sociedad Ambiente Marino (SAM) has a history of more than two decades of implementing social strategies in coastal communities in Puerto Rico for engaging volunteers. The interest and desire of those who enjoy their passion for the sea are a great source of motivation to protect their resources. Sharing scientific knowledge with coastal communities through a participatory model has transformed time, motivation and energy of a group of volunteers into knowledge and action, providing them with solid tools and empowerment to fulfill their purpose in the conservation and rehabilitation of coral reefs. This has empowered SAM to develop a multiplicity of conservation-oriented projects, transforming marine conservation activities into hypothesis-driven research. SAM has produced over 70 scientific presentations in more than 12 international scientific meetings, generating over 20 peer-reviewed publications, through a wide spectrum of students and community volunteers. By changing paradigms, reversing the equation through technical empowerment, and fostering its member's professional career evolution related to marine conservation, SAM has become a role model for other small Caribbean organizations.

SEDIMENT PRIMARY PRODUCTION UNDER EXPERIMENTAL WARMING AND ELEVATED $pCO_2$ IN SHALLOW MARINE ECOSYSTEMS OF OKINAWA, JAPAN (Abstract ID: 28554)

Environmental change challenges the structure and function of shallow marine ecosystems by stressors such as increased seawater temperature and elevated $pCO_2$. This study was designed to understand the effects of IPCC (Intergovernmental Panel on Climate Change) predicted (for the year 2100) global warming (+4°C) and $pCO_2$ (936ppm $CO_2$) on sediment primary production of coral reef lagoon, seagrass and mangrove environments. Sediment and seawater samples from each sub-environment were incubated under ambient conditions, high $pCO_2$ (936 ppm), high temperature (+4°C), and combined stresses. Neither high temperature nor high $pCO_2$ alone had a significant impact on sediment primary production. However, combined stresses increased primary production synergistically, except in coral reef lagoon. Under ambient condition respiration exceeds primary production in coral reef lagoon but stress changed this system to autotrophy. Greater uptake of silicate in sediments from each environments reflected predominant activity of diatoms. Heterotrophic community activity increased but did not exceed that of autotrophic compartments during incubation experiment. Dissolved organic carbon production and bacterial abundance increased under stress. In summary, mangrove and seagrass sediments minimize the negative impacts of combined stressors via increased primary production and carbon storage. Lagoonal sediments also act as a carbon sink under stress.

DEVELOPING BASELINES OF CORAL SKELETAL GROWTH AND BIOEROSION FROM THE INDIAN OCEAN (Abstract ID: 28766 | Poster ID: 11)

The Natural History Museum's collections include thousands of coral specimens collected from the Seychelles, Maldives and Chagos Archipelago in the 1960s and 1970s. Prior to the 1980's global monitoring of reefs was rare, so these collections provide an irreplaceable snapshot of the coral and the endolithic boring communities present on these reefs over 50 years ago. Here I will demonstrate how we are applying non-destructive three-dimensional computerized tomography (micro-CT) on complete coral colonies to obtain species-specific growth rates, identify epi- and endobionts, and quantify skeletal bioerosion rates from these specimens. Without this historic baseline data it will be impossible to show how processes and patterns have shifted in the recent period, to what we observe on Indian Ocean reefs today.

COMPARISON OF DIFFERENT VOLUNTARY MANAGEMENT MODELS FOR WISE USE COASTAL CONSERVATION IN HIGH USAGE AREAS. (Abstract ID: 29397 | Poster ID: 606)

Increasing populations on small islands is threatening coastal environments already being affected by climate change. Degradation is often to the detriment of low income coastal communities. The challenge for conservationists is to preserve healthy ecosystems while ensuring the financial benefit of coastal inhabitants. Voluntary Marine Conservation Areas (VMCAs) are being tested in Mauritius as a possible solution. The first attempt at a VMCA failed due to a lack of understanding by the local communities of what was required and benefits. Consequently, three other models are being tested with different degrees of involvement by the scientists, communities and tourism operators. The first model showed that with community involvement an external organisation is necessary to build capacity, guide and focus conservation efforts. The second model involved fishermen that were already switching employment to the tourism sector and gained their support quite easily. A third site involved exclusively a group of hotels. Three key points can be highlighted from these models: commitment by all stakeholders to be actively involved is needed for successful conservation; tangible short term and long term benefits to local communities; long term funding for effective on-going management. Could sustainable management of coastal environments be led by the tourism industry? Could this model be expanded to benefit neighboring communities through capacity building to provide alternative sources of income?

VERTICAL MOVEMENT PATTERNS OF JUVENILE WHALE SHARKS*RHINCODON TYPUS* AT A SEASONAL AGGREGATION IN SAUDI ARABIAN RED SEA (Abstract ID: 28832 | Poster ID: 515)

Large marine species have been a focus of scientists and the public for their unique role in the ecosystem as well as in conservation. To study the behaviors of large marine species, electronic tagging is a direct and reliable method. Researchers have been utilizing technological advances in biologging tags on multiple spatiotemporal scales. This study provides a detailed insight into the vertical movement of whale sharks in a newly described seasonal aggregation concentrated on a coral reef near the coast of Al Lith in the Saudi Arabian Red Sea. Two biologging tags were fitted on two juvenile whale sharks over a period of 22 hours each. Fine-scaled diving behavior was recorded with a sampling rate of 10 Hz and energy consumption was generated from 3D acceleration sensor data. Tagged whale sharks exhibited intensive and consistent diving behaviors throughout the day except for a period of prolonged surface swimming in the morning and a brief surfacing period around sunset. In multiple stages of the diel cycle, whale sharks utilized different depths in the water column, most possibly optimizing energy consumption from foraging efforts. Combined with previous studies on horizontal movement of whale sharks in this aggregation, this study reveals one of the most comprehensive pictures of the movement behaviors of juvenile whale sharks. We hope this study will benefit the management of this hotspot of whale sharks and even larger-scale ecosystems, revealing the potential consequences of excessive human activities (e.g. ecotourism, aquaculture) and global climate issues.

HERBIVOROUS FISH SELECT MACROALGAE ON FRINGING REEFS IN MO'OREA, FRENCH POLYNESIA (Abstract ID: 29945 | Poster ID: 283)

Current research on herbivorous fish in coral reef communities has focused on species identities and functional redundancy and complementarity. Identifying functional redundancy is important for assessing the resilience of specific coral reefs. My objective was to determine species-specific grazing by herbivorous fish on different macroalgal species on fringing reefs in Mo'orea, French Polynesia. I deployed bioassays of seven common macroalgae on a fringing reef. Video cameras recorded bioassays and provided fish species identity and bite rates on the different macroalgae. Herbivorous fish took more bites of Padina boryana (56% of all bites) and Sargassum mangarevense (28% of all bites) than the other macroalgae presented. Similarly, of the 208 individual fish observed taking bites, 57% of them bit Padina, while 33% of them bit Sargassum. For scarids, including Calatomus carolinus, 99% of observed bites were on 2 of the 7 macroalgae (Padina and Sargassum). In comparison, for acanthurids, including Acanthurus nigrofuscus, Ctenochaetus striatus, and Naso literatus, 91% of observed bites were on Padina and Sargassum and 8% were on an additional 3 macroalgae (Dictyota sp, Turbinaria ornata, and Galaxaura sp). However, the majority of bites on Dictyota and Acanthophora spicifera were by the striped triggerfish, Balistapus undulatus. Overall, Padina and Sargassum are highly selected for by herbivorous fish, and acanthurids and scarids predominantly consume the same macroalgae. This knowledge is useful for the appropriate management of herbivorous fish communities on coral reefs.

IMPACTS OF MACRO ALGAE ON THE CORAL TRANSPLANTATION/RESTORATION EFFORTS IN THE GULF OF KACHCHH, NORTH-WEST COAST OF INDIA (Abstract ID: 28159 | Poster ID: 467)

Southern shore of Gulf of Kachchh encompasses 42 islands with unique faunal and floral diversity. Its semi-diurnal tidal amplitude fluctuations coupled with heavy sediment depositions make a major portion of the Gulf to expose and left the region without any major reef formations. Moreover, effluents from various types of petrochemical, fertilizer, ship building, thermal power industries and dependent human populations, bordering the shore turning Kachchh more and more eutrophic, leading to exponential growth of macro algae in the coral reef areas. Over growth of macro algae on coral reefs leads to community 'phase shifts' and subsequent ecosystem degradation. As a part of improving the quality of coral reefs through restoration efforts, an area of about 1000m2 was restored in the three spatially distinct sites along the Gulf with native as well as branching coral transplants, which extirpated thousands of years ago. These restoration efforts were stressed considerably due to the ever increasing macro algal growth especially during post monsoon and winter months, which not only cut off much needed light for corals but also compete for space. A total of 69 macro algal species were recorded on the artificial coral restoration structures during the study period. Density of macro algae varied from 0.03%/m2 to 0.08%/m2. Site specific ocean engineering interventions were introduced to curb the menace to possible extent. Seasonal variation, diversity and distribution of macro algae in three sites were studied. Strategies and recommendations to counter the menace of macro algae to enhance the coral growth on the reefs of the Gulf and similar impacted areas are discussed.

DYNAMIC MODEL OF CORAL REEFS ECOSYSTEM MANAGEMENT AT THE PRAMUKA ISLAND, THOUSAND ISLANDS MARINE NATIONAL PARK – INDONESIA (Abstract ID: 28044 | Poster ID: 446)

The increasing number of tourists since 2003 and the development of community-based tourism in protected areas of Pramuka Island in the Thousand Islands Marine National Park caused the pressure on the quality of resources, especially coral reefs ecosystem and also the pressure on the environment. Therefore required a strategy of sustainable management of coral reef resources for tourism activities and coral reefs resources to be sustainable. This study aim is to build a dynamic model of management strategies that can be relied upon in doing the management of coral reef resources in Pramuka Island. Simulations was carried out on 5 scenarios. Based on multicreria analysis of all scenarios using trade-off analysis that scenario E is the best mangement for sustainability of coral resources at Pramuka island. Management of biology sub-system, marine environments sub-system and socio-economic sub-system are closely related to one another and should be implemented in an integrated manner to ensure the sustainability of coral reef resources. Integrated management of coral reef ecosystem at Pramuka island include the management of the factors that threaten coral reefs; minimum fee into conservation areas of Pramuka Island of Rp 36 000,00 (US$ 3.6) for the tourist; minimum wastewater treatment by 30% before being discharged directly into waters. Integrated management not only ensure the sustainability of coral reef resources, but also to ensure social and economic sustainability at Pramuka Island.

MARINE TOURISM IMPACT ON CORAL REEFS IN SERIBU ISLANDS NATIONAL PARK, INDONESIA (Abstract ID: 27943 | Poster ID: 617)

The beauty of coral reef ecosystem is tourist attraction that could generate significant local and regional revenues. However, coral reef ecosystem also has high levels of vulnerability to human impact such as marine tourism activities. Kicking, trampling, touching, and physical contact with divers and their diving gears are the four identified tourist behavior potentially damage the corals. Objective of this study was to assess impact of marine tourism activities on coral reef ecosystem in Panggang sub-district of Seribu Islands National Park, Jakarta, Indonesia. Data were collected through direct survey, observation, and interview with tourists, tourist guide, and local community. This study revealed that coral covers in this area are under bad to medium condition with low level of mortality. Kicking coral is the most often done by tourist during diving and trampling during their snorkling. Annual potential damage due to snorkeling and diving to coral cover in the study area are about 7.6% and 8.2%, respectively. This study provides strategies to minimize impact from marine tourism activities.

CORAL DISEASE ETIOLOGIES AS MOVING TARGETS: A 20-YEAR CASE STUDY OF WHITE POX DISEASE IN THE FLORIDA KEYS, 1994-2014 (Abstract ID: 28805)

The moving target hypothesis describes the etiology of a contemporary coral disease that differs from that of its historical disease state. Hitting the target with coral disease etiology is a complex pursuit that requires understanding of host and environment, and may lack a single pathogen solution. White pox disease (WPX) affects the Caribbean coral Acropora palmata. Acroporid serratiosis is a form of WPX for which the bacterial pathogen (Serratia marcescens) has been established. We used long term (1994-2014) photographic monitoring and molecular analyses to evaluate historical and contemporary epizootiology and etiology of WPX affecting A. palmata at eight reefs in the Florida Keys. Ranges of WPX prevalence over time (0% to 71.4%) were comparable for the duration of the 20-year study. Whole colony mortality and disease severity were high in historical (1994-2004), and low in contemporary (2008-2014), outbreaks of WPX. Acroporid serratiosis was diagnosed for some historical (1999, 2003) and contemporary (2012, 2013) outbreaks, but this form of WPX was not confirmed for all WPX cases. Our results serve as a context for considering etiology as a moving target for WPX and other coral diseases for which pathogens are established and/or candidate pathogens are identified. Coral etiology investigations completed to date suggest that changes in pathogen, host, and/or environment alter the disease state and complicate diagnosis.

PRECAUTIONARY APPROACH FOR CORAL REEF CONSERVATION IN A RAMSAR SITE IN THE GULF OF THAILAND (Abstract ID: 28684 | Poster ID: 675)

Mu Ko Ang Thong, an archipelago in the Gulf of Thailand, was established as a marine national park in 1980 and was also registered as a Ramsar site in 2002. The park consists of 42 islands and covers a total area of 102 $km_2$. The main islands are Phaluai, Ang Thong (Wua Ta Lap), Wua Ta Lam (Mae Ko), Sam Sao, Hin Dap, Nai Phut and Phai luak. This case study provides a precautionary approach for coral reef conservation in Mu Ko Ang Thong National Park, a Ramsar site, in the Western Gulf of Thailand . The islands are surrounded by relatively shallow and turbid water which is greatly influenced by river water from the mainland. The coral reefs on the islands are not well developed

and were restricted to a narrow band around each island. The most popular tourist attractions are a viewpoint at the top of Ko Ang Thong and a huge emerald lagoon situated in the middle of the limestone mountain in Ko Wua Ta Lam. Canoeing, kayaking and snorkeling are also popular tourist activities at some islands. Coral damages caused by tramping and high sedimentation were frequently observed. Assessing coral health and resilience in the national park was carried out to provide scientific data for establishing a master management plan. The management strategies include coral reef zoning for multiple uses, effective tourism management and prevention of land-based pollution. This study highlights the importance of science-based management of coral reefs in marine protected areas for sustainable tourism in Thailand.

INTERSPECIFIC AND SPATIAL COMPARISONS OF INITIAL POST-SETTLEMENT SURVIVAL FOR *ACROPORA* SPATS USING A GRID PLATE (Abstract ID: 28313)

Direct seeding of coral larvae could accelerate recovery of coral assemblage after disturbance. However, the spatial or interspecific tendency of post-settlement survival (PSS) remains uncertain due to the difficulty of direct observation of coral spats on natural substratum. To evaluate PSS of coral spats at initial stage, we compared the PSS of artificially settled *Acropora*spats on a lattice-structured plate (hereafter, grid plate), which is suitable for coral settlement and growth. We used 3 species; an upper slope dominant *A. digitifera*, a lower slope dominant *A. tenuis*, an inner reef dominant *A. yongei*, for interspecific comparison. Larvae of each species were quantitatively settled on a grid plate, and the number of living spats was counted at 3d, 1mo, 3mo, 6mo, and 15mo after settlement. We clarified significant differences between species; the PSS of *A. digitifera* was 0.9% at 6mo after settlement, whereas that of *A. tenuis* was 24.6% at same time. Second, we set 40 grid plates at 5 different coral cover sites. The number of living spats was counted at the same timing with the first experiment, and the size of each spat was measured at 15mo after settlement. We found that the average spat sizes in the high coral cover sites was significantly larger than those in the low coral cover sites, whereas the PSS was not different among sites. These results suggested that direct seeding may be a useful method for restoring a certain*Acropora* assemblage because the PSS was not reduced even in the low coral cover sites.

PRODUCTION OF CYCLO-ENOL IN CORAL BLEACHING: A STRATEGY TO AVOID OXIDATIVE DAMAGE (Abstract ID: 28147 | Poster ID: 114)

We examined the morphology and pigment composition of zooxanthellae in corals subjected to normal temperature (27 °C) and thermal stress (32 °C). We observed several normal and abnormal morphological types of zooxanthellar cells. Normal cells were intact and their chloroplasts were unbroken (healthy); abnormal cells were shrunken and had partially degraded or broken chloroplasts, or they were bleached and without chloroplasts. At 27 °C, most healthy zooxanthellar cells were retained in the coral tissue, whereas shrunken zooxanthellae were expelled. Under thermal stress, the abundance of healthy zooxanthellae declined and the proportion of shrunken/abnormal cells increased in coral tissues. The rate of algal cell expulsion was reduced under thermal stress. Within the shrunken cells, we detected the presence of a chlorophyll-like pigment that is not ordinarily found in healthy zooxanthellae. Analysis of the absorption spectrum, absorption maxima and retention time (by HPLC) indicated that this pigment was $13^2$, $17^3$-cyclopheophorbide *a* enol (cPPB-*a*E, cyclo-enol), which is frequently found in marine and lacustrine sediments, and in protozoans that graze on phytoplankton. The production of cyclo-enol in shrunken zooxanthellae suggests that the chlorophylls have been degraded to cyclo-enol, a compound that is not fluorescent. The lack of a fluorescence function precludes the formation of reactive oxygen species. We therefore consider the formation of cyclo-enol in shrunken zooxanthellae to be a mechanism for avoiding oxidative stress.

ROLE OF CORAL REEF SCIENCE FOR CONSERVATION UNDER THE MULTIPLE STRESS (Abstract ID: 28603 | Poster ID: 727)

Coral bleaching and disease are the most impacting process that is affecting coral survival under elevated sea surface temperature, high irradiance scenario, high-CO2 and also infection of bacteria. However its mechanism is not well understood. This is due to the high complexity of the coral symbiosis and metabolisms and multiple stressors. Over the past 10 years MC (Mitsubishi Co.) project team has worked towards identifying environmental stressors affecting the health of the corals, resulting in coral bleaching and diseases at several reef areas of Okinawa. The scope of the research varies, from field-monitoring and socio-ecological impacts on coral reefs to laboratory-based experiments to decipher mechanisms of coral reefs that can reveal health and stressful conditions. The projects provide outstanding opportunities to engage citizens, students and young scientists in field and laboratory research. We had successfully identify and clarify bleaching mechanisms and several coral diseases common in our study area and had shown that anthropogenic stresses (as input of nutrients and pathogenic microbes) in combination with environmental stresses (as high sea-surface temperature) can result in amplified effects causing reef deterioration and face shifts. These results can influence and change policies directly relating to marine and reef based issues, and also to increase awareness of the value of marine ecosystems to communities, policy makers and governments.

SYMBIODINIUM THERMOTOLERANCE AND CORAL SUSCEPTIBILITY TO BLEACHING (Abstract ID: 28751)

Twenty-five years of genetic assessment of *Symbiodinium* diversity has revealed nine clades circumscribing more than 400 phylotypes, and fostered a nascent understanding of sub-phylotype diversity and population genetics. This diversity is meaningful for their symbiotic associations with corals, as the subset of phylotypes that have been assessed may differ in their physiological capabilities to acquire nutrients, produce photosynthetic products, and resist oxidative and thermal stress. These physiological differences translate into differential bleaching susceptibility of the holobiont and allow corals associated with thermotolerant phylotypes to persist under thermal conditions that would otherwise cause bleaching. This increased resistance is often associated with a tradeoff that may limit the optimal frequency of association with thermotolerant phylotypes to periods of thermal stress. Although the effects of *Symbiodinium*thermotolerance on bleaching susceptibility is a central focus of ongoing research, our ability to apply these data to conservation or remediative efforts is limited by the scope of comparable information across phylotypes. Here we present a novel quantitative index of thermotolerance for 110*Symbiodinium* phylotypes based on an iterative partial-rank aggregation method of consensus estimation from available qualitative partial rankings. This new framework for analysis will allow quantitative assessment of hypotheses on the effects of *Symbiodinium* thermotolerance on coral bleaching.

QUANTITATIVE ASSESSMENT OF ESA CORAL POPULATIONS AND THE APPLICATION OF RESOURCE SELECTION THEORY (Abstract ID: 28841)

The status and extinction risk determinations leading to the decisions to list 22 coral species as threatened under the U.S. Endangered Species Act (ESA) were based on sparse observational data of species distributions, abundances, and vulnerabilities to a diverse range of threats. The listing process demonstrated the general lack of adequate ecological and demographic information for most coral species and the limitation in our collective ability to answer questions about the status of all coral populations or assess potential impacts. Yet, managers need to know the status of threatened species in specific geographic areas to address ESA compliance, manage risk, establish or improve the effectiveness of marine protected areas, and identify potential areas for coral restoration and recovery actions. This study uses existing spatially-explicit datasets and applies the theory of resource selection to quantitatively assess the status of threatened coral species within the Florida Coral Reef Tract. This assessment incorporates benthic habitat maps and coral abundance, size, and condition data in a step-wise process to determine population-level estimates and habitat use (spatial habitat estimates) within the ecosystem. Habitat use analysis can quantitatively address a suite of management needs for threatened coral species. Since a species' habitat use has ties to population regulation (recruitment, growth, mortality) and persistence over time (productivity), spatial patterns of habitat use infer spatial variation in overall productivity.

DYNAMIC CHANGES IN THE CORAL MICROBIOME WITH COLONY AGE: IMPLICATIONS FOR ACCLIMATISATION AND ADAPTATION (Abstract ID: 28068)

Recent studies, using the massive coral Coelastrea aspera, have shown significant changes in microbial diversity over temporal scales ranging from days (within a tidal cycle) to years (when different coral age-groups were compared). Dramatic alterations in the coral's microbial associates occurred over a 4 day period during a spring tide where corals were aerially exposed and subject to large fluxes of seawater. Baseline differences in bacterial communities in C. aspera were also evident between different age groups with a step-wise increase in bacterial richness as the corals aged. Such changes resemble a successional process similar to that seen in ageing higher organisms. The pattern of changes detected over a tidal cycle in 4 and 9-10 year old corals was also markedly different. Microbial associates of younger corals changed rapidly in response to altered environmental conditions while those of older corals remained stable during the early stages of the tidal cycle, changing only when challenging physical conditions ameliorated. Explanations for the latter observations may involve variations in the initial composition of the microbiome of different age-groups, bacterial interactions and host energetics, particularly with respect to mucus supply and composition. Older corals are likely to expend more energy in reproduction, sediment-shedding and lesion-healing than younger corals. Our results highlight the little-studied changing physiology of corals throughout their life-history with implications for their scope to adapt/acclimatise in a changing world.

NON-INTRUSIVE P700 REDOX KINETICS PROBE TO DETERMINE THE FUNCTIONALITY OF BOTH PHOTOSYSTEM II AND PHOTOSYSTEM I IN WHOLE CORAL TISSUES (Abstract ID: 28231)

The productivity of coral reefs depends on the symbiosis of cnidarians and photosynthetic dinoflagellates from the genus Symbiodinium. Thus, assessment of photosynthetic capacity of the endosymbiont alga is crucial in understanding the function of the holobiont. Non-invasive techniques such as chlorophyll (Chl) fluorescence analyses have been widely used to estimate the photosynthetic performance of Symbiodinium in hospite. However, since the spatial origin of the fluorescence in coral tissues is uncertain, the signal gives no information on photosynthetic performance of the whole tissue. By contrast, detection of absorbance changes in the near infrared (NIR) region samples greater tissue depths due to weak absorption and multiple scattering of NIR light in coral tissues. While extensively utilised in plants, these bio-optical techniques are seldom applied to corals. In this study, we sought rapid, non-intrusive measurements of redox kinetics of the special Chl pair in Photosystem I (P700) in intact corals. Since the redox state of P700 depends on the operation of both Photosystems I and II (PSII and PSI), important information can be obtained about the functionality of sections of the electron transfer chain. In the current study, by using P700 redox kinetics we aim to i) advance the knowledge on PSII-PSI inter-system electron transfer capacity in Symbiodinium in hospite, in whole coral tissues, and ii) explore how PSI-PSII coupling and stability can start to untangle our understanding on processes downstream of PSII that may govern bleaching- induced PSII dynamics.

EVALUATION OF SIZE-FRACTIONATED PARTICULATE ORGANIC MATTER AS A FOOD SOURCE FOR CROWN-OF-THORNS STARFISH LARVAE (Abstract ID: 29184 | Poster ID: 216)

An explosive increase in the number of the crown-of-thorns starfish (*Acanthaster plaunci*) has been reported in various reef areas, causing severe feeding damage on corals and economic strain for management. One of the major hypotheses to explain such a population explosion is increased larval survival due to enhanced availability of phytoplankton. In Okinawa, however, the explosive increase has often occurred under the condition in which chlorophyll-a (chl-a) concentration was lower than larvae's demand, implying that the larvae feed on not only phytoplankton but also other organic particles. The present study, therefore, intended to evaluate the possible importance of particulate organic matter (POM) by analyzing both chemical and biological compositions by rearing experiments of the larvae. The POM sample collection was conducted at Sesoko Island, Okinawa, Japan in July 2015. In addition to Concentrations of chl-a, bacteria and flagellate were determined either fluorometrically or microscopically and their values were converted to carbon amounts. As a result, non-living organic matter, or detritus, shared 53.1 to 93.1 percent to the total carbon, while phytoplankton-derived carbon ranged only 7.0 to 20.7 percent and never exceeded the energy demand of the larvae. Our results indicated that the carbon amount of living materials including bacteria and flagellate was not sufficient enough to ensure the high survival rate of the larvae, and thus detritus likely contributed as an important carbon source.

MOLECULAR CYTOGENETIC STUDY ON SCLERACTINIAN CORAL COELASTREA ASPERA (VERRILL 1865) (Abstract ID: 29095 | Poster ID: 497)

Molecular cytogenetic study on the scleractinian coral Coelastrea aspera (Verrill 1865), was performed, which commonly distributes along temperate coasts in Japan (30–35°N) and in coastal oacean areas in the Indian and Pacific oceans. G- and C-bandings of C. aspera was successfully done, though the banding patterns are not clear enough as that of in mammals. It is of interest that this coral had a homogenously staining region (hsr) in chromosome #11 based on its karyogram. This hsr derived from rDNA related genes which was demonstrated by fluorescence in situ hybridization (FISH) with the probe generated using the rDNA primers, chromosome microdissection and the following FISH techniques. We also confirmed that the hsr was not positive by Ag-NOR staining. This coral C. aspera had the hsr close to 50% of the metaphase spread analyzed. This observation of the presence of an hsr may explain the diversity of coral rDNA which suggested by molecular study of sequence analysis. Furthermore, we found that human telomere and Alu repeated sequences were present in this coral C. aspera. Accordingly, probes derived from human Alu sequences expect to play an important role in classifying scleractinian corals. Overall, our findings can be of value in taxonomy of scleractinian coral species and developing coral genetics, including chromosomal evolution.

POTENTIAL CHANGES IN CORAL DISPERSAL AND CONNECTIVITY IN THE EAST CHINA SEA UNDER FUTURE CLIMATE SCENARIOS (Abstract ID: 28691)

Changes in current patterns and speeds of the Kuroshio Current and its branches would affect the latitudinal limits and/or distributions of subtropical and temperate coral species in the East China Sea, due to changes in the dispersal rate of these species. Using an offline particle-tracking model coupled with a one-way, doubly-nested eddy-resolving ocean model based on the Regional Ocean Modeling System (FRA-ROMS), we simulated early summer coral-spawning events in the East China Sea. To gain insights into potential changes in coral dispersal and connectivity in this region, the particle-tracking simulations were performed under historical and two global warming scenarios (RCP2.6 and 8.5) for three periods (1996-2005, 2026-2035, and 2086-2095). Results under the historical simulation suggest that Ryukyu Islands would be important sources of coral larvae for islands south of Kyushu. Furthermore, coastal areas of Taiwan and China may be remote sources for the western coastal areas of Kyushu and Tsushima Island, where world's northernmost coral reefs exist. Under the RCP8.5 scenario, on the other hand, an enhanced countercurrent in the south of Ryukyu Islands would limit the poleward expansion of corals from Ryukyu Islands to islands south of Kyushu. These results suggest that strategies for conserving corals in the East China Sea will need to consider future changes in current patterns as well as the other environmental factors such as rise in water temperatures.

SIMPLE RULES FOR ESTABLISHMENT OF EFFECTIVE MARINE RESERVES (Abstract ID: 28056 | Poster ID: 651)

Marine reserves often play a central role to guarantee sustainable fisheries management and improve fisheries benefit. Even though many studies have been conducted to understand how marine reserves are introduced effectively, deducing theoretical conditions

guaranteeing that the introduction of marine reserves will increase fisheries yields can still have potential to improve our insight significantly. Deriving these theoretical conditions in mind, a simple mathematical model is developed that follows an age-structured metapopulation dynamics of a sedentary marine organism where each population is connected by the dispersal of eggs. The obtained simple results suggest that a sufficiently high fishing mortality rate and moderate recruitment success of an individual's eggs is a necessary for marine reserves to increase fisheries yields. The numerical calculations are also conducted with the parameters of red abalone (*Haliotis rufescens*) to visualize the obtained results.

DRIVERS FOR BENTHIC METABOLISM AND ITS FEEDBACK TO CARBONATE CHEMISTRY ON A CORAL REEF IN BERMUDA (Abstract ID: 29050)

It is well documented that the bulk seawater chemistry over a coral reef is significantly modified through benthic metabolism (i.e. net community production (ncp) and net community calcification (ncc)). However, the relative importance of the various factors that influence the water chemistry such as metabolism, advection, and depth is still not fully understood. Here, we present autonomous measurements of ncp and ncc made every 10 minutes at Hog reef in Bermuda between July 26 and 29, 2015. The metabolism rates were measured using the Benthic Ecosystem Acidification and Metabolism System (BEAMS), a novel system which utilizes pH and O2 gradients in the benthic boundary layer to quantify the benthic metabolic fluxes. Both ncp and ncc were highly dependent on light levels, reaching on average 20 mmol O2 m-2 hr-1 and 5 mmol CaCO3 m-2 hr-1 when irradiance was 500 micro quanta m-2 s-1. We interpret the effects of the benthic metabolism on the water chemistry over a large spatial context (several km2) using distributions of surface total alkalinity and dissolved inorganic carbon, in addition to three autonomous pH and O2 sensors deployed across a depth gradient located several km apart.

HISTORICAL RUNOFF SOURCES TO PELEKANE BAY, SOUTH KOHALA, HAWAI'I: IMPLICATIONS FOR REEF HEALTH (Abstract ID: 29829)

Sedimentary records can provide insight about physical processes that influence the structure and function of coral reefs, such as terrestrial sediment runoff. On the south Kohala coast of the Island of Hawai'i, coral reefs flourished for more than 400 ka but are today variably impacted by sediment. Archaeological studies at Pu'ukohola Heiau National Historic Site describe shoreline progradation at the head of Pelekane Bay arising from land-clearing by early Hawaiians. Land use practices of the 19th and 20th centuries likely accelerated sediment runoff, and harbor construction reduced oceanic flushing. As a result, terrestrial sediment has recently accumulated in Pelekane Bay and on the reef, decreasing species richness. The goal of this study was to identify historical sediment sources to Pelekane Bay by comparing sediment trace and rare earth element signatures in reef sediment and uplands. Upland sediment derives from weathering of basalt and alkalic lavas that are geochemically and geographically distinct from each other. A sediment core collected from the reef flat and dated with 210Pb and 137Cs shows that for the past 50 yrs terrestrial sediment in Pelekane Bay had a basaltic signature similar to that at lower elevations of the watershed. The predominance of sediment runoff from the lower watershed suggests that watershed restoration and runoff control efforts aimed at improving reef health should target these regions. Recent conservation efforts in Pelekane watershed appear to have reversed precipitous declines in coral and fish communities.

*ACROPORA TENUIS* LECTIN ATTRACTS SPECIFIC *SYMBIODINIUM* CULTURE STRAINS (Abstract ID: 29376)

Most reef-building corals acquire symbiotic dinoflagellates, *Symbiodinium* spp., from surrounding environments and establish symbiosis with *Symbiodinium*. Since *Symbiodinium* occur in low densities in the water column, corals would attract symbionts using chemotactic compounds to acquire them. We found a coral *Acropora tenuis* crude water extract attracted specific Symbiodinium strains, including strains NBRC102920 (clade A) and CCMP2556 (clade D), but not strains GTP-A6-Sy (clade A), CCMP421 (clade E) and CS-156 (clade F). The chemotactic activity in crude *A. tenuis* water extract remained after dialysis, but lost completely after heat treatment, indicating that the chemotactic compounds are water-soluble, heat-labile macromolecules. Juvenile *A. tenuis* tend to acquire the strains which attracted by the crude water extract, so chemoattraction seems to be inhibited by inhibitors of acquisition, like *N*-acetyl-D-glucosamine (GlcNAc). As expected, GlcNAc inhibited the chemotactic activity and thus, a candidate of a chemoattractant is a GlcNAc binding lectin. The lectin purified from crude water extract, ActL, demonstrated 70% of the chemotactic activity in the crude water extract. The attracted strains by ActL were same as those by crude water extract. As mentioned above these strains were acquired by juvenile *A. tenuis*, suggesting that chemoattraction is an important step for acquisition to establish symbiosis between corals and *Symbiodinium*.

SEXUAL REPRODUCTIVE PATTERNS OF COMMON BRANCHING CORAL, ACROPORA NOBILIS, ON THE COASTS OF PENINSULAR MALAYSIA (Abstract ID: 29052 | Poster ID: 174)

Sexual reproduction is an essential element in population viability for the scleractinian coral. However, the information on sexual reproduction of scleratinian coral in Malaysia is scarce. Here we investigated the spatial variation in sexual reproductive characteristics of common branching scleractinian coral, *Acropora nobilis*, from east (Redang Island) and west (Sembilan Group of Islands) coasts of Peninsular Malaysia. *A. nobilis* is a hermaphroditic coral with both ovari and sperm bundle were observed in the same colony. High proportion (89%) of the *A. nobilis* colonies at islands of west coast were found fecund in January 2015. Oocytes size ranged between 130 μ m and 250 μ m. The oocytes size suggested that ovary were still in developmental stage. Similarly, small immature spemary sacs were found in testes of *A. nobilis* samples from the west. On the other hand, colored oocytes were found in samples from the Redang Island in September with average size over 500 μ m. From the oocytes size and testes development condition, *A. nobilis* colonies at the west coast of Peninsular Malaysia were predicted to spawn in March or April, which was different from the predicted spawning time (in September and October) for *A. nobilis* at east coast. The spatial variation in reproductive patterns observed here could be an adaption of allopatric population to local environment.

MAPPING SCLERACTINIAN CORAL COMMUNITIES OF SINGAPORE USING THE GEOGRAPHICAL INFORMATIONS SYSTEM (GIS) (Abstract ID: 27919 | Poster ID: 78)

The scleractinian reef communities of 44 fringing and patch reefs located south of Singapore mainland were studied using Line Intercept Transact. Altogether 118 sites accounting for a total of 11.9 km of reefs were surveyed. Results indicate that high species diversity still exists in Singapore, with a total of 53 genera of hard corals representing 17 families and 141 species (including non-scleractinian reef-building *Heliopora* sp. and *Tubipora* sp.) documented. Live coral cover at the reef crest was found to fluctuate widely between reefs, ranging from 4.47% to 78.71%. About 63% of the 118 transacts showed live coral cover of > 30%. Diversity indices, species evenness and abundance measures were used to determine the ecological state of the reefs, and results were incorporated into a GIS basemap using ESRI® ARCGIS. Multivariate nMDS ordination indicated a loose clustering of the reefs into four main groups with similar scleractinian coral assemblages. Human activities in the area around the reefs were also mapped to assess their impacts on the reefs. Spatial analysis highlighted a possible link between anthropogenic activities in close proximity to the coral reefs, and diversity, evenness and coral abundance indices. The preliminary GIS basemap in this current study is a first for Singapore, and one of the most direct and useful applications is establishing linkages between mapped variables. As more data from future research is incorporated, this basemap could be a useful tool for management decisions on conservation and development.

EFFECTS OF NITRATE AND PHOSPHATE AVAILABILITY ON THE BIOMASS, STABLE CARBON ISOTOPES, AND GROWTH RATES OF THE SCLERACTINIAN CORALS (Abstract ID: 28498 | Poster ID: 117)

The scleractinian corals *Montipora digitata* and *Porites cylindrica* were cultured in filtered seawater in the laboratory, and the effects of nitrate and phosphate availability on their physiological status were evaluated. Carbon (C) biomass of the endosymbionts was higher in the nitrate + phosphate (+NP) treatment than in the control but the enhancement was not observed for the animal host C. Nitrogen (N) biomass was higher in the +NP treatment than in the control for both the animal host and endosymbionts. These results suggest that seawater-derived inorganic N was incorporated into the host and endosymbionts as organic N but the N incorporation into the host proceeded using organic C stored in the host tissue. Stable C isotopes (δ13C) in the host and endosymbionts decreased in all of the treatments during the study, suggesting that the coral was catabolizing heavier isotope lipids resulting in the animal δ13C value decreasing. The decrease in δ13C was enhanced by the addition of nutrients, suggesting that the endosymbionts in additional nutrient treatments were reliant on host-derived dissolved inorganic C more than those in the control treatment. The nutrient addition decreased the calcification rates of *P. cylindrica* but not *M. digitata*. The present experiment concludes that when coral heterotrophy is reduced, inorganic nutrients become an important factor to affect the coral physiological status.

EVALUATION OF THE CONTRIBUTION OF CORAL-DERIVED ORGANIC MATTER TO TOTAL SEDIMENTARY ORGANIC MATTER BY ELEMENTAL AND ISOTOPIC ANALYSIS (Abstract ID: 27942 | Poster ID: 89)

The carbon sequestrated in marine ecosystems has been termed "blue carbon". Coastal ecosystems are the most dominant blue carbon stocks, contributing to the mitigation of global warming. Recent studies have revealed that the amount of sedimentary organic matter (SOM) in tropical and subtropical coasts is comparable to temperate SOM. Understanding the origins of SOM is important to conserve these blue carbon stocks. Seagrasses, terrestrial plants and microalgae have been considered as origins of SOM but little attention has been given to corals although they are some of the major primary producers and the major components of sediments in tropical and subtropical coasts. Using sediment core samples and organisms taken from fringing reefs, located around Ishigaki island, Japan, we analyzed the elemental and isotopic ratios (carbon and nitrogen) of SOM and major primary producers including corals. We then calculated the contribution of coral-derived organic matter to total SOM using a Bayesian mixing model. We took sediment core samples from seagrass meadows and non-vegetated two areas near the seagrass meadows and coral colonies on the reef flat. Also, we collected dominant corals (*Heliopora coerulea*, massive and branching *Porites spp.* and branching *Acropora spp.*) from near the shore to the reef crest. Results showed that the $\delta^{13}C$ value and C/N ratio of SOM were lower than those of seagrasses, indicating that other organisms such as corals and microalgae may account for the origin of SOM in addition to seagrasses.

RESPONSE OF FAVITES COLEMANI LARVAE TO OCEAN WARMING AND ACIDIFICATION (Abstract ID: 29171 | Poster ID: 202)

Coral susceptibility to environmental stressors is deemed to be greater during the dispersive larval stage. However, there have been few studies exploring the vulnerability of coral larvae to ocean warming and acidification. In this study, we investigated the acidification and thermal stress response of Favites colemani from Bolinao-Anda Reef Complex, Philippines. Three-day old larvae were exposed to present day and predicted IPCC near-future ocean pH levels (8.1, 7.8, 7.6) cross-factored with seawater temperatures (27C, 30C, 33C). Larval survival was recorded after short (3d), and long (10d) term exposure to treatments. Larval metamorphosis and survival were also determined under induced metamorphosis (with crustose coralline algae) after 3d exposure to treatments. Results suggest that increased temperature and decreased pH did not significantly affect survival for both 3d and 10d exposure to these stressors. However, larvae exhibited decreased tolerance to combined pH and thermal stress after 10d exposure. During metamorphosis stage, survival was significantly lower than during larval swimming stage; with significant decrease under both thermal stress, and combined pH and thermal stress. Metamorphosis rates were also relatively lower under high thermal stress, and under combined low pH-high thermal stress; although not statistically significant. These findings indicate that elevated seawater temperatures in synergy with decreased pH pose greater detrimental impact on F. colemani larvae, and that its sensitivity to these stressors heightens during metamorphosis.

CHARACTERISTICS OF WHALE SHARKS (RHINCODON TYPUS) IN TELUK CENDERAWASIH NATIONAL PARK, INDONESIA (Abstract ID: 30068 | Poster ID: 272)

The whale shark (Rhincodon typus) is an iconic species for Teluk Cenderawasih National Park (TCNP), West Papua and Papua. They have appeared regularly near lift-net fisheries (bagans) year round in some areas, especially near Kwatisore in West Papua, resulting in the development of limited tourisms since 2009. The objective of our study was to document the characteristics (i.e., number, size, sex) of whale sharks that occur in TCNP. We used photographs to identify whale sharks, from natural patterns (white spot pattern) and other body markings. We also made subjective estimates of the relative sizes of each shark and determined whether they were male or female from the presence or absence of claspers. We obtained, 8.530 photos of sharks from February 2010 through June 2015. From that database we tentatively identified 126 sharks, 83% of them male, 14% female and 3% undetermined. The estimated length of the sharks averaged 4.4 m (± 1.25 m, range = 2 m to 8 m). Around 40% of the individuals had scars, mostly around their mouths and fins. Most (59%) of the sharks were seen in only one year with 3% seen in more that one year during the five year study. Juvenile male whale sharks appear to be transient and highly mobile in Cenderawasih Bay. Because of the increased tourism for whale sharks and the interactions of whale sharks with the fishing bagans, we recommend continued systematic observations of whale sharks and vigilant surveillance for understanding the dynamics of interactions among tourist activities, fishing operations, and whale sharks.

JUVENILE CORAL REEF FISH IN TROPICAL SHALLOW MACROPHYTE HABITATS (Abstract ID: 29456)

Landscape matrix and habitat differentiation are recognised to shape and impact coral reef fish communities. Densities and abundance of certain reef fish are shown to be linked to the presence or absence of adjacent nursery habitats, such as seagrass and mangroves. However, there is limited information on nursery functions of other macrophyte areas such as macroalgal beds. For successful management and conservation of the coastal zone it is important to identify key habitats for fish recruitment. We examined fish assemblages of macroalgal beds, seagrass meadows and a shallow coral reef, with emphasis on juvenile reef fish communities, in a shallow water bay in Zanzibar, Tanzania. Fish densities were determined by visual census in belt transects, where fish were identified and classified into age categories depending on length estimates. Juveniles generally dominated in macroalgal beds, whereas subadults were the dominating age category both in seagrass beds and the coral reef. Juveniles of coral reef associated species were significantly more abundant in seaweed beds than in seagrass meadows, as was species utilized by fisheries. Also interesting is that juveniles of Labridae and Scaridae were significantly smaller in macroalgal than in seagrass beds, indicating a role of algal beds as initial juvenile habitats for both coral and seagrass associated species. Our results indicate that juvenile fish use a range of different macrophyte habitats, and that macroalgal beds can be important recruitment grounds for coral reef fish species.

INORGANIC CARBON UPTAKE AND PROCESSING FOR PHOTOSYNTHESIS IN THE CORAL-*SYMBIODINIUM* SYMBIOSIS: A QUANTITATIVE PICTURE (Abstract ID: 27895)

The process by which corals take up dissolved inorganic carbon (DIC) from the water column for photosynthesis by their *Symbiodinium* symbionts has long been described, but not fully quantified. However, in light of changing oceanic conditions, this quantitative description is essential to understanding potential alterations to the symbiosis. Using membrane inlet mass spectroscopy methods, we have directly quantified key aspects of DIC supply in three different coral taxa. By measuring $^{18}O$ isotope exchange rates, we de-

termined carbonic anhydrase (CA) activity in various areas of the coral and *Symbiodinium*. Activity levels are high both internally and externally in the coral, as well as within the *Symbiodinium*. Inhibiting external coral CA showed the relative equal contributions of $CO_2$ and $HCO_3$ to net photosynthetic production. All of this information was put into the context of photosynthetic requirements for corals and *Symbiodinium* to produce the overall, quantitative picture of DIC uptake and processing. The final description showed that, despite the ability of corals to efficiently concentrate more DIC than strictly necessary to support photosynthesis, the*Symbiodinium* were carbon scarce *in hospite*. This suggests the potential for the corals to regulate the flow of DIC to the *Symbiodinium*.

COMPLEMENTARY MANAGEMENT PRACTICES TO ENHANCE FISH BIOMASS IN INDONESIA (Abstract ID: 28668)

Karimunjawa National Park (KNP) is a marine park in Indonesia, established in 1999 and rezoned in 2005. To examine the effects of the re-zoning, we examined the in situ biomass of reef fish from 2005-2013, and changes in fish catch landings from 2009-2014. We evaluated changes in reef fish populations and reef fish catch landings over time in no-take zones, in gear restriction zones and in control areas outside the park. Overall fish biomass decreased by more than 50% from 2005-2009, likely attributed to non-compliance within no-take zones. In 2009 measures to improve community compliance with fishing regulations included co-management enforcement operations and livelihood incentives. From 2005-2011 the percentage of local inhabitants that supported park regulations more than doubled. Reef fish biomass increased by more than 250% from 2009 to 2013, largely explained by increases in five trophic groups. Village laws afforded several Serranidae species additional protection through bans on some species, periodic closures and fishing gear restrictions. Since the measures were implemented, Caesionidae, Lutjanidae and Serranidae biomass increased by up to 200% until 2013. Handline and speargun catch per unit effort (CPUE) remained stable from 2009-2014, while the trap CPUE increased over this period. Interestingly both overall reef fish biomass and coral cover showed comparable increases at locations outside KNP, which suggests they also benefited from the bans on exploitative and destructive fishing in the Karimunjawa Islands.

RESILIENT FISHERIES MANAGEMENT OUTCOMES: CASE STUDY ANALYSES FROM FOUR FIJIAN AND TORRES STRAIT COMMUNITIES (Abstract ID: 30145 | Poster ID: 588)

Adaptive co-management is an emerging approach to fisheries management which aims to create cross-scale, collaborative management strategies, that foster resilience in social-ecological systems.Adaptive fisheries co-management is relatively new to Australia where the fisheries have mostly been centrally or government-managed. Fiji has had a decade of experience in trialing and improving the process of adaptive fisheries co-management using a community-based approach as the starting point. However, the governance arrangements, social mechanisms and processes which create and sustain successful adaptive fisheries co-management are still under-investigated and often misunderstood. The observed livelihood benefits of adaptive fisheries co-management are also not fully understood, especially in wealthy communities and at the early stages of the adaptive fisheries co-management process. This study sought to measure the changes in the observed governance, social and livelihood benefits as adaptive fisheries co-management progresses in Australia and Fiji through four case studies. The study concluded that working towards a shared and delegated type of governance between government and communities built on trust, shared vision, shared knowledge and networking are critical to consider for a resilient fisheries management outcomes and sustainable livelihoods.

NETWORKING SUPPORTS THE PROLIFERATION OF LOCALLY MANAGED MARINE AREAS (LMMAS) IN THE PACIFIC (Abstract ID: 30079)

Coastal communities worldwide are facing challenges to food security and are vulnerable to disasters and climate change impacts. Local marine management undertaken by communities has often achieved benefits that may have eluded top-down MPAs. In the Pacific, locally managed marine areas (LMMAs) have proliferated and a growing network of communities, managers and practitioners strengthened since 2000. The approaches are built on a unique feature of the region – customary tenure and resource access – and often making use of traditional knowledge and governance. LMMAs in the Pacific are implemented by over 600 communities spanning 17 independent countries and territories, representing a unique global achievement. Other examples also exist around the world. The spread and endurance of LMMAs is attributable to communities' perceptions that benefits are very likely to be achieved. The main innovation that has supported the proliferation of LMMAs is the operation of clusters of communities supported by regional, national and sub-national umbrellas or social networks. The regional LMMA Network includes Fiji, Solomon Islands, Papua New Guinea, Indonesia, Philippines, Palau and Federated States of Micronesia each of which have developed affiliated national and provincial sub-networks. Key success and challenges facing LMMAs and their supportive social networks are also discussed. In essence, LMMAs serve as building blocks for integrated island management and sustainable development by communities.

GLOBAL PATTERNS OF INTRASPECIFIC LIFE-HISTORY VARIATION REVEAL HIERARCHICAL IMPORTANCE OF ENVIRONMENTAL DRIVERS IN WIDESPREAD CORAL REEF FISHES (Abstract ID: 27833)

Metabolic rate in ectotherms is largely dependent on the interaction between ambient temperature and body size; hence, there are predictable demographic trends within species that arise along latitudinal gradients across broad spatial scales, whereby largest body size and greatest life span are often achieved with decreasing temperature at higher latitudes. The past decade of coral reef fish research has highlighted many examples, however, of substantial variation in life-history traits at various spatial scales that are not correlated with temperature, but rather demonstrate the importance of factors such as density-dependent competition, predation, habitat variability, reef geomorphology, anthropogenic fishing pressure and primary productivity. We examined life-history variation across the entire range of the bullethead parrotfish (Chlorurus sordidus [Red Sea – Indian Ocean] and C. spilurus [Pacific]). Otolith-derived length-at-age profiles of populations from over 30 locations spanning from the Northern Red Sea to Moorea provided estimates of growth rate, lifespan, length at sex change, and asymptotic length, and constituted the most extensive investigation of intraspecific life-history variation in any coral reef fish to date. Our research demonstrates that while temperature and productivity gradients strongly influence life history, other drivers of variation are constrained by the observed spatial scale, which pervades as the underlying context from which significance can be assessed.

EXTENDING SOUNDSCAPE SURVEYS OF CORAL REEFS USING AUTONOMOUS OCEAN GLIDERS (Abstract ID: 29674)

Autonomous ocean gliders are platforms advantageous for surveying large geographic regions to study bioacoustic and anthropogenic noise. Under a Navy Oceanographic Office and NOAA partnership, we deployed a Slocum ocean glider outfitted with a low-power, lightweight "Remora-ST" passive acoustic recorder attached to the exterior hull during a mission to characterize the oceanography and soundscape around the island

of St. Croix, US Virgin Islands during March 2015. The glider mission was designed to transit marine protected areas near Lang Bank, the shelf edge, and the southwest promontory of the island, locations in which groupers and snappers are thought to form spawning aggregations. Many species of grouper use sounds to communicate among conspecifics during spawning periods, but most spawning locations are poorly located or undescribed. During the glider mission, sounds from reef fishes, including squirrel fishes and sounds consistent with those made by groupers, were detected and traced to areas where spawning activity has been suspected near outlying reefs and promontories. We further discuss considerations for interpreting passive acoustic data from ocean gliders and propose expanded use of these autonomous platforms for extending the coverage of research of soundscapes in coral reef ecosystems.

INTERACTIONS BETWEEN SEDIMENTS AND HERBIVOROUS FISHES ON CORAL REEFS (Abstract ID: 28513)

The epilithic algal matrix (EAM) is often the most widespread form of benthic cover on coral reefs. All EAMs trap sediments within the algal turfs. These sediments attract little attention, yet may be of critical importance in mediating benthic ecological processes, including herbivory. We quantified the loads and grain size distributions of EAM-based sediments, across broad spatial scales. Distinct differences in total loads and grain size distributions were revealed between biogeographic zones across the Great Barrier Reef. These patterns, of EAM sediment distribution, were then examined with regard to the influence of herbivorous fishes in shaping sediment dynamics. In some zones sediment production by parrotfishes may contribute substantially to EAM loads, as they produce sediments equivalent to the loads within EAMs in just three days. In other areas it would take parrotfishes three months to produce similar quantities of sediment. These broad scale patterns of sediment production and retention have the potential to mediate rates of herbivory across similar scales. Currently we do not know if the broad scale patterns of EAM sediment distribution are temporally stable, or how increased terrestrial sediment inputs may affect EAM loads. However, as EAM sediments are concealed within the algal turfs of the EAM, changes to EAM sediment loads may go unnoticed during standard reef monitoring, despite their potential for long term ecological consequences.

QUANTIFYING THE MAGNITUDE OF SMALL-SCALE CORAL REEF FISHERIES IN THE CORAL TRIANGLE (Abstract ID: 27999 | Poster ID: 269)

Small-scale fisheries are crucial to the socio-economic livelihood of coastal communities in the Coral Triangle, but uncontrolled, have led to widespread coral reef degradation. The magnitude of catch taken from coral reefs is poorly reported and is a major barrier to informed management. We address this knowledge gap by estimating coral reef fish catches in the Coral Triangle from 1950 to 2010. The reconstruction supplements officially reported fisheries statistics with unreported catch amounts estimated from published and gray literature, as well as expert opinions. Our analysis suggests that coral reef fish catches are strongly underestimated in the Coral Triangle on the basis of under reporting in the small-scale subsistence and artisanal fisheries of six countries – Sabah (Malaysia), Philippines, Western Indonesia, Timor Leste, Papua New Guinea, and Solomon Islands. Reconstructed catches of the traditional sector in Sabah were 3.7 times higher than reported catches, while coastal subsistence and artisanal fisheries in Papua New Guinea were under-estimated by about 3 times. The reconstructed catch for Solomon Islands included 200,000 t of previously unreported subsistence catch, and in Timor Leste the dominance of subsistence fisheries was reflected in high composition of reef fishes in the reconstructed catch. Our study suggests that coral reef fish exploitation is much higher than official statistics indicate. These previously unquantified extractions must be considered when designing fisheries policies for ecosystem and human well-being in the Coral Triangle.

ALDABRA ATOLL WORLD HERITAGE SITE – THE VISION OF A GENIUS OR A MADMAN? (Abstract ID: 29498)

In 1964, David Stoddart serendipitously learned of the British military's plans for expansion of its presence in the Indian Ocean while in a bar in the Maldives. Of particular note was the plan to turn Aldabra Atoll (Seychelles) into a Royal Air Force facility that would compromise its unique biodiversity, something he referred to as an "ecological disaster of the first magnitude". Upon returning to England and raising his concerns with the Royal Society and Ministry of Defence, Stoddart embarked on an expedition to Aldabra Atoll (1966) that would change his life forever, and set in motion a conservation movement on the value and importance of tropical marine protected areas. Within a few minutes of landing on Aldabra that first time Stoddart realised it "was one of the most remarkable islands on the earth" –which, coming from a man who had already been to the far corners of the planet, spoke volumes. The work of Stoddart, along with many others, led to Aldabra Atoll being inscribed as a World Heritage Site in 1982. Today Aldabra remains just as unique as it was when Stoddart landed there in 1966 although it has not been unscathed by the impacts of climate change that we see with increasing frequency. The UK Ministry of Defence branded Stoddart 'useless' but it was this 'useless scientist' that paved the way for modern ocean governance and marine protection on scales never imagined. This session will explore Stoddart's formidable work that led to Aldabra's protection for the benefit of humankind and his influence on the creation of vast tropical marine protected areas.

UNDERSTANDING REEF FLAT SEDIMENT REGIMES AND HYDRODYNAMICS CAN INFORM EROSION MITIGATION ON LAND (Abstract ID: 28260)

The objectives of this work were to understand the role of coastal oceanic and biophysical processes in mediating the effects of sedimentation in shallow reef environments, and to assess the efficacy of land-based sediment remediation in the coastal areas near Maunalei reef, Lāna'i Island, Hawai'i. We developed ridge-to-reef monitoring systems at two paired stream bed-to-reef sites, where one of the reef sites was adjacent to a community stream sediment remediation project. The two reef sites had different sediment removal rates and were also exposed to different amounts of sediment runoff. The community stream sediment remediation project appeared to keep at least 77 tonnes of sediment off the reef flat in one wet season. We found that resuspension of sediments on this reef was similar to that on north-facing and south-facing reefs that also are exposed to the trade winds. We posit that sites with slower sediment removal rates due to slower current velocities or high resuspension rates will require more robust sediment capture systems on land to reduce sediment input rates and maximize potential for reef health recovery. This suggests that interventions such as local sediment remediation and watershed restoration may mitigate sediment delivery to coral reefs, but these interventions are more likely to be effective if they account for how adjacent coastal oceanographic processes distribute, accumulate, or advect sediment away from reefs. Our results on the effectiveness of gabion dam sediment capture may help guide scalable solutions for erosion control on islands.

MONITORING AND EVALUATION OF CORAL TRANSPLANTATION TO MITIGATE DREDGING WORKS (Abstract ID: 28695)

To protect marine life from direct impact by dredging works for creating a port access channel in New Providence, Bahamas, over 1400 viable hard coral colonies and a broad range of associated invertebrates were relocated to recipients sites outside of the demarcated dredge and impact zone. Large coral boulders were transported using a multipurpose vessel equipped with a crane, smaller coral mounds and associated benthic invertebrates were relocated submerged with purpose-designed floating underwater cages. Most corals were transplanted to recipient sites that mimicked the donor sites in environmental conditions to enhance success rates, and a small sample was used to experiment with survival rates at significantly deeper waters, and with re-attachment to steel surfaces (ship wreck). Transplantation took place in February 2015 when environ-

mental conditions were optimal for maximum coral resilience. Monitoring was carried out 2, 8 and 26 weeks after transplantation to determine survival, growth, detachment, bleaching and predation of the coral colonies. One year after relocation a full growth and health status assessment has been executed. Preliminary data suggest survival rates in excess of 90% and excellent calcification rates. This paper evaluates the success of the coral transplantation program and presents best practices for future implementation as a mitigation measure in marine infrastructure development projects.

GENETIC VARIATION IN TRAITS OF SYMBIODINIUM: POTENTIAL FOR EVOLUTIONARY RESCUE VIA SYMBIONT ADAPTATION (Abstract ID: 29841)

The breakdown in the mutualism between coral reef species and their algal symbionts (Symbiodinium) that occurs as a result of increasingly warmer ocean temperatures is a major threat to coral reefs around the globe. Species may respond to this rapid environmental change through either acclimatization or adaptation, but the long generation times of most host species may result in slow rates of adaptation. However, high rates of somatic mutation have resulted in significant genetic variation within Symbiodinium populations, which could provide the raw material for natural selection and adaptation to increased temperature on contemporary time scales. Such genetic variation, coupled with strong selection pressure and short generation times of symbionts (Symbiodinium) afford the potential for rapid evolution and adaptation of the symbiont population. We measured trait variation among genotypes within Symbiodinium antillogorgium. We found significant variation in traits that are likely to affect the strength of the mutualism with host species, including chlorophyll content, quantum yield, growth rate, and nitrogen use. Further, we exposed genotypes to ambient and elevated temperatures and found that genotypes varied in their trait and fitness responses to temperature, indicating a potential for selection on traits. Selection for particular genotypes may confer adaptation of the holobiont to increased temperatures on coral reefs and provide some hope for evolutionary rescue of reef species via adaptation of their symbionts.

ILLEGAL HARVESTING AND TRADING OF BLACK CORALS (ANTIPATHARIA) IN MADAGASCAR: THE NECESSITY OF FIELD STUDIES (Abstract ID: 28610)

Black corals (Cnidaria: Antipatharia) have been used for medicinal purposes or in jewellery manufacturing since a long time in many parts of the world. Except in Hawaii where these fisheries are well known, black coral harvests are usually made without any control and management. This is the case in many tropical islands and particularly in Madagascar, where the illegal trade that exists since decades has expanded dangerously during the last years. Since 2011, an illegal traffic of black corals has been occurring in the main cities of the southern and coastal regions of the country. Hundreds of kilograms of black coral skeletons and a lot of diving material were seized by the authorities and efforts were made by scientists and politicians to stop this illegal trade. Despite this and the continual harvesting of these natural resources, there has been no study in the Indian Ocean region on the biology and ecology of antipatharians. Our research aims at studying black coral populations of the southwestern coast of Madagascar. Here, we explain the current black coral harvesting occurring in the country and present the first insights into the structure and biodiversity of a black coral meadow in Toliara. We identified 19 different morphotypes and described the skeleton spines, mesenteries structures and general morphologies. Due to the general difficulty to identify species among the Order Antipatharia, we also worked on ribosomal ITS regions to assess phylogenetic relationships among these black corals.

A MODERN APPROACH FOR SPECIES DELIMITATION IN THE CORAL GENUS *GONIOPORA* (Abstract ID: 28652)

We investigated the species boundaries of the scleractinian coral genus *Goniopora* from several localities in the Indian and Pacific Ocean and from the Saudi Arabian Red Sea. We used an integrated morpho-molecular approach to better clarify the complex scenario derived from traditional classification efforts based on skeletal morphology. Molecular analyses of evolutionary relationships between different traditional morpho-species of *Goniopora* were performed to re-evaluate the informativeness of macromorphological and micromorphological features. Several lineages were molecularly resolved within *Goniopora* samples on the basis of four molecular markers: the mitochondrial intergenic spacer between Cytochrome b and the NADH dehydrogenase subunit 2, the entire nuclear ribosomal internal transcribed spacer region, the ATP synthase subunit β gene, and a portion of the Calmodulin gene. DNA sequence data were analyzed under a variety of methods and exploratory species-delimitation tools. Subsequent analyses of micromorphological and microstructural skeletal features identified the presence of distinctive characters in each of the molecular clades. Unique *in vivo* morphologies were associated with the genetic-delimited lineages, further supporting the molecular findings. Some colonies show a peculiar genetic pattern that could indicate hybridization. The proposed re-organization of *Goniopora* will resolve several taxonomic problems in this genus while reconciling molecular and morphological evidence.

*SYMBIODINIUM* DISTRIBUTION ALONG THE SOUTHWESTERN ATLANTIC COAST (Abstract ID: 29462 | Poster ID: 126)

The Brazilian coast has the only true shallow water coral reefs of the Southwestern Atlantic Ocean. However, coral-Symbiodinium relationship patterns are still poorly understood in this area. In order to assess these patterns, the diversity and distribution of Symbiodinium were sampled in 2 corals, 1 hydrocoral and 1 zoanthid species at 5-15 locations along the Brazilian coast. Symbiodinium strains were assessed by 18S and 28S rDNA PCR/RFLP analyses and ITS2 cloning and sequencing. The symbiosis patterns seem to be driven more by host identity than by environmental variations. Palythoa caribaeorum had a specific association with Symbiodinium clade C (C1/C3) along the whole coast. Favia gravida was dominated by clade C (C1/C3), except at Rocas Atoll, where it was associated with clade A. Mussismilia hispida and Millepora alcicornis were quite generalist, harboring clades A, B (B1, B30, B39) and C (C1/C3) with different association patterns along the coast. In both species, colonies from the central Brazilian coast (Bahia State) hosted different symbiont communities from those observed at all others locations. High sedimentation rates coupled with its seasonal variability could explain this unique pattern. A latitudinal pattern was also observed, with upwelling events favoring the mixture of clades in M. hispida and the presence of a new Symbiodinium strain (B39), associated with M. alcicornis. Our results represent the first major investigation of Symbiodinium diversity along the Southwestern Atlantic and are relevant for future studies and conservation strategies.

THE CONTRIBUTION OF LARGE DECAPODS TO MAINTENANCE OF CORAL REEF COMMUNITY INTEGRITY (Abstract ID: 29543 | Poster ID: 285)

Overexploitation and habitat loss have resulted in declining marine capture fisheries worldwide even as our general understanding of the ecosystem consequences of such changes lags behind. There is now a general recognition that chronic overexploitation can alter living communities which may no longer facilitate previous levels of fisheries harvest and other critical ecosystem services. Despite the significance of large decapod fisheries around the world and a number of studies illustrating decapod top-down control in temperate systems (e.g. kelp beds) the ecological role of large decapods in maintaining tropical coral reef integrity and resilience is relatively poorly understood. Beyond the impact on lobster populations and loss of income to fisheries dependent households, the overexploitation of Caribbean Spiny lobster may have disproportionally high levels of impact on coral reef health and resilience given their naturally high abundance and involvement in a diverse set of trophic interactions. A number of other

large coral reef dwelling decapods (e.g. Caribbean King crab Mithrax spinosissimus ) are also involved in complex trophic dynamics within coral reef ecosystems. As such, can the abundance and population structure of large decapods on coral reefs, influenced by fishing on reefs and possibly use of artificial structures in other habitats, be significantly correlated with metrics of coral reef community integrity and be useful indicators of the past, present and future state of coral reefs?

OCEANIC FARMED FLORIDA ACROPORA CERVICORNIS: SPAWNING, VIABILITY, TRANSPORTING AND SETTLING IN LAND-BASED AQUACULTURE FACILITIES AS A RESTORATION STRATEGY (Abstract ID: 29668 | Poster ID: 558)

Land-based aquaculture of endangered coral species has been identified as a significant potential strategy for coral restoration efforts, warranting more work in this area. The Florida Aquarium has been participating in the natural coral spawn of Acropora cervicornis in the Florida Keys since 2010. Working closely with the Coral Restoration Foundation and University of Florida, after several years of failure refining techniques and timing, this collaboration has successfully captured gametes in the field, fertilized them in the laboratory, and transported the product long distances to research facilities in central Florida for settling for the last 3 years. In 2014 and 2015 we collected 280K and 520K bundles, respectively using modified cone nets over 2-3 nights each season. In 2015, we calculated 67% (350K/520K) viability. Post fertilization, samples were packed at a density of 5000 larvae/1L, in 1L plastic bottles using supersaturated system water while being maintained at 24°C for up to an 8 hour journey by road to our research facilities. Multiple techniques have been used in an attempt to settle the larvae, which is proving an ongoing bottleneck. Substrate, water flow, feeding regimes, tanks size and shape and husbandry have all been examined. To date, the most promising approach has been the use of seasoned tiles with adult corals in situ to provide zooxanthellae. All other variables have produced mixed results. Success rates are still below those that could be of use to mass restoration using land-based aquacultured corals to our imperiled reefs.

PLACE-BASED OPERATIONALIZATION OF THE SOCIAL-ECOLOGICAL VULNERABILITY FRAMEWORK TO FOSTER SOCIAL-ECOLOGICAL RESILIENCE (Abstract ID: 28191)

Human-environment interactions, including feedbacks, are now explicitly considered in social-ecological system conceptual frameworks. However, there is a crucial need to develop case-specific operationalization of such frameworks to inform place-based management. The social-ecological vulnerability assessment framework - that incorporates sensitivity, adaptive capacity and exposure of both socio-economic and ecological sub-systems to change or stressors - holds great promise to be an effective tool for conducting systematic, coupled-system analysis. To date, much effort has been dedicated to model and assess social-ecological vulnerability to climate change. Here, we have adapted and tested this framework on the reef fisheries of Moorea, French Polynesia, to identify the local ecological, socio-economical and cultural processes supporting potential for social-ecological sustainability. Our key contributions to social-ecological frameworks are: 1) the development of a novel, mixed approach to map each dimension of vulnerability at the system-level; and 2) the explicit consideration of reciprocity and feedbacks between the social and ecological vulnerabilities. Our results show that key sources of vulnerability differ considerably between locations on the island, providing important insights into the types and design of policy interventions that may help to reconcile conflicting conservation and socio-economic objectives in this developing island.

ROLE OF SEA URCHIN CENTROSTEPHANUS TENUISPINUS (CLARK, 1914) AS A BIO-ERODER- IN HALL BANK REEF (32 2.002◦S AND 115 42.957◦E) WESTERN AUSTRALIA (Abstract ID: 28715)

Among many reefs in Western Australia, Hall Bank reef is unique in its geographical position (closer to the 20°C isotherm), nearshore location, presence of higher hard coral cover and absence of macroalgae. Sea urchins play a key role in many benthic marine habitats as grazers and bioeroders and hence, are considered as reef engineers. Due to their strategic position in marine food webs as grazers, they can have a drastic impact on their habitat. Thus, presence of sea urchins in high densities is thought be the reason behind the absence of macro algae on Hall bank reef.This study focused on evaluating the role sea urchins, Centrostephanus tenuispinus, on Hallbank reef. Gut contents of 78 urchins were analysed for organic and inorganic components during winter 2015. CaCO3 ingestion rates were calculated. Fifty urchins were kept in sea water flow through aquarium. Five urchins were dissected at time intervals 0, 4, 8, 16, 24, 36, 48, 60, 72 and 96 hr to estimate the gut evacuation rate. Five under water cages (6 urchins/cage) were maintained in the adjacent sea grass bed to estimate the correction factor for newly eroded CaCO3 experiment. Urchin densities were estimated using ten haphazardly laid belt transects (20m X 0.5m). Mean sea urchin density in winter was 5.26±1.25. Mean percentages for organic gut contents, calcium carbonate and other siliceous inorganic components were 8.83±0.23%, 86.96±0.43% and 4.25±0.34% respectively. Daily gut turnover rate was 0.24 day-1. Newly eroded CaCO3 percentage was 20.3 %. Food ingestion rate was 1.23±0.46 (gut dry weight individual-1 day-1). Bio-erosion rate for winter was 0.36±0.13 g CaCO3 individual-1 day-1.

CURRENT STATUS AND THE EFFECT OF SHADING ON PROGRESSION OF THE CORAL KILLING SPONGE (TERPIOS HOSHINOTA) ON THE REEFS OF PALK BAY, INDIA (Abstract ID: 29012 | Poster ID: 220)

Terpios sponge outbreaks cause significant decline in living coral cover and recently Terpios has been reported on reefs in Palk Bay located on the southeast coast of India. However, no information was available on its progression across corals and the rate of spread in the affected area. In this study, we investigated the progression and the rate of spread of Terpios over live coral colonies, and potential variation in progression rate between species. The effect of light on the progression of sponges over live corals was examined by conducting in situ shading experiments for a 6 month period. The presence of T. hoshinota in our study site was confirmed via molecular analysis. Surveys along belt transects revealed that, all observed coral genera (Symphylia, Porites, Acropora, Platygyra, Favia and Favites) and other non coral organisms including coralline algae were found to be covered by this sponge. The proportion of colonies affected by the sponge (prevalence) increased from 24% to 33% within a 6 month period. An average progression rate of 2 cm/month over live coral colonies was observed irrespective of species. Shading stoped sponge progression without any apparent affect on the shaded live coral portion. This preliminary study suggests that Terpios sponge is spreading within Palk Bay reef and the shading method may reduce the impact of the sponge on coral. Studies are needed to further develop and test the shading as a method of sponge control to reduce the sponge's impact on the coral reef ecosystem.

A LONG ROAD TO RECOVERY: USING RNA-SEQ TO UNDERSTAND THE CORAL STRESS RESPONSE TO NATURAL BLEACHING EVENTS (Abstract ID: 28792)

Rising global temperatures are a major threat to coral reefs worldwide, and the increasing frequency of regional bleaching events poses serious challenges to the maintenance of healthy coral reef systems. While transcriptome-wide gene expression analyses (e.g. via RNA-seq) have greatly improved our understanding of coral responses to heat stress, most work to date has focused on the responses of corals to experimental heat stress in a controlled environment and there remains a lack of in situ field expression data from natural bleaching events. In this study, we use a combination of RNA-seq, co-expression analyses, and guava flow cytometry to examine the coral stress response to a warm-water event that struck American Samoa in early 2015. We incorporate information from acute experimental heat stress and sub-bleaching field stress data to focus our analyses on groups of co-expressed genes (transcriptional modules) that are responsive to heat stress, allowing us to examine both the magnitude and duration of the stress response mounted by corals during natural bleaching events. Transcriptional modules previously associated with experimentally-induced bleaching and sub-bleaching field stress also increased during the natural bleaching event. Interestingly, the response of these modules was greatest four months after bleaching was observed, despite colonies showing visual signs of recovery and symbiont densities returning to normal levels. These results suggest that the physiological stress response mounted by corals to warm-water events lasts for several months, well after corals have regained pigmentation.

ASSESSING AND COMMUNICATING THE STATUS OF CORAL COMMUNITIES USING A CONDITION INDEX BASED ON MULTIPLE INDICATORS RELEVANT TO WATER QUALITY (Abstract ID: 28092)

A critical component of environmental decision making process is the regular assessment of environmental condition against which to gauge the success, or otherwise, of management actions. Condition of coral reefs is influenced by multiple pressures, making it difficult to isolate individual stressors or responses of importance. Using, as an example, coral monitoring associated with the Reef Water Quality Protection Plan (RWQPP) for the Great Barrier Reef World Heritage Area (GBR), we report the development of an multi-indicator index of coral community condition. Index formulation included selection of indicators that were: relevant to pressures associated with runoff, responsive on the time scale (years) of likely outcomes of the RWQPP, and able to be efficiently monitored across the scale (100's of km) of the program. Thresholds were set that allowed the state of each indicator to be scaled along a condition gradient, and then aggregated into an overall index score with associated uncertainty estimates. Trends in the index yielded a demonstrable relationship to loads of contaminants entering the GBR in runoff. Several consecutive years of high annual rainfall resulted in increased runoff from the GBR catchments and a concurrent decline in index scores. A return to more moderate rainfall saw a decline in runoff and some improvement in the index scores. The sensitivity of the index to the cumulative impacts affecting reefs exposed to runoff emphasizes its utility as a cost-effective condition assessment and reporting tool to inform the environmental decision making process.

VARIABILITY IN REEF CONNECTIVITY IN THE CORAL TRIANGLE (Abstract ID: 29558)

Larval connectivity plays as critical role in maintaining viable coral populations; however, the variability in larval dispersal over decadal timescales is poorly understood. We examine variability in reef connectivity in the Coral Triangle following April and September spawning over a nearly 50-year period (1960-2006) using a 5-km resolution Regional Ocean Modeling System developed for the Coral Triangle (CT-ROMS) and a Lagrangian particle-tracking tool (TRACMASS). We found that potential connectivity in the CT is highly variable, emphasizing the importance of simulations that are at least 20 years long for identifying connectivity patterns and thus management targets. This connectivity variability is driven primarily by stochasticity in surface currents, though the impacts of ENSO and the IOD on the South Equatorial Current also play an important role. Although mean potential connectivity over the 47-year simulation suggests that reefs in this region are primarily self-seeded, exceptions highlight important source and sink regions and pathways for recovery following disturbance. The spatial pattern of "subpopulations" based solely on the physical drivers of connectivity between reefs closely match major phylogenetic lines and regional patterns of biodiversity, suggesting that physical barriers to larval dispersal may be a key driver of reef biodiversity. 21st Century simulations driven by the Community Earth System Model RCP8.5 scenario suggest that these major barriers to larval dispersal persist into the future, despite some regional changes in reef connectivity.

REMOTE SPECTROSCOPIC RETRIEVAL OF APPARENT OPTICAL PROPERTIES AND BOTTOM REFLECTANCE IN SHALLOW CORAL ECOSYSTEMS (Abstract ID: 29573)

Remote spectroscopy in the 400-800 nm range can observe reflected light from shallow water benthic environments, simultaneously characterizing water properties and bottom composition. Specifically, airborne mapping spectrometers such as NASA's Portable Remote Imaging SpectroMeter (PRISM) are powerful tools to map coral reefs over wide areas. However, such inversions are difficult due to the intrinsic ambiguity in separating bottom reflectance, depth, and water optical properties, which leads to non-unique retrievals. While many retrieval algorithms have been developed, true operational spectroscopic mapping of coral reefs remains elusive. This work describes a method for accurate and stable bottom reflectance retrieval at speeds suitable for large remote sensing datasets, such as those of the forthcoming COral Reef Airborne Laboratory (CORAL) investigation. We capture water constituents using two apparent optical properties (AOPs): backscatter, and the "operational" attenuation term of Maritorena et al. (1994). These coefficients, along with depth, glint, and bottom reflectance, define a simple model for subsurface irradiance reflectance. Both AOPs and bottom reflectance use a nonnegative mixture representation, a subspace of variability based on a library of endmembers drawn from simulated or field data. We evaluate the approach by mapping Eelgrass and sediment in the Elkhorn Slough, and coral reef communities in the Florida Keys. The method provides stable results that are consistent with field validation, presaging its utility for mapping coral reefs over wide areas.

DO CORALS ADAPT THEIR ANNUAL SYMBIOTIC METABOLISM STRATEGIES TO COPE WITH SEASONAL TEMPERATURE STRESS AND NITROGEN POLLUTION? (Abstract ID: 29298)

Rising global sea temperatures and localized eutrophication threaten the integrity of the coral-algal symbioses in coastal reef communities. The propensity to adapt host-symbiont metabolic interactions during periods of warming may mediate negative effects to their overall physiology, such as bleaching. Coral species vary in their capacity for heterotrophy which, for corals, relies on passive suspension feeding. This study examines five coral species in Hong Kong (*Acropora digitifera*, *Montipora peltiformis*, *Galaxea fascicularis*, *Oulastrea crispata*, and *Porites lobata*) and explores changes in their metabolic strategies from autotrophy to heterotrophy, and vice versa, in accordance with seasonal temperature extremes as an adaptation to cope with unprecedented nitrogen pollution. We monitored host lipid content, *in hospite Symbiodinium* photochemistry using PAM flourometry, and photosynthesis/respiration (P/R) of the holobiont every month from August 2015 until the present. We have found that during colder, winter months (December/January) *A. digitifera* and *G. fascicularis* exhibited higher P/R ratios and greater photochemical efficiency, whereas *P. lobata* showed no change. These data indicate that some species are adapting their metabolic strategies according to seasonal temperature changes. This adaptation may offset the burden *Symbiodinium* imposes under conditions of high, localized nitrogen pollution during warmer, summer months (July/August/September).

SURF AND TURF; PHYSICAL STRUCTURING OF BENTHIC COMMUNITIES AT NINGALOO REEF, WESTERN AUSTRALIA (Abstract ID: 28491)

Physical forcing, such as wave energy, plays a major role in the physical erosion of carbonate material and subsequently the structuring of coral reef communities. Extreme wave energy can reduce coral cover and alter community composition by favouring the most mechanically tolerant hard coral growth forms and low-profile macro algae, turfs and crustose coralline algae. Extreme wave energy can also reduce three dimensional complexity of the reef; when the rate of carbonate removal exceeds that of production. At Ningaloo Reef in Western Australia, wave energy is likely to be an important structuring force on the reef slope because (i) the reef is located adjacent to an extremely narrow section of the continental shelf (therefore wave generated energy gradients are steep); (ii) the reef is afforded no protection from large waves by nearby islands or continents; and (iii) it is located at a latitude where severe cyclones are frequent. Here, we present results from the first year of the Ningaloo Outlook shallow reefs project; a five year collaboration between BHP Billiton and CSIRO. Using the historical meteorological record, a high resolution wave model and photo mosaics of the seafloor, we predict some demographic consequences for coral reef communities growing on the Ningaloo reef slope. We also discuss the implications for community structure and carbonate budgets within these high energy environments.

TRACING CABON FLOW THROUGH CORAL REEF FOOD WEBS USING A COMPOUND-SPECIFIC STABLE ISOTOPE APPROACH (Abstract ID: 29479)

Coral reefs support spectacularly productive and diverse communities in tropical and sub-tropical waters throughout the world's oceans. Debate continues, however, on the degree to which reef biomass is supported by water column or benthic primary production and recycled detrital carbon. We coupled analyses of stable carbon isotopes in essential amino acids with Bayesian mixing models to quantify carbon flow from pelagic primary producers, benthic macroalgae and autotrophic symbionts in corals, along with detrital carbon, to coral reef fishes across several feeding guilds and trophic positions, including apex predators (gray reef and black tip reef sharks), on reefs in the Phoenix Islands Protected Area in the central tropical Pacific. Excellent separation in multivariate isotope space among end-members at the base of the food web allowed us to quantify the relative proportion of carbon produced by each of the end-members that is assimilated by focal reef fish species. Low local human impacts on the study reefs provided the opportunity to examine carbon fluxes in fully functioning reef food webs, thereby providing an important baseline for examining human impacts in food webs on stressed reefs in more populated regions in the tropics. The study reefs are located along a significant gradient in dissolved N concentrations, allowing us to test if end-member proportions vary as a function of pelagic primary productivity levels. Our work provides insights into the roles that diverse carbon sources may play in the structure, function and resilience of coral reef ecosystems.

POPULATION DENSITY OF CROWN OF THORNS STARFISH IN DIVE SITES OF THAILAND (Abstract ID: 28669 | Poster ID: 676)

The crown-of-thorns starfish (*Acanthaster planci*) is one of the major threats of coral reef degradation worldwide, especially in the Indo-Pacific region. Two principal hypotheses that account for starfish outbreaks are predator removal and terrestrial runoff. Tour boat operations, diving expeditions, eco-tourism and other tourist attractions based on reef environments are all at risk of economic loss due to damage caused by the coral-feeding starfish. This study aimed to investigate distribution and abundance of *A. planci* at 67 dive sites in the Gulf of Thailand and the Andaman Sea during 2013 – 2015. The surveys illustrated that the occurrence of *A. planci* in dive sites of Thailand, both in the Gulf of Thailand and the Andaman Sea, was not significantly different. Among the 67 dive sites, only two dive sites were categorized as abundance, i.e. Ko Ngam Yai, Mu Ko Chumphon, the Western Gulf of Thailand and Ao Losama, Mu Ko Phi Phi, the Andaman Sea. Three dive sites were classified as common while eight dive sites were categorized as rare. The population densities of *A. planci* from this study, except at Ko Ngam Yai and Ao Losama, are still much lower than that causes the outbreaks in other regions. The severe destruction of coral communities in Thailand caused by *A. planci* was not clearly recorded during the last three decades. This study contributes the important background information for establishing the management strategies to prevent the outbreaks of *A. planci* in dive sites of Thailand.

ENGAGING RESOURCE USERS TO IDENTIFY SOCIAL AND ECOLOGICAL CHANGES IN AUSTRALIA'S CORAL TROUT FISHERY. (Abstract ID: 28463)

Resource users provide valuable information on marine ecosystem change, but their observations and perceptions of change may differ from other sources of available monitoring data. This creates potential for conflict and may reduce the legitimacy of management measures in the eyes of resource users. Coral trout is targeted throughout the Asia-Pacific for the live finfish trade, and this market forms an economically significant fishery in Queensland, Australia. While monitoring occurs in the Queensland fishery, detailed data have only been collected over the last few decades. Through interviews with 120 commercial and recreational coral trout fishers, we assessed ecological and social changes in Queensland's coral trout fishery across a period of 60 years to inform baseline conditions and to highlight areas of contention and agreement between scientific data and resource user observations. The majority of resource users observed declines in catch rate of coral trout. These declines began several decades prior to the commencement of scientific monitoring. Recent trends in recalled catch rates corresponded to aspects of fisheries landing trends, but contrasted with ecological data. Resource users also provided information on the impact of management measures on the fishery. Our findings suggest that data from resource users can be useful for closing gaps in knowledge of long-term trends, in addition to informing fisheries management of the social and cultural context in which resource users operate, including which aspects of assessment may be contentious with resource users.

MICROHABITAT USE OF JUVENILE CORAL REEF FISH IN BOLINAO-ANDA REEF COMPLEX (BARC) (Abstract ID: 29113)

In a pristine reef environment, abundance of early juvenile reef fish is simultaneously determined by microhabitat structure and resident predator size. However, for disturbed reef environments, very little is known on the strength of this association. In this study, we quantified the structural differences among dominant microhabitats in a long exploited reef in the Philippines and determined the degree of association among microhabitat types and juvenile reef fish. The influence of foraging space, predator size and confamilial attraction on the abundance of juvenile pomacentrids was also determined to elucidate crucial post-settlement interactions. The results showed strong similarities in juvenile reef fish communities across different habitat types investigated. The abundance of herbivorous, egg brooding damselfishes across microhabitat types strongly influenced the overall similarities observed in juvenile reef fish assemblage. In general, juvenile pomacentrids settled more in areas with relatively small foraging space and in the presence of adult members of their family. The observed heterospecific grouping, especially in large numbers, enhances concealment of the smaller juveniles from predators, especially in circumstances where the environment does not provide much cover. This is seen as a strategy to minimize predation in a low complexity, predator accessible environment. Furthermore, the results also provide compelling evidence that the continued degradation of coral reef microhabitats strongly impact its associated reef fish community structure.

ASSESSING THE FUNCTIONAL DIVERSITY OF REEF FISH HERBIVORES (AND DETRITIVORES?) USING A COMPOUND-SPECIFIC STABLE ISOTOPE APPROACH (Abstract ID: 28844 | Poster ID: 513)

Tropical coral reefs around the world are known to support a wide diversity and abundance of herbivorous reef fishes. These fishes play a key role in helping to maintain healthy reef ecosystems by clearing algae and creating space for corals to settle. The term herbivore however, includes a wide variety of species with different feeding methods, including browsing, excavating, grazing, and scraping, which all may help these fishes specialize their diets to specific plants, (epilithic) algae, or other components of the detrital pool. We use compound-specific stable isotope analysis (CSIA) paired with Bayesian mixing models to compare the functional dietary diversity of herbivorous reef fishes. We compare the isotopic signatures of &delta$^{13}$C values in fish tissue, fish foreguts, and dietary end members across acanthurids, scarids, and other fishes with dietary end members represented by brown, green, red, and epilithic algae groups. CSIA mixing model results and diet diversity will be discussed in the context of niche partitioning on coral reefs. The partitioning of herbivorous reef fishes into multiple food niches may help explain why such a high diversity and abundance of herbivorous fish species are found on some reefs, despite outwardly appearing to feed on the same food source.

EXPLORING ENVIRONMENTAL AND GEOGRAPHIC PATTERNS OF CORAL REEF CRYPTOFAUNA COMMUNITIES (Abstract ID: 28725)

One of the most fundamental questions in ecology concerns the drivers of community assembly, i.e. the relative roles of abiotic and biotic factors in determining species' distributions and abundances. Here we examine motile marine invertebrate cryptofauna communities captured within Autonomous Reef Monitoring Structures deployed across Pacific Islands. Using raw data and distance-based approaches of beta-diversity, we examine to what extent environmental factors, such as nutrients, temperature and coral cover, and geographical location explain variation in community organization. Through variance partitioning and the "decay of similarity with distance", we investigate whether the environment or geography have a greater influence in observed cryptofauna composition. Observations on species occurrence, diversity, and abundance, together with environmental correlates, are starting points to understanding the distributions and community organization of reef cryptofauna. Further analyses on historical biogeography and evolution will need to additionally take place in order to better understand the mechanisms that may have shaped these communities.

UNDERSTANDING CORAL'S SHORT-TERM ADAPTIVE ABILITY TO WATER POLLUTION USING GENETICS AND PROTEOMICS (Abstract ID: 28208)

Corals in Maunalua Bay, Hawaii are under chronic pressure from sedimentation and terrestrial runoff containing multiple toxicants as a result of large-scale urbanization that has taken place in the last 100 years. However, some individual corals thrive despite the prolonged exposure to these environmental stressors, which suggests that these individuals may have adapted to withstand such stressors. The lobe coral Porites lobata from the 'high-stress' nearshore site had an elevated level of stress induced proteins, compared to those from the 'low-stress,' less polluted offshore site, and genetic analysis revealed clear genetic differentiation between corals at the two sites, which are less than 2 km. To understand whether selection is driving the observed differentiation, a 30-day reciprocal transplant experiment was conducted. Protein expression profiles, as well as other stress-related physiological characteristics were compared in corals between the sites. The results suggest that the nearshore genotype can cope better with sedimentation and pollution than the offshore genotype, which indicates that the observed genetic differentiation is due to selection for tolerance to these environmental stressors. Understanding the little-known, linage-scale genetic variation in corals offers critical insight into their short-term adaptive ability, which is indispensable for protecting corals from impending environmental stressors and climate change.

COMPARATIVE PHYLOGEOGRAPHY IN A MULTI-LEVEL SEA ANEMONE SYMBIOSIS: EFFECTS OF HOST SPECIFICTY ON PATTERNS OF CO-DIVERSIFICATION AND GENETIC DIVERSITY (Abstract ID: 28182)

Specialist and generalist life histories are expected to result in contrasting levels of genetic diversity at the population level, yet symbioses are expected to lead to patterns that reflect a shared biogeographic history and co-diversification. We test these assumptions using a comparative phylogeographic approach for six co-occurring crustacean species that are symbiotic with sea anemones on western Atlantic coral reefs, yet vary in their host specificities. We first conducted species discovery analyses to delimit cryptic lineages, followed by classic population genetic diversity analyses for each delimited taxa. The demographic history for each taxon was reconstructed using traditional summary statistics, Bayesian Skyline Plots, and approximate Bayesian computation to test for signatures of recent and concerted population expansion. The genetic diversity values recovered here contravene the expectations of the specialist-generalist variation hypothesis and classic population genetics theory: all specialist lineages had greater genetic diversity than generalists. Demographic reconstruction recovered evidence of recent population expansions using summary statistics, yet Bayesian skyline plots and approximate Bayesian computation suggest the timing and magnitude of these events were idiosyncratic. These results do not meet the a priori expectation of concordance among symbiotic taxa and suggests that the intrinsic aspects of species biology may contribute more to the phylogeographic histories of each taxon than extrinsic forces that shape whole communities.

SYMBIOSIS AND NUTRITIONAL STATE ALTER THE CNIDARIAN CELL CYCLE IN THE SYMBIOTIC ANEMONE *AIPTASIA* SP. (Abstract ID: 29814)

The cnidarian-dinoflagellate endosymbiosis relies on the cellular coordination of its two partners, algal symbionts and the host cnidarian cells that contain them. We examined the effect of nutritional status and symbiotic state on host cell proliferation in the sea anemone *Aiptasia* sp., and its resident algal symbionts *Symbiodinium* clade B1, a model system for coral-dinoflagellate symbiosis. Anemones under three different symbiotic conditions: symbiotic, aposymbiotic (without symbionts) and colonizing (aposymbiotic animals being re-colonized with algae) were labeled with S-phase marker ethynyl deoxyuridine (EdU), G2/M-phase marker histone H3pSer10, and Hoechst dye. In symbiotic anemones, host DNA replication and cell division was lowest at night and significantly peaked in the afternoon. Symbiotic state and nutritional status had a strong interaction effect; starvation significantly increased replication and division rates in aposymbiotic anemones but decreased rates in symbiotic anemones. Gastrodermal tissue of starved aposymbiotic animals had significantly higher replication and division rates than the gastrodermis of symbiotic and fed aposymbiotic animals. We also examined division rates during onset of symbiosis. There were no significant rate changes between nutritional states, and rates appeared similar to those of aposymbiotic groups. Starvation also had a positive effect on symbiont proliferation. Our results suggest that host cell cycle and proliferation respond to long-term environmental change and symbiont state.

ARE SEA FAN SCLERITES THE FIRST LINE OF DEFENSE AGAINST PATHOGENS? (Abstract ID: 29507 | Poster ID: 135)

Sessile organisms such as octocorals cannot avoid threats such as predation, parasitism or fungal infections through evasive responses. Instead, they relay on strategies that deter or reduce the impact of these threats. One such strategy is the development of anatomical structure known as sclerites, which are minute calcium carbonate structures laying on top of the ectoderm and within the mesoglea and gastrodermal tube walls. Sclerites have multiple roles, including structural support of the colony and predator deterring. However, the role of sclerites as a physical barrier that deters fungal infection is yet to be studied. In this study, we examine the potential role of sea fan sclerites as protection from fungal infection. To accomplish this, we inoculated four different fungi isolated from healthy sea fans into 5ml pipettes filled with culture media and on top of it sclerites from healthy and diseased fans. To determine whether chemical compounds associated with the sclerites impact infection, sclerites from healthy and diseased fans were extracted for several days with acetone prior to inoculation. Results showed that the sclerite layer delayed fungal infection of the agar when compared to controls (pipettes with agar but no sclerites). There were no difference between pipettes with healthy and diseased sclerites, but there were differences among sclerites extracted with acetone. This study indicates that, in addition to the structural support and predator deterring roles, sclerites may also play a role as physical and chemical barriers to fungal infection.

TEMPERATURE SHUFFLES CORAL-ALGAL SYMBIOSIS IN THE SOUTH CHINA SEA (Abstract ID: 30046 | Poster ID: 132)

With sea surface temperature (SST) increasing, scleractinian corals are exposed to bleaching threats but may possess certain flexibilities in terms of their associations with symbiotic algae. Previous studies have shown a close symbiosis between corals and Symbiodinium; however, the spatial variation of the symbiosis and the attribution underlying are not well understood. In the present study, we examined coral-algal symbiosis in Galaxea fascicularis and Montipora spp. from three biogeographic regions across ~10° of latitude in the South China Sea. Analysis of similarities (ANOSIM) indicated a highly flexible coral-algal symbiosis n both G. fascicularis and Montipora spp. at the subclade level and redundancy analysis (RDA) using subclade data suggested that temperature was the main factor contributing to the diversity of Symbiodinium across three regions. The geographic specificity of the Symbiodinium phylogeny was identified, revealing possible environmental selection across the three regions. In addition, Symbiodinium ITS2

sequences derived from congeneric corals were more likely clustered together, revealing a correlated coral-algal evolution. In conclusion, our study demonstrated that coral-algal symbiosis was highly flexible in both G. fascicularis and Montipora spp., and temperature served as a major factor shuffling coral-algal symbiosis in congeneric scleractinian corals. These results suggest that scleractinian corals may have the ability to regulate Symbiodinium community structures under different temperatures and thus be able to adapt to gradual climate change.

## WINNERS AND LOSERS OF CYCLONES AND BLEACHING: BENTHIC COMMUNITY CHANGES AFTER MULTIPLE DISTURBANCES (Abstract ID: 28022)

Climate change poses two main challenges for reef building corals: an increment in the frequency and severity of tropical storms; and ever increasing water temperatures. The differential susceptibility of coral species to these disturbances means that the affected coral assemblages temporarily or permanently reconfigure following such disturbances. To adapt management to the altered ecosystems, we need to better understand how coral assemblages change and for how long these changes are likely to persist. In this study I document the effect of a category 5 tropical cyclone and a subsequent thermal bleaching event on an inshore fringing reef of the Great Barrier Reef. Further to the transition from branching to massive/encrusting dominance in coral assemblages immediately following the cyclone, and the differences in bleaching mortality among coral taxa, I show evidence for the density dependence of the recruitment of brooding corals in the aftermath of the disturbance. I also present a novel method for rapid reef mapping using geotagging of coral colonies and custom made GIS scripts.

## CHARACTERIZING SYMBIODINIUM DIVERSITY IN CANDIDATE RESILIENT CORAL SPECIES (Abstract ID: 29049 | Poster ID: 123)

Identifying resilient coral species and understanding determinants underlying resilience have important implications for coral reef restoration efforts. A key factor contributing to coral resilience is its obligate symbiotic relationship with photosynthetic single-celled dinoflagellates (zooxanthellae) predominantly belonging to the genus *Symbiodinium*. Zooxanthellae composition has been shown to be associated with coral survival in adverse environmental conditions. Currently however, there is little information on the diversity and distribution of *Symbiodinium* clades hosted by coral populations in Philippine archipelagic waters. In this study, we utilized various molecular approaches to characterize *Symbiodinium* diversity across coral species collected from a) natural populations which exhibit varied susceptibilities to environmental stress; b) coral fragments subjected to elevated temperature and lowered pH in a controlled hatchery environment, and fragments exposed directly to anthropogenic nutrient stress. Initial results show the utility of clade-specific PCR amplification in elucidating dominant *Symbiodinium* clades in coral fragments and PCR-DGGE fingerprinting of the zooxanthellae ITS2 gene region in identifying *Symbiodinium* to the subclade level. We present information on the diversity and distribution of zooxanthellae from candidate resilient coral species, which will be useful to characterize the potential influence of *Symbiodinium* on tolerance and resilience of the coral holobiont to environmental stress.

## HISTORICAL AND SPATIAL DIMENSIONS OF HUMAN PROCESSES AND THEIR EFFECTS ON MARINE ECOSYSTEM SERVICES (Abstract ID: 30109)

Overfishing and terrestrial runoff are among the most important anthropogenic threats to marine ecosystem services. These threats are apparent in Puerto Rico, where research has shown persistent fish stock declines and coral reef degradation. Despite decades of management strategies, including controversial fishing regulations and the implementation of marine reserves, coral reef ecosystems continue to decline due to local threats and global climate change. Our work aimed to quantify environmental transformations observed in watershed, coastal and marine areas, and subsequently understand the relative importance of human dimensions over reported fish stocks in a spatial and historical context. We focused on Puerto Real, a traditional fishing community in southwest Puerto Rico, by generating and analyzing detailed decadal land cover maps (1963-2010), conducting reef characterizations, deriving water quality parameters from Landsat imagery and watershed modeling using Open-NSPECT, and by compiling local fish stock reports. We found striking historical changes in land cover, including a significant reduction in agricultural lands (54.8-0.5%) that gave way to increases in pasture lands (27.1-49.3%), forest cover (14.4-26.6%), and urban areas (4.4-22.7%). Analyses demonstrate that the positive effects of reforestation on water quality are outweighed by urban settlements along the coastal watersheds. Furthermore, temporal degradation and linear gradation between nearshore and off-shore coral reefs condition appears related to their proximity to sources of in-land pollution. These findings are strong evidence of the need for rigorous controls over land use practices.

## DIFFERENCE OF CALCIFICATION RATE IN THE CORAL *PORITES LOBATA* FROM THE EASTERN TROPICAL PACIFIC: THE EFFECT OF THE MORPHOTYPE AND THE GENDER (Abstract ID: 27910)

Morpho-plasticity in colony structure is an adaptive strategy upon which some coral species rely to take advantage of changes in their environment. Despite the importance of morphologic variability, growth and calcification rates of different coral morphotypes, as well as gender effects on coral morphology, have not been undertaken in the Eastern tropical Pacific. Comparisons of annual extension rate (cm $yr^{-1}$), skeletal density (g $cm^{-3}$), and calcification rate (g $cm^{-2}$ $yr^{-1}$) was evaluated in columnar, massive, and free-living morphotypes of the common reef-building coral *Porites lobata* distributed in the Central Mexican Pacific. The results showed significant differences in extension rate, skeletal density, and calcification rate among morphotypes, and also differences in the interaction of the morphology and the gender. Massive form presented 33% faster rates in growth parameters compared with columnar and free-living corallith forms. Male colonies showed 40% faster calcification rate, than females for both columnar and corallith forms. These data reveal the extensive plasticity of this species and highlight the fact that each morphotype x gender group results in a different physiological response to environmental conditions. Therefore, *P. lobata* appears to be able to readily modify their growth form and efforts, developing different forms and growing at different rates, which helps to the species to maintain their distribution over the coral reef and contribute as a framework building species in the region.

## ENVIRONMENTAL CONTROLS ON THE DEVELOPMENT AND DEMISE OF FLORIDA'S CORAL REEFS (Abstract ID: 28061)

The extraordinary scale and magnitude of recent coral-reef degradation highlights the urgent need to better understand the long-term controls on reef decline and resilience. One way to gain insight into the future of coral-reef ecosystems is to evaluate their response to environmental disturbances in the past. Although the decline in Florida's coral populations is a recent phenomenon, we show that reef accretion has been negligible on the Florida Keys reef tract (FKRT) for several millennia. Using more than 60 reef cores from throughout the FKRT, we reconstructed region-wide trends in reef development over the last 10,000 years. We used these records to evaluate the relative contributions of regional changes in sea level, climate, and oceanography to the historic shutdown of reef building. Our results support previous research (i.e., the inimical waters hypothesis), which suggested that changes in regional oceanography associated with rising sea level contributed to the collapse of reefs in the middle Keys by the mid-Holocene; however, our records imply that these changes occurred at least 1000 years earlier than previously thought. Furthermore, the region-wide decline in reef accretion by the late Holocene indicates that the demise of Florida's reefs may have ultimately been driven by larger-scale changes in climate and/or sea level. We conclude that although the increasing frequency of environmental disturbances will likely continue to threaten reef development, local oceanography may have the potential to modulate the response of reefs to larger-scale perturbations.

MARINE MONITOR: A LOW COST RADAR FOR MARINE PROTECTED AREAS (Abstract ID: 28884)

Effective surveillance is essential for marine protected area (MPA) enforcement. Currently, local managers often lack affordable technology, especially in remote locations in the developing world. To address this gap, the Anthropocene Institute (AI) has developed the Marine Monitor (M2) system to lower the cost of MPA enforcement. M2 uses off-the-shelf radars to automatically detect up to 30 vessels up to 10nm offshore. Managers can define MPA boundaries and trigger alarms based on vessel speed and time spent within zones. E-mail alerts can also be configured and sent based on vessel activity. AI's software enables real-time viewing and playback of stored vessel activity, through a public, online map interface. Using live and historical vessel data, managers can focus their efforts on specific protected areas, view human use patterns within MPAs, and strategically enforce regulations. M2 incorporates a low power off-the-shelf radar, satellite telemetry, a dedicated PV power source, and shippable marine grade radar mast. The M2 system has been successfully tested in California at a fraction of the cost of current MPA surveillance systems. We are completing the first field installation in Micronesia in partnership with OneReef Worldwide Stewardship, and will continue improving software and overall system functionality. Local communities are requesting this resource in Micronesia, Palau, Indonesia, and beyond. By providing affordable radar enforcement, M2 will play a critical role in the successful implementation of nearshore MPAs and enhance conservation efforts globally.

THE RELATIONSHIP BETWEEN HETEROTROPHY AND INORGANIC NUTRIENT AVAILABILITY IN THE SCLERACTINIAN CORAL T. RENIFORMIS UNDER SHORT-TERM TEMPERATURE INCREASE (Abstract ID: 27789)

Coral bleaching caused by global increases in surface seawater temperature is one of the greatest threats facing coral reefs. Eutrophication, i.e. increased inorganic nutrients, caused by coastal runoff can exacerbate the effects of bleaching on corals. However, coral feeding on zooplankton (heterotrophy) can alleviate the effects of bleaching on some corals and confer resilience. Paradoxically, in nature it is rare to find high zooplankton densities without high inorganic nutrients. This study aimed to disentangle the effects of heterotrophy and inorganic nutrients on the physiological response of *Turbinaria reniformis* subject to short-term thermal stress. Three different inorganic nutrient ratios were tested: control (ambient SW, 0.5 µM NO3, and 0.1 µM PO4), NO3 only (ambient SW and 2 µM NO3), and NO3+PO4 (ambient SW, 2 µM NO3, and 0.5 µM PO4). Each nutrient level was replicated four times such that two tanks were exposed to heterotrophic food sources, and two were not. The results show a detrimental effect of NO3 alone on coral photosynthetic processes and calcification rates under thermal stress when associated with heterotrophy. However, NO3+PO4 enrichment maintained coral metabolism and calcification under thermal stress and enhanced physiological parameters when in concert with heterotrophy. These results shed light on the complex relationship between inorganic nutrients and heterotrophy, and highlight the relevance of N:P stoichiometry as a determining factor for the health of the holobiont that may be adapted to specific nutrient ratios in the surrounding environment.

AN ACCURATE AND COST-EFFECTIVE REEF SURVEY METHOD: VIDEO TRANSECTS WITH GOPRO® TECHNOLOGY (Abstract ID: 29727 | Poster ID: 549)

As climate change continues to threaten coral reef ecosystems, the importance of efficient and accurate means of assessing coral reef health continues to grow. Traditionally, scientists have utilized manual survey methods to quantify species richness, abundance, and diversity on coral reefs. These manual survey methods require technical coral identification skills in the field and can be time intensive for sites with high coral cover and diversity. Here, we quantified coral abundance and diversity of 13 reef sites along the Mesoamerican Barrier Reef System (MBRS) using two methods: 1) a modified Atlantic and Gulf Rapid Reef Assessment (AGRRA) manual survey methodology and 2) video assessments using GoPro® video technology, a less expensive alternative to more popular stereo-video techniques. At each site, 60m$^2$ of reef was surveyed via the AGRRA methodology and 120m$^2$ was surveyed via the video methodology. Both methods identified the same trends in coral species richness, abundance, and diversity at each site; however, the video method also allowed for a more accurate calculation of percent coral cover. The congruent results of the two methods used here indicates that the use of GoPro® video technology can allow for faster surveys that are as accurate as manual survey methods while remaining more cost effective than stereo-video methods. The use of GoPro® video technology in reef surveys will allow for greater efficiency and reliability of monitoring in the field, an important advancement for scientists, reef managers, and conservationists worldwide.

IS PHOTOSYNTHESIS REQUIRED FOR SYMBIOSIS ESTABLISHMENT AND/OR MAINTENANCE IN CNIDARIANS? (Abstract ID: 28465)

The mechanisms by which cnidarians recognize and take up their Symbiodinium endosymbionts remain largely unknown and may involve the physical, chemical, and/or metabolic properties of the algae. When some Symbiodinium strains are grown in glucose-containing medium, they undergo a loss of peridinin and chlorophyll pigments, a reduction in photosynthetic activity, and alterations to the cell surface. In this study, we used the sea-anemone model system Aiptasia to ask if these changes in the algae affect their uptake by a host. In comparison to algae grown without glucose, the glucose-grown algae were taken up significantly more slowly, if at all, by both aposymbiotic adults and larvae, even when no glucose was present in the seawater during infection. Moreover, addition of 28 mM glucose to the seawater during infection inhibited uptake of algae by both adults and larvae even when the algae had been grown without glucose. To ask if these effects of glucose reflected the reduction in algal photosynthesis, we attempted to infect adult, aposymbiotic animals with algae that had been cultured in the light without glucose, but performing the infections either in the dark or in the presence of 25 µM DCMU, a specific inhibitor of photosystem II activity. In both cases, little or no algal uptake was observed. Taken together, these results suggest that although other factors (such as recognition of algal surface markers by host receptors) may also be involved, algal photosynthesis plays a key role in initiation, establishment, or maintenance of cnidarian-Symbiodinium symbiosis.

FINE –SCALE SAMPLING OF A. HYACINTHUS DURING AN ACUTE HEAT SHOCK, ILLUMINATES POTENTIAL IMMUNE GENE REACTIONS AND INTERACTIONS (Abstract ID: 27982)

Little is understood about when immunity and stress genes are activated during heat stress in coral reefs. Previous studies examining heat stress in corals collected samples after at least a day of heat stress. Nothing is known about when genes become active during heat stress, and what their temporal patterns of expression look like. In order to address this, we have sampled six individual corals every half an hour, over a 5-hour acute heat shock to understand the fine scale pattern of gene expression. From this dataset we have found that there are varying patterns of expression between individual immunity genes, and co-expression modules predictive of stress or bleaching found in previous studies, have fluctuating expression profiles. This dataset is the first to examine fine scale timing of heat stress, and will inform us about reaction times of genes and immunity gene interactions.

HETEROTROPHY PROMOTES PHOTOSYNTHATE TRANSLOCATION IN A SYMBIOTIC CORAL DURING THERMAL STRESS (Abstract ID: 28250)

Large-scale coral bleaching events, as a result of elevated seawater temperatures, have been identified as one of the major causes for worldwide coral mortality. The energetic status of corals is emerging as a particularly important factor that determines the corals' vulnerability to thermal stress. However, detailed studies that trace the flow of carbon (energy) from symbionts to coral host are still missing, although such studies are essential to assess the nutrient status of corals and predict their resilience to the stress. The pres-

ent study reveals the impact of thermal stress on the nutritional interactions between symbionts and host in the scleractinian coral *Stylophora pistillata*. First, we demonstrated that the amount of photosynthetically assimilated carbon retained in the symbionts was significantly higher during thermal stress than under non-stressful conditions. This higher photosynthate retention in symbionts lowered the rates of energy transfer to the host, which required the use of tissue energy reserves to sustain its respiratory needs. In addition, we found a strong positive correlation between carbon translocation and coral calcification, thus a significant decrease in skeleton growth was observed during thermal stress. This study also provides evidence that heterotrophy modulates the negative effects of thermal stress on coral physiology, and enhances the re-establishment of normal nutritional exchanges between symbionts and host.

THE EMERGENT GEOGRAPHY AND GEOPOLITICAL (MIS)ALIGNMENT OF DISPERSAL CORRIDORS AND BARRIERS ACROSS THE INDO-WEST PACIFIC (Abstract ID: 30029)

Although barriers to dispersal are known to contribute to the distinctiveness of communities, species and populations, the importance of the biophysical processes associated with permeable barriers is not well understood. In this study, we predict the geographic location and strength of multitaxon dispersal barriers across the Indo- West Pacific Ocean. Specifically, we ask three questions: (1) What biological attributes are important in influencing the location and strength of dispersal barriers? (2) What is the geographic configuration of multitaxon dispersal barriers? (3) Is there geographic concordance with previously described and empirically based barriers? Although individual taxa varied in their predicted fine-scale population connectivity, there was broad-scale consistency in the location of dispersal barriers. Across all trait combinations, reproductive output (fecundity and density of reproductive adults), reproductive strategy (spawning phenology) and the length of the larval dispersal phase determined the strength of barriers across the seascape. Finally, I describe a new approach for quantifying the ecological-institutional alignment and mismatch across this environmentally and politically complex seascape. Intersecting these dispersal barriers and corridors with estimates of cross-country institutional linkages related to marine management, we identify geopolitical fit and misfit between the region's ecological processes and its governance.

CELLULAR LOCALIZATION AND POTENTIAL PHYSIOLOGICAL ROLES OF VACUOLAR PROTON ATPASE, SODIUM POTASSIUM ATPASE, SLC4S, AND PLASMA MEMBRANE CALCIUM ATPASE IN CORALS (Abstract ID: 29734)

The movement of molecules across cell membranes and epithelia is facilitated and energized by ion-transporting proteins such as ATPases and ion exchangers, co-transporters and channels. We studied the cellular localization and physiological roles of some ion-transporting proteins potentially involved in calcification, photosynthesis and pH regulation in the corals Acropora yongei and Stylophora pistillata. The vacuolar proton ATPase (VHA) was abundantly present in symbiosome membranes and participates in a carbon concentrating mechanism for Symbiodinium photosynthesis. Additionally, VHA was present in the coelenteron-facing membrane of aboral gastrodermal cells, suggesting it removes H+ away from the site of calcification. The Na+/K+-ATPase (NKA) was abundantly present in the basolateral membrane of calicoblastic cells, indicating a role in calcification. However, only A. yongei expressed NKA in the apical membrane of oral ectodermal cells, suggesting a species-specific mechanism for taking up molecules from seawater. Slc4 HCO3--transporters displayed a similar species-specific localization pattern. Finally, a plasma membrane Ca2+ ATPase (PMCA) was found throughout coral tissues. Surprisingly, PMCA was not located in the plasma membrane of calicoblastic cells, thus questioning the previously assumed role of PMCA in transporting Ca2+ into the subcalicoblastic fluid. Knowledge on protein cellular localization and function can greatly contribute to our understanding of coral cell biology, which in turn is essential for studying and predicting coral responses to stress.

TERRESTRIAL SEDIMENT EFFECTS ON HAWAIIAN CORAL REEFS: PAST, PRESENT, AND FUTURE (Abstract ID: 28950)

Long-term estimates of erosion rates on Hawaiian watersheds range from 0.01 to 0.1 mm/yr. In contrast, recent measurements shows erosion rates up to 10 mm/yr. One explanation for this increase is the arrival of humans and the accompanying large-scale changes across the landscape due to land development, feral and domestic ungulates, and agriculture. Sediment effects on reef ecology depend on grain size and composition, depositional area, total load, wave energy, water circulation, and the coral community composition. There is uncertainty about how climate change will alter terrestrial sediment impacts to Hawaiian reefs. We lack forecasts of rain intensity (which drives terrestrial erosion). Existing models indicate that by the year 2100, average rainfall across watersheds near coral reefs will stay the same or decrease. It seems unlikely that the overall changes in precipitation will lead to a substantial increase in terrestrial runoff compared to current levels. Management of terrestrial sediment on Hawaiian reefs may be best ameliorated by management of sediment sources in watersheds regardless of climate change. Watersheds that discharge into protected bays and areas of restricted circulation are more likely to affect reefs in those environments than reefs in high-energy marine settings. Finally, additional research on the ability of Hawaiian corals to adapt to sediment loading, in conjunction with other climate-change impacts, may provide insights on how reefs in Hawaii will develop in the future.

AN ASSESSMENT OF SOCIO-ECONOMIC AND INSTITUTIONAL LINKAGES IN TRANSBOUNDARY MARINE PROTECTED AREA NETWORKS IN THE PHILIPPINES (Abstract ID: 29932)

The decentralized government system of the Philippines impedes establishment of functional marine protected area (MPA) networks, because local governments are limited by their jurisdictions. To address this challenge, transboundary governance arrangements were recommended to scale up to form networks. The Philippine Marine Key Biodiversity Area Project, a technical assistance and development initiative, aims to improve conservation success of existing and new MPAs and networks by addressing gaps in protection of ecological processes. However, since transboundary governance is key to implementing networks, we suggest consideration of institutional and socioeconomic parameters in optimal network designs. We conducted case studies of five MPA networks with different governance arrangements to determine key socioeconomic and institutional design parameters. We found that various configurations of the networks, emerged based on the strength or weakness of the following parameters: (i) consistency of policies between relevant local governments; (ii) financial benefits are exported beyond the MPA governance boundary; (iii) existence of medium to long term plans with funding commitment developed by regional or national planning agencies; (iv) support from communities, and bridging organizations; and (v) adherence to unified policies or other transboundary agreements Our findings reiterate the need to consider social, economic and political complexities for designing MPA networks in order to reduce transaction and management costs, and improve their sustainability.

ASSESSMENT OF THE CURRENT STATUS OF CORALS AND ASSOCIATED FAUNA OF SINDHUDURG COAST IN MAHARASHTRA, INDIA (Abstract ID: 29505)

Information on corals and associated fauna of Sindhudurg coast in India is not adequately known. Intertidal, subtidal and underwater surveys were conducted to ascertain the presence of corals and associated fauna along the Sindhudurg coast of Maharashtra in India for two years from November 2013 to November 2015. Permanent Monitoring Plots were established for health assessment of corals. Effect of anthropogenic activities and factor influencing the distribution and abundance of corals and associates along the Sindhudurg coast was also enumerated. Coral coverage was assessed through employing photo-quadrats and LIT. Representative samples of species were collected from the site for proper identification and for deposition at the NZC of ZSI. The survey conducted revealed >20 species of corals along Sindhudurg coast along with seven new records among which Polycyathus verrilli Duncan, 1889, Goniopora minor, Pavona bipartita Nemenzo, 1980 and Leptastrea purpurea (Dana, 1846) are unique records. The sub-tidal/underwater surveys conducted also revealed several species of interesting coral associated Fishes, Seahorse, Sponges, Gorgonians, Seafans, bivalves, Chiton, Opisthobranch, Brittle stars, Polychaete and Blue Button Jellyfish. There are anthropogenic pressures viz. tourism, fishing etc. mounting on the ecosystem. This paper deals with assessment of corals and associated fauna of Sindhudurg coast, one of the important coral reef ecosystems in the mainland west coasts of India along with conservation measures.

PRELIMINARY REA OF MYEIK (MERGUI) ARCHIPELAGO, MYANMAR (Abstract ID: 29408)

Myanmar has a reported total coral reef area of 187,000ha, although they remain largely unexplored and to a large extent, reefs in Myanmar have been assumed to be in similar condition to hundreds of years ago, due to political and geographic isolation. However, over the past few years, reports from tour operators suggested that the marine resources of the Myeik Archipelago had been severely degraded. Between February 2014 and March 2015, four survey voyages were undertaken and more than 100 sites were surveyed by researchers under the auspices of IUCN and FFI along the 600km length of the Archipelago. Here, we present a precis of data from those surveys. More than 280 species of hard coral, and 400 species of teleost fishes were observed, along with 73 species of echinoderms, more than 100 species of mollusc and 45 species of sponges. The surveys found that – for the most part – the abundance of key reef infrastructure species is generally low, and the overall condition of most coral reefs is either poor or very poor. Reefs closer inshore varied widely in condition; where they were accessible or easy to fish, the reefs were often badly degraded. Where conditions made fishing difficult, or where the fishermen were generally unaware of the reef habitat (usually, it would seem, because of high turbidity and strong currents), reefs were often outstandingly diverse and generally healthy. Biogeographic affiliations within the Myeik Archipelago and eastern Indian Ocean are as yet unclear, although diversity and level of endemism appear higher than in Thailand to the south.

DRIVERS OF RELATIVE SPECIES ABUNDANCES REGULATE THE DIVERSITY-STABILITY RELATIONSHIP OF CORAL REEF FISHES (Abstract ID: 28527 | Poster ID: 215)

Fish communities are important for maintaining the stability of coral reef ecosystems. High species richness in a fish community stabilizes total abundance fluctuations (i.e., higher species richness increases community stability), ensuring continued ecosystem function despite environmental perturbations. Additionally, even when species richness is constant, factors that drive relative species abundances can influence community stability. However, little is known about how species richness and drivers of relative species abundances interact to regulate community stability in nature, particularly at spatial scales comparable to the scale of marine reserves. Here, we used a fish community time series dataset across a large spatial extent of the Great Barrier Reef to show that (1) community stability increases with species richness, and (2) community stability increases with the strength of niche-driven, more than stochastic-driven, variations in relative species abundances. Moreover, species richness and drivers of relative species abundances appear to influence stability through inter-specific asynchronous dynamics and intra-specific population fluctuations, respectively. The two effects are not correlated, indicating that richness-related and relative abundance-related drivers of community stability did not covary over the coral reef seascape. Our findings elucidate multiple pathways of stability in reef fish communities. Spatial planning of large-scale marine reserves should consider not only species diversity but also niche-forming mechanisms if the goal is to sustain ecosystem stability.

HIGH TOLERANCE OF CORALS FROM MARGINAL ENVIRONMENT IN HONG KONG TO HYPOSALINITY AND PREFERENCE OF CORALLIVORY ON OSMOTIC-STRESSED CORALS (Abstract ID: 29475 | Poster ID: 304)

Interactive effects of environmental variables could affect the health of coral colonies which are reported to be sensitive to fluctuation in seawater salinity. We hypothesize that the osmotic-stressed corals may subsequently become more prone to other disturbances like corallivory. This hypothesis was tested with a series of laboratory-based experiments set up to determine the osmotic tolerances of four coral species (*Acropora valida, Pavona decussata, Platygyra acuta* and *Porites lobata*) found in the marginal community in Hong Kong. These corals were first treated separately at 9, 12, 15, 18, 24 and 34 psu for 3 days, before being exposed to corallivorous snails*Drupella* for a prey preference assay. The results indicated Hong Kong corals were generally tolerant to hypo-salinity stress as low as 18 psu and with *P. lobata* being the most tolerant. It survived under 9 psu with only around 5% of tissue loss. *Drupella* snails preferentially attacked corals exposed to lower salinities. Additional *Drupella* prey-choice assays were conducted to assess the relative vulnerability of these four coral species exposed at 18 psu (stressed) and 34 (normal) conditions. A shift in prey preference was observed with *A. valida* exposed to 18 psu being the most preferred prey. These findings supported our hypothesis and demonstrated that changes in salinity could alter the prey-preference of corallivores. This could subsequently affect the composition of a coral community by removing the more vulnerable species. This project is supported by RGC-GRF 14122215.

OCTOCORAL COMMUNITY ECOLOGY AT TWO SITES OF CONTRASTING ENVIRONMENTAL CONDITIONS IN ST JOHN, US VIRGIN ISLANDS (Abstract ID: 28888)

To better understand how octocoral communities on Caribbean coral reefs respond to environmental conditions, we quantified their synecology on two reefs (9 m depth) with contrasting physical conditions. One reef at Cabritte is exposed to easterly winds and waves, while the other, in Europa Bay (1.4 km west) is partially sheltered and characterized by higher sedimentation. Octocoral population density was 2-fold higher at Cabritte than Europa Bay, and the most abundant species (Antillogorgia americana, Gorgonia ventalina, Eunicea flexuosa) were taller at Cabritte. Densities of octocoral recruits were lower at Europa than Cabritte in winter, but similar at both sites in summer. Species richness was similar between sites, with 34 species at Europa Bay, 35 at Cabritte, and 30 common to both sites. Multivariate analysis of species-specific abundance of adults and recruits revealed that the two sites differed in octocoral community structure. The large number of common species at the two sites suggests that these species have broad ecological niches defined by a wide spectrum of environmental conditions. However, their differences in colony sizes and relative abundances suggest that their populations respond differently to the variation in environmental factors. In comparison to seminal octocoral studies conducted in the Caribbean in the 1970's, the species composition and community structure of octocorals in St. John is similar, suggesting that recent reports of increasing abundance of octocorals in the Caribbean reflect community range extensions and not novel communities.

IMPROVING CONSERVATION OUTCOMES FOR DATA-POOR CORAL REEFS AFFECTED BY FUTURE OIL PALM DEVELOPMENT IN PAPUA NEW GUINEA (Abstract ID: 28473)

Clearing forests for oil palm plantations is a major threat to tropical biodiversity, and may potentially have large impacts on downstream marine ecosystems (e.g., coral reefs). We coupled terrestrial and marine biophysical models to simulate changes in sediment/nutrient composition on reefs, and predict the response of coral and seagrass ecosystems to different oil palm development scenarios. The condition of almost 60% of coastal ecosystems were predicted to heavily degraded (more than a 50% decline from their initial state) after 5 years if all suitable land was converted to oil palm. We evaluated the benefits of using global sustainability criteria for oil palm plantations, and found only slight improvements in ecosystem condition compared to the scenario where all forest was converted to oil palm. More stringent restrictions are required to substantially lower the risk of degradation; in particular limiting new plantings to hill slopes below 15 degrees. Evaluation of current plans for oil palm expansion identified ecosystems in marine conservation priority areas that will likely be heavily degraded in the future. We show marine conservation plans should be modified to prioritize turbid areas where coral communities may be more tolerant of increased suspended sediment in the water. The approach developed here provides guidelines for modifying marine conservation priorities in areas with oil palm development. Importantly, oil palm development guidelines cannot be truly ecologically sustainable unless modified to account for oil palm impacts on coastal marine ecosystems.

HOW INVASIVE INDO-PACIFIC RED LIONFISH INTERACT WITH FISH PARASITES AND CLEANING MUTUALISMS NATIVE TO ATLANTIC CORAL REEFS (Abstract ID: 29030)

What makes invasive species successful, and how do they alter native populations and communities? We addressed these key questions within the context of the invasion of Atlantic coral reefs by Indo-Pacific red lionfish (Pterois volitans). To assess the role of parasites in this invasion, we compared infection rates of lionfish with sympatric carnivorous fishes at multiple locations in their invasive and native ranges. We found that invasive Atlantic lionfish had extremely few parasites when compared both to native Pacific lionfish and to native Atlantic fishes. Such "enemy release" may help to explain this successful invasion if lionfish consequently allocate more energy to growth and reproduction than to costly immune defenses. With few parasites to limit them, lionfish may consume ecologically important species, including cleaning gobies (Elacatinus spp.): ubiquitous, conspicuous fishes that clean parasites off other reef fishes. However, while lionfish will eat cleaning gobies during laboratory and field experiments, they quickly learn to avoid them, due to a previously undescribed skin toxin in these gobies. Additional field experiments revealed no change in the growth, survival, and behavior of newly recruited cohorts of the cleaner goby (E. genie) in the presence vs. absence of lionfish. Thus, cleaning gobies are among the few inhabitants of invaded reefs that escape the jaws of lionfish. Given their broad and voracious appetites, however, invasive lionfish will continue to affect native reef communities via predation on other ecologically important fishes.

SUPER TYPHOON HAIYAN: INUNDATION, EROSION AND GROUNDWATER RECOVERY: KAYANGEL STATE, REPUBLIC OF PALAU (Abstract ID: 28262 | Poster ID: 393)

On November 06-07 2013, Super typhoon Haiyan passed directly over Kayangel Atoll in the northern area of Palau. The storm generated massive waves in the atoll's northeast through southeast quadrants and severely damaged reefs on the outer slope on the northern and eastern exposures. The waves eroded areas of the eastern shores of the islands, caused changes in the sand banks and flats within the lagoon, but left western to southwestern outer reefs and lagoon seagrass and patch reef communities largely untouched. Salt water intrusion from inundation and salt spray contaminated the fresh water lens of Kayangel Island. The impact of salt water intrusion and the recovery of the fresh water lens were examined in the year following the storm. The relations between lagoon and island ground water lenses were concluded using pressure loggers while salinity/depth of the island ground water lens was measured using hand-held water quality monitors. Aerial photographs before, immediately after and continuing to the present were used to examine inundation zones and recovery of vegetation on the islands. Ground truth surveys were used to validate interpretation of aerial images. At the nearby Ngeruangel/Velasco reef sunken atoll system the single island (Ngeruangel) was swept clean by the storm waves. The island grew slightly in size and elevation and migrated about 50 m distance from the storm. Marine communities on Velasco Reef were severely affected with massive shifting of sediments and erosion of the unusual Thalassodendron ciliatum beds found on the sunken atoll rim.

ASSESSING THE PREVALENCE OF CYANIDE-CAUGHT FISH IN THE U.S. MARINE AQUARIUM TRADE (Abstract ID: 28852)

The United States is the world's largest consumer of coral reef fishes for aquariums with upwards of 11 million fish imported annually. The largest exporters of marine aquarium fish (MAF) are the Philippines and Indonesia, both of which are known for the widespread use of cyanide ($CN^-$) in MAF capture. $CN^-$ is metabolized into thiocyanate ($SCN^-$), and fish exposed to $CN^-$ excrete $SCN^-$ in their urine for at least 28 days post exposure. The detection of elevated levels of $SCN^-$ in seawater that held MAF indicates likely exposure to $CN^-$. In our study, the top ten MAF species imported by the U.S. were identified and purchased from a number of retailers and wholesalers across the U.S. We held individual MAF specimens in synthetic seawater for 24 hours and utilized High-Performance Liquid Chromatography with ultraviolet detector (HPLC-UV) to screen for $SCN^-$ in the holding water. $SCN^-$ was detected in a significant number of samples. No $SCN^-$ was detected in holding water that contained control specimens obtained from captive breeding facilities. This study shows that detection of $SCN^-$ in holding water is applicable in the U.S. supply chain and can be used to non-invasively and non-destructively screen MAF for exposure to cyanide during collection in source countries.

PIGMENTED PSEUDOALTEROMONAS SPECIES CAN PROTECT CORAL MONTIPORA CAPITATA FROM INFECTION BY THE PATHOGEN VIBRIO CORALLIILYTICUS STRAIN OCN008 (Abstract ID: 29242 | Poster ID: 136)

Coral reefs are among the most diverse and productive ecosystems in the ocean and are threatened by a number of bacterial infections. *Vibrio coralliilyticus* OCN008 is a bacterium that induces acute *Montipora* White Syndrome (aMWS), a tissue-loss disease affecting *Montipora capitata*, a major reef-building coral in Kaneohe Bay, Hawaii. The bacteria that colonize the coral surface are hypothesized to protect against bacterial pathogens like OCN008. Two species of pigmented bacteria, *Pseudoalteromonas rubra* and*P. luteoviolacea*, were isolated from healthy *M. capitata* and displayed antibacterial activity against OCN008. When healthy fragments of *M. capitata* were pre-inoculated with the pigmented strains and then exposed to OCN008, the infection rate was reduced by 60% and 100%, respectively. Neither of the pigmented strains had any observable detrimental effects on*M. capitata*. It is hypothesized that inoculation with these pigmented bacteria act as probiotics and protect *M. capitata* from OCN008 infection through the production of antibacterial compounds. Therefore, a genetic screen was developed to determine what compound(s) are produced by these bacteria and if antibacterial activity is involved with protection of the coral. This is the first *in vivo* evidence to show how bacteria of the coral microflora can protect the host from infection.

ENVIRONMENTAL REGULATION OF THE SYMBIODINIUM PROTEOME (Abstract ID: 29207)

The vast genetic diversity of Symbiodinium denotes a great adaptability to different environments. Genome sequencing has been used to unveil differences in the physiological machinery to explain different adaptations. However, environmental regulation of acclimation pathways including, photochemistry and photoprotection for Symbiodinium appear to be governed post-translationally and thus undetectable via transcriptomics. Proteomics therefore provides an extremely powerful platform to support the increasing use of transcriptomics to understand the physiological 'wiring' adapted among Symbiodinium to thrive across different environments. Therefore we contrasted the changes in the proteome among Symbiodinium species in culture (ITS2 types A1, A13 and C1) with known differences in stress tolerance and life history ("mutualists" versus "parasites"), and how their proteomes are further modified at different growth light (photonflux:100/350µmol•m2•s-1) and temperature (26/30°C) as well as at thermal stress (33°C). Using 2D-PAGE and LC/MS-MS proteomics we observed differential regulation between clades of chloroplast precursors, structural motifs, transcriptional regulators and heat shock proteins. These results in addition with characterization of growth rates and photo-physiological traits provide new insight into how emergent physiological trait expression is underpinned by complex re-organisation of the proteome; consequently, new understanding of the pathways at play that regulate Symbiodinium competitive fitness under both steady state and anomalously stressful conditions.

THE ROLE OF PATHOGENS, PROBIOTICS, AND THE BACTERIAL MICROFLORA IN ACUTE *MONTIPORA* WHITE SYNDROME (Abstract ID: 28517)

Tissue loss diseases destroy coral and can lead to colony mortality, which exacerbates the deteriorating state of the world's reefs. To defend against pathogens, the bacteria colonizing the coral, termed the normal microflora, are thought to protect the coral host through competition for nutrients and space or the production of antibacterial compounds. The bacterial pathogen*V. coralliilyticus* strain OCN008 infects and causes tissue loss in the reef-building coral *Montipora capitata* and produces the antibiotic an-

drimid. Under laboratory conditions, 85% of *M. capitata* fragments exposed to OCN008 developed tissue loss, however, a mutant strain incapable of producing andrimid displayed a 60% reduction in infection rate. Treatment of *M. capitata* fragments with antibiotics that cleared the microflora allowed the mutant strain to infect at wild-type levels, implicating andrimid in mitigation of the protective effects of the coral microflora. Strains of*Pseudoalteromonas luteoviolacea* and *P. rubra* isolated from healthy *M. capitata* release compound(s) into culture medium that inhibit OCN008 growth. When *M. capitata* fragments were pre-inoculated with *P. luteoviolacea* or *P. rubra*, OCN008 infection was reduced by 60% and 100%, respectively. Antibiotic production by OCN008 or its proximal effect, alteration of the coral microflora, is required for optimal infection and demonstration of a probiotic effect from bacteria of the coral microflora provides *in vivo* evidence for competitive antibacterial production between pathogens and the normal microflora.

GENETIC LARVAL IDENTIFICATION AND QUANTIFICATION AS NEW TOOLS TO INVESTIGATE EXTEND AND CAUSES OF CROWN-OF-THORNS OUTBREAKS (Abstract ID: 28604)

Predation by Crown-of-Thorns Seastars (CoTS) is a major contributor to the coral reef decline in the Indo-Pacific Region. Testing hypotheses about CoTS outbreaks is hampered by our inability to investigate distribution of larvae because they resemble other asteroid and some holothuroid larvae. We developed several genetic markers and tested these on plankton samples in outbreak areas of the northern Great Barrier Reef (GBR), and in Okinawa, Japan. The method was verified through microscopy and amplification of single wild and cultured larvae. Most samples collected during the spawning season on the GBR contained CoTS larvae, suggesting very high larval numbers in the plankton. Larvae were also identified in several samples in Okinawa. During the spawning season In Japan, several early larvae were identified near Miyako Island and dense population of later stages were found near Sekisei Lagoon. A newly developed rtPCR assay reliably quantified gene copy numbers over 7 orders of magnitude. We now started monitoring to quantify larvae to test several aspects of their ecology. These studies include a) resolving the exact spawning times by temporal studies over the spawning season, and b) spatial quantification (small scale vertical and large scale horizontal) in relation to water quality parameters to further test the 'nutrient hypothesis'. The latter work is complemented by studies on the role of food quantity and quality and the effect of other environmental variables on larval development and survivorship.

SEASONAL VARIATION IN, AND PROJECTED EFFECTS OF CLIMATE CHANGE ON, CALCIFICATION RATES OF ACROPORA DOWNINGI IN THE NORTHEASTERN PERSIAN GULF (Abstract ID: 29188 | Poster ID: 316)

With on-going climate change, there is a strong interest in understanding how changes in environmental conditions will impact on coral growth and thereby, reef accretion. In this study, we explore seasonal variation in in-situ calcification rates of Acropora downingi in the northeastern Persian Gulf, where there are marked seasonal differences in temperature, irradiance, and aragonite saturation (Ωarag). Calcification rates of A. downingi varied greatly among seasons and had a significant, but non-linear, relationship with temperature ($r2 = 0.30$) and a significant linear relationship with irradiance ($r2 = 0.36$). There was not, however, any apparent effect of Ωarag on intra-annual variation in calcification ($r2 = 0.02$). Differences in calcification were largely attributable (~ 57.4%) to seasonal differences in irradiance, while temperature accounted 37% of intra-annual variation in calcification, largely constraining coral growth in warmer months. As such, we predict that ocean warming will lead to declines in calcification during spring, fall, and especially summer, though possibly enhancing calcification during the winter months. Overall, there is likely to be a net decline in annual calcification for A. downingi in the Persian Gulf. Comparisons of our findings to other recent studies show that proportional declines in annual calcification of A. downingi were very similar to that reported for other corals in subtropical locations. As such, we suggest that ongoing climate change (and specifically, ocean warming) will have generally negative effects on coral growth, even at subtropical locations.

PROTECTING CORALS UNDER THE ENDANGERED SPECIES ACT CAN PROMOTE CORAL REEF RECOVERY (Abstract ID: 28940)

Reef-building corals are dying at accelerated pace due to climate change and other anthropogenic threats, resulting in negative effects for ecosystem function and services. Although the science on the causes and consequences of coral loss is comprehensive, conservation actions have been largely insufficient to actively reverse coral decline. The U.S. Endangered Species Act (ESA), one of the world's strongest biodiversity protection laws, has prevented the extinction of 99 percent of species under its care and has effectively promoted recovery. Currently, 22 coral species are listed as threatened under the ESA with seven species in the Atlantic Ocean and 15 in the Pacific Ocean. We discuss how the ESA works, the tools it provides to conserve threatened corals and how protection can ultimately promote coral reef recovery. ESA protection requires the development of recovery plans that provide coordination, evaluation, and funding for coral conservation and new research. It leads to the protection of critical habitat areas in U.S. waters. It requires federal agencies to consult with biologists to minimize harms to corals and their critical habitat from government-approved activities including dredging, commercial fishing, construction, and projects emitting significant greenhouse gas emissions that contribute to warming. ESA protection also promotes greater awareness about threats to corals and public engagement in coral conservation. These protections can result in ecosystem-wide benefits by improving water quality, reducing pollution, and restoring degraded ecosystems.

SIZE FREQUENCY DISTRIBUTION OF PORITES CYLINDRICA IN AN OFF-SHORE PHILIPPINE REEF (Abstract ID: 29869 | Poster ID: 657)

Life-history processes provide crucial information on reef responses to prevailing environmental conditions that are crucial in reef health studies and their implications to marine resource management. This study was conducted to provide species-specific information on the population dynamics of Porites cylindrica, a common coral species in an off-shore marine sanctuary in the Zamboanga peninsula, Philippines. It aims to track changes in size frequency distribution (SFD), mortality and growth patterns of P. cylindrica colonies inside the marine sanctuary over two time periods (2014 and 2015). Fifty one 1m x 1m quadrats in three (3) sites (n= 153) at 10-12m depth located around the island were photographed annually. Site 1 being the most exposed to land based sedimentation and 3 being the farthest. The cover, density and size structure of P. cylindrica were analyzed and compared for the two time periods. Also, Forty five (45) haphazardly chosen colonies were in situ photographed, tagged and measured for growth rate during 2014 and in 2015. P. cylindrica colonies were larger and denser in sites 2 and 3 compared to site 1. These results may serve as a benchmark indicator for coral reef health during marine sanctuary monitoring for upcoming disturbances and may give insights to the resiliency of P. cylindrica to sedimentation stress.

STABILITY AND FUNCTIONALITY OF THE MICROBIAL COMMUNITIES ASSOCIATED WITH TEMPERATE GORGONIANS AND THE PRECIOUS RED CORAL *CORALLIUM RUBRUM* (Abstract ID: 29288)

Gorgonians are key habitat-forming species of temperate benthic communities. However, local human impacts and mass mortality events caused by elevated seawater temperatures related to climate change and microbial disease outbreaks are responsible for significant declines in gorgonian populations. Despite these threats, relatively little is known about the symbioses between gorgonian hosts and their microbial associates. While *Endozoicomonas* from the order Oceanospirillales are commonly associated with most anthozoans (up to 95%), we report that the microbiome of *Corallium rubrum* is dominated by Spirochaetes (70%) and to a lesser extent Oceanospirillales of the ME2 family (25%). This core microbiome, consisting of 12 bacterial species, was found to be highly stable on both spatial and temporal scales, suggesting that these bacteria are important symbionts of the red coral. In contrast, the *Endozoicomonas*-dominated microbiomes of other temperate gorgonians were found to undergo significant changes depending on local conditions. To elucidate the function of these divergent gorgonian-associated microbial communities and the effects elevated seawater temperatures, ocean acidification and eutrophication may have on their functionality, we conducted

meta-transcriptomic analyses on gorgonians and the red coral impacted by these stressors in experimental settings. We will present results from these studies showing a novel microbial symbiotic association within Anthozoans and how stress may impact the health of the coral holobiont through the disruptions of host-microbial symbioses.

THE FIGHT AGAINST FINNING: WHO IS WINNING THE WAR? (Abstract ID: 27857)

Despite the current protection efforts as well as the introduction of more stringent laws regulating the hunting and trading of sharks (especially their fins), shark conservation is still recognized a major environmental challenge. The rapid growth in the demand for raw dried shark fins has led to a global exploitation of many elasmobranch species. Recent studies have also confirmed that the United Arab Emirates (UAE) is being used as an export hub and is currently the fourth largest exporter of shark fins to Hong Kong, with a large proportion of fins traded considered to be from species at high risk of global extinction (based on the International Union for Conservation of Nature (IUCN) Red List of Threatened Species)). Current management frameworks still reveal significant deficiencies with regard to legal protection of elasmobranchs, specifically associated with fishing methods and monitoring of finning practices. These problems however are not unique to the UAE but reiterate the facts that there are far-reaching issues pertaining the global management and protection of shark species. Even in a realm of improving conservation efforts, the current data on the success of shark finning prohibition might be mendacious when viewed in the light of looming species extinction. This paper therefore considers the regional regulatory framework that seeks to enhance shark protection and conservation.

INCREASED TEMPERATURE IS THE DOMINANT DRIVER OF CLIMATE CHANGE IMPACTS ON *ACROPORA FORMOSA* (Abstract ID: 29173)

Increased seawater temperatures and ocean acidification due to rising $CO_2$emissions have serious impacts on coral reef ecosystems, although a full understanding remains elusive due to the large number of non-manipulative, correlative studies. Our experiment investigated the physiological and metabolic performance of the symbiotic coral *Acropora formosa* under temperature and $pCO_2$ conditions (both as individual factors and as combined treatments) expected by the end of this century under business-as-usual emissions. After eleven weeks of exposure to increased $pCO_2$ concentrations alone, no significant changes were observed in productivity, net growth and calcification rates (measured using the alkalinity anomaly technique), and survival rates compared to the control treatment. However, when exposed to increased temperatures whether or not in combination with increased $pCO_2$, *Acropora formosa* responded with a sharp decline in productivity. Over time, these changes produced a net negative energetic budget, followed by a cessation of growth, negative calcification rates (i.e. decalcification) and extensive mortality. Our results indicate that temperature is the dominant factor in reducing growth and metabolism of *Acropora formosa* under future climatic conditions.

DOWNSCALED PROJECTIONS OF CORAL BLEACHING CONDITIONS THAT CAN INFORM CONSERVATION PLANNING (Abstract ID: 29484)

Increasingly frequent severe coral bleaching is among the greatest threats to coral reefs posed by climate change. Global climate models (GCMs) project great spatial variation in the timing of annual severe bleaching (ASB) conditions; a point at which reefs are certain to change and recovery will be limited. However, previous model-resolution projections (~1x1°) are too coarse to inform conservation planning. To meet the need for higher-resolution projections, we generated statistically downscaled projections (4-km resolution) for all coral reefs; these projections reveal high local-scale variation in ASB. Timing of ASB varies >10 years in 71 of the 87 countries and territories with >500km2 of reef area, indicating the projections warrant consideration in most reef areas during conservation and management planning. The global average projected timing for ASB onset is 2043. Locations projected to experience ASB after 2052 and before 2034 are relative climate winners and losers, respectively. There are relative climate winners and losers in 16 of the top 20 countries in terms of reef area. Among these, Cuba (11.3%) and Australia (8%) have the highest percentages of relative climate winners. Coral reef futures clearly vary greatly among and within countries. Emissions scenario RCP4.5 represents lower emissions mid-century than will eventuate if pledges made following the 2015 Paris Climate Change Conference (COP21) become reality. RCP4.5 adds ~15 years on average before ASB occurs when compared to RCP8.5; however, >75% of reefs still experience ASB before 2070 under RCP4.5.

REEFGUARD: AN INDUSTRY LED APPROACH TO ASSISTED REEF REHABILITATION WITH 'LAB'-CULTURED JUVENILE CORALS OBTAINED FROM NATURAL CORAL SPAWNING EVENTS (Abstract ID: 28713)

In 2010, Dutch dredging and marine contractor Van Oord launched a Coral Rehabilitation Initiative (2010 – 2015). Its aim is to enhance the assisted rehabilitation of degraded natural coral reefs by out-planting (tens to ultimately hundreds of thousands) 'lab'-cultured juvenile corals obtained from natural coral spawning events. A key challenge is to demonstrate that already proven small-scale coral breeding techniques can be scaled-up and applied in the field to promote environmental gain around marine infrastructure projects. An innovative mobile laboratory, named ReefGuard, was developed to ensure the availability of a controlled environment to facilitate fertilisation, primary settling and initial outgrowing of the larvae before outplacement. After its construction in 2013, ReefGuard was applied in three field trials. The first two trials were executed near Ningaloo Reef in Coral Bay Australia (2014 and 2015). The third trial was executed in Coral Harbour on New Providence, Bahamas (2015). The trials involved three species of acropora corals, in-situ as well as ex-situ gamete collection, and employed 10.000, 36.000 and 20.000 settlement tiles respectively. Tiles with settled larvae were placed in the field as part of a scientific survival experiment. The results that are going to be presented include the design of the ReefGuard, its use in up-scaling consecutive breeding steps, the settlement and mortality rates encountered and a number of practical aspects that are crucial in bringing this technology towards operating standards that are acceptable to industry.

THE DIVERSITY AND ROLES OF CORAL-ASSOCIATED VIRUSES (Abstract ID: 27822)

The cellular microorganisms associated with corals are known to confer benefits to their host by various mechanisms, including photosynthesis, nitrogen fixation, enhancing calcification and infection prevention. Conversely, under conditions of environmental stress, certain microorganisms cause coral bleaching and disease. Stress responses and tolerance limits of corals are the result of complex interactions with their various symbionts, but the extent to which each member contributes to a particular trait is poorly understood. The viruses associated with corals have received little attention, and their diversity and functions in the ecology and evolution of corals are virtually unknown. We have started to explore the diversity of coral-associated viruses in a range of coral species on the Great Barrier Reef (GBR), in healthy and diseased/bleached coral tissues, and in laboratory cultures of Symbiodinium isolated from coral. Our results show that the viral assemblages of corals are highly diverse. GBR Symbiodinium cultures are targeted by three groups of viruses; a retrovirus-like virus of filamentous morphology, a virus with genetic similarities to a ssRNA virus known to infect free-living dinoflagellates and with an icosahedral morphology, and a large dsDNA virus also of icosahedral morphology. We found evidence for regulation of viral genes during a laboratory heat stress experiment on cultured Symbiodinium. I will discuss the diversity of GBR coral and

Symbiodinium viruses and new insights gleaned into the roles that viruses play in corals. http://www.findanexpert.unimelb.edu.au/display/person726007

FISHERY MANAGEMENT IN A RISKY AND UNSTABLE ENVIRONMENT: A SPATIAL MODELING APPROACH APPLIED TO THE GIANT CLAM TRIDACNA MAXIMA IN FRENCH POLYNESIA (Abstract ID: 28078 | Poster ID: 620)

The giant clam Tridacna maxima has been largely overexploited in many tropical regions over the past decades, and was therefore listed in appendix II of the Convention of International Trade in Endangered Species (CITES) in 1985. In French Polynesia, several atolls harbor the world's highest stocks of giant clams in very shallow and accessible areas, but massive (natural) mortality events also occurred in some semi-closed atolls of Tuamotu's archipelago. These natural fluctuations of stocks complicate management recommendations. Here, we report on the use of a spatially explicit population dynamics model applied for one atoll (Tatakoto, Tuamotu's archipelago) affected by both fishing pressure and natural mortality events. Giant clam abundances, growth, mortality, recruitment, and fishing effort were estimated in situ and used to design a network of spatial planning units following an integrated approach. The spatially explicit population model then simulated future trends of T. maxima abundances following a stochastic approach and evaluated the best management strategies to optimize future stocks. In the risky and uncertain environment of Tatakoto atoll lagoon, abundances were a trade-off between recruitment and high mortality. Our results suggested that fishing effort had low impact on giant clam abundance compared to the natural fluctuation of stocks, but reducing fishing pressure through quotas was the most efficient management tool to increase resilience and accelerate the recovery of stocks after a massive mortality event.

DEVELOPING COST EFFECTIVE METHODS FOR QUANTIFYING THE HABITAT BENEFIT OF WATERSHED RESTORATION (Abstract ID: 29440)

Since 2011, NOAA has funded watershed restoration projects on Culebra Island, Puerto Rico to reduce land-based sources of pollution (LBSP) discharged to coral reef habitats. However, due to budgetary constraints, performance based monitoring has generally been limited. NOAA's Restoration Center, in coordination with other NOAA line offices and independent scientists, developed a cost-effective multi-spatial and multi-temporal monitoring protocol to evaluate the performance of the LBSP management actions, inform adaptive management strategies, and better understand linkages of management actions to coastal habitat health. In 2014, monitoring was initiated to test this protocol and includes: crude modeling of pre- and post-restoration sediment loads, studies to quantify the sediment mass reduction at the management practices, establishing baseline metrics of nearshore water quality, seagrass health, and coral health. Preliminary results indicate that watershed restoration projects reduce sediment loads by 85% at-the-practice. Baseline nearshore water quality is dynamic, yet mean annual turbidity, water clarity, and chlorophyll a are correlated to known LBSP impairments. Furthermore, water quality indicators are correlated to metrics of seagrass and coral reef health. Comparisons of these results to similar watershed scale studies suggest that investments in low-cost long-term water quality and habitat quality monitoring could provide a cost-effective approach to evaluating linkages between LBSP management and coral reef health.

REGIONAL ANALYSIS OF ACROPORA PALMATA POPULATION AND RESILIENCE DYNAMICS USING STOCHASTIC MATRIX MODELING (Abstract ID: 29569)

*A. palmata population* dynamics reveal important patterns of change in abundance and cover that cannot be realized by straightforward trend analysis. Using data collected between 2004 and 2011 in three primary (Florida, Curacao, and Jamaica) and three secondary (Virgin Gorda, Navassa, and Puerto Rico) locations across the Caribbean, we estimated rates of change and variability in population size using stochastic matrix modeling. The most striking difference we quantified was between Jamaica, where population size is projected to grow by 2% / y, and all other locations, where population sizes are projected to remain stable or decline. This is likely due to the recovery of the sea urchin *Diadema antillarum* on Jamaican reefs, where density (3.5 +/- 0.6 / m^2) is an order of magnitude greater than in the other study locations. We also discovered a distinct contrast in resilience dynamics. Florida and Curacao populations each weathered severe storms during the study period and the dynamics exhibited during the calm years -- 2%/y growth in Florida where severe storms are relatively frequent versus 4% /y decline in Curacao where severe storms are infrequent -- were fundamentally different from each other, suggesting that populations have varying degrees of resilience to storms. Characterizing *Acropora palmata*dynamics across space can help us design location-specific management criteria -- although the conservation goals (increase abundance and extent) may be common, techniques and expected outcomes should be different.

DETERMINING THE EFFECTIVENESS OF WATERSHED MANAGEMENT ACTIVITIES TO REDUCE LAND-BASED POLLUTION ON WEST MAUI (Abstract ID: 28118)

As an approach to reduce the effects of land-based sources of pollution on coral reefs, the U.S. Coral Reef Task Force and NOAA's Coral Reef Conservation Program identified West Maui as one of two Pacific Region priority areas for the implementation of the Ridge-to-Reef management initiative. There are five priority watersheds in West Maui: Wahikuli, Honokowai, Kahana, Honokohua, and Honolua. This study summarizes work completed to establish a baseline against which to assess the effectiveness of future upland management activities aimed at reducing sedimentation stress to the adjacent coral reefs. Permanent, replicate coral community monitoring transects were established adjacent to seven drainages within the five priority watersheds. Benthic reef community structure and coral population demographic parameters, including percent cover, coral colony density, size class structure, and health condition data were collected. In addition, terrestrial sediment loading was evaluated by turbidity, sediment composition, and sediment accumulation data at a subset of sites. While this baseline assessment provides a framework to assess change over time, it also underpins the wide range in the overall health status and condition among adjacent coral communities in relation to land use, in addition to highlighting data and informational gaps. This information is a pivotal component of the watershed characterization process as it helps support decision-making regarding watershed restoration efforts aimed at reducing land-based pollution impacts to high-priority reefs.

A MORPHO-FUNCTIONAL APPROACH IN CORALLINE ALGAE (RHODOPHYTA) TO UNDERSTAND NICHE PARTITIONING AND THEIR DIFFERENTIAL SENSITIVITY TO GLOBAL CHANGE (Abstract ID: 29512 | Poster ID: 282)

The capacity and efficiency of the photosynthetic tissue to absorb light are two key functional properties involved in the regulation of the amount of solar energy that can be transformed into organic carbon and the carbonate skeleton of the photosynthetic calcifiers. Their variation may explain how organisms adequate differentially to a changing environment, maximizing photosynthetic production and minimizing the costs of photodamage and repair. As part of a general analysis of the response of coralline algae to global change, we investigated the optical properties of three coral reef species representing the main coralline growth-forms: rhodoliths, articulated and crustose algae (CCA), in relation to basic structural and functional traits of the thalli. Rhodoliths and the CCA absorb light more efficiently than the articulated alga, and were more productive either per projected area, the former, or per dry mass the later. However, the larger capacity of the articulated algae to extend its light collecting area would explain why this growth-form is the most successful and productive in a wider number of habitats. In absence of a fixed substrate, under very high hydrodynamics or at low irradiance levels, the other growth-forms can compete more successfully with the articulated alga. Moreover, the larger respiratory demand of the articulated growth-form under elevated temperature, explains its particular sensitivity to global warming within a group with an already documented fragility.

CORAL RESTORATION, PAST, PRESENT AND FUTURE TECHNOLOGIES (Abstract ID: 29682)

Coral restoration efforts historically, have evolved from reef stabilization, to the present active restoration methods using propagation nurseries to outplant reef organisms. This presentation will review the development of newer methods of active restoration, using corals produced under aquaculture propagation techniques for outplanting. Case studies of the commonly used branching coral, or Acropora species, for reef restoration will be

compared to some emerging technologies. New technologies for restoration of the massive reef building species will be presented with findings of accelerated growth, and the production of larger number of colonies than ever previously predicted. The potentials of this technology also allows for the repair and replacement of new living tissue on the surface of dead coral heads, makes this a new and novel technology. This technology is now possible at a rate and scale comparable to the majority of branching coral restoration projects. Future technologies of larger number of sexual recruits for restoration are having greater advances in the recent years and will provide the ability to do genetic crosses to produce more plantable materials and better selection and genetic diversity. Novel techniques that can enhance future resilience by accelerating growth to sexually mature sizes are being developed as new tools for reef restoration efforts that can utilize more resilient strains for restoration.

IMPROVING THE UNDERSTANDING AND INFLUENCE OF INDIGENOUS FIJIAN FUNERAL PRACTICE ON CORAL REEF-SOCIO-ECOLOGICAL SYSTEMS (Abstract ID: 30080 | Poster ID: 601)

A majority of research on community based Marine Protected Areas (MPAs) has been on areas intended for conservation and reef restoration, for the purpose of food security. These are often larger in size and span more than two years. In Fiji, there are more than 400 community based MPAs as part of the successful Fiji Locally Managed Marine Area (FLMMA) network. However, what is little known and understood is the geographic spread, extent and frequency of community based MPAs that are established culturally following the burial of an indigenous Fijian. These funerary MPAs, although only established for 100 nights and small in area, could have influenced the establishment of larger, longer term community based MPAs in Fiji. More importantly, to know how this knowledge is utilized and built upon in community engagement and management of coral reef socio-ecological systems in Fiji. This paper is aimed at presenting preliminary findings on the above.

A POSSIBLE ROLE FOR VITAMIN C IN CORAL CALCIFICATION (Abstract ID: 29670 | Poster ID: 26)

The biological components of the calcification process in coral reefs are poorly understood. Because calcification must involve the transport of molecules across cell membranes, we postulate that it could have similarities to transport mechanisms in vertebrates. We want to identify the specific membrane transporters underlying skeleton formation. As a model, we are using larvae from the ubiquitous Caribbean coral, Porites astreoides. Using Illumina RNAseq, we assembled a transcriptome and compared gene expression between swimming larvae and recently settled ones that had just started the calcification process. As expected, we identified many ion transporter, pump and channel that were upregulated in settled larvae. Surprisingly, the most upregulated transcript appeared to encode a Na-dependent vitamin C transporter (SLC23A). In vertebrates, SLC23A plays a vital role in bone morphogenesis where vitamin C is an essential cofactor for the collagen formation. In corals, collagen has been identified as a component of the skeleton's extracellular matrix. Using in situ hybridization, we showed that the P. astreoides SLC23A messages were expressed in regions adjacent to rapid skeleton formation. To confirm that the coral clone is indeed a vitamin C transporter, we expressed it in Xenopus oocytes and studied its activity using voltage-clamp. Preliminary data demonstrate that it induces a current that is activated by Na and vitamin C. This approach will help us better understand the molecular mechanisms underlying calcification and how they might respond to environmental change.

THE IMPLEMENTATION OF RARE EVENTS LOGISTIC REGRESSION TO PREDICT THE DISTRIBUTION OF MESOPHOTIC HARD CORALS ACROSS THE MAIN HAWAIIAN ISLANDS (Abstract ID: 28437)

Predictive habitat suitability models are powerful tools for cost-effective, mathematically robust ecological assessment of the environmental drivers of species distributions. The aim of this study was to develop a predictive habitat suitability model for two genera (Leptoseris and Montipora) of mesophotic scleractinian corals across the main Hawaiian Islands. The mesophotic zone (30 - 180 m) is challenging to reach, and therefore historically understudied, because it falls between the maximum limit of SCUBA divers and the minimum typical working depth of submersible vehicles. Here, we implement a logistic regression with rare events corrections to account for the scarcity of presence observations within the dataset. These corrections reduced the coefficient error and improved overall prediction success (73.6% and 74.3%) for both original regression models. Predictions were translated to spatially independent habitat suitability maps of the main Hawaiian Islands at 25 x 25 m resolution. Our maps are the first of their kind to use extant presence and absence data to examine the habitat preferences of these two dominant mesophotic coral genera across Hawai'i.

RETHINKING CORAL MICROBIOLOGY PARADIGMS: DESTABILIZATION VERSUS ALTERNATIVE STABLE STATES AS CRITICAL HALLMARKS OF STRESSED CORAL ECOSYSTEMS (Abstract ID: 28764)

Microbiologists have studied the structure and function of the bacteria and viruses associated with corals for decades. Our collective knowledge has revealed several important properties of the holobiont and how it responses to environmental perturbation. For example, a standard paradigm in the field is that stressors disrupt the normal patterns of host control, allowing for growth and production of pathogenic or opportunistic bacteria and viruses. These disruptions are most commonly conceptualized in terms of shifts between alternative stable states or the rise and fall of individual pathogens. Thus our studies of coral disease and dysbiosis have focused on evaluating whole community shifts or blooms of specific taxa. However, our recent work suggests that these approaches can miss some categories of community changes that occur in the microbiomes and viromes of hosts experiencing a variety of stressors, leading to the generation of false negatives. We present the hypothesis that many disturbances to the coral microbiome, especially those that promote opportunism, increase beta-diversity (sample to sample variation) of the microbiome and virome. This hypothesis will be discussed in light of data from coral and other marine hosts. We will present a meta-analysis of microbiome and virome data, to lend support for this hypothesis, including the analysis of a long term dataset where nutrients and algal cover were manipulated and temperature varied.

SPATIO-TEMPORAL CHANGES IN CORAL PHOTOSYNTHETIC EFFICIENCY, REEF PRODUCTIVITY AND WATER TURBIDITY AT FLORIDA KEYS PATCH REEFS (Abstract ID: 28375)

Coral reef productivity is driven by light availability and depends in part on a complex set of chemical processes, biological diversity, the health of the coral community, and hydrographic regimes. We assessed the spatial and temporal variability of stony corals photosynthetic yields in relation to coral reef productivity and water turbidity in three sites in the Florida Keys. Two nearshore turbid patch reefs off Sugarloaf Key and Cheeca Rocks, and one outer reef tract by Crocker Reef where water is typically less turbid, were surveyed in May and October 2012, and May 2013. At each site, net ecosystem productivity (NEP) was measured within mesocosm enclosures, the photosynthetic efficiency of healthy corals was monitored with PAM fluorometry, and water quality parameters were measured with optical instruments. The photosynthetic efficiency was not significantly different among coral species or between seasons, but was different between sites. Corals at Crocker Reef had the lowest mean photosynthetic efficiencies (< 0.55) despite being located in the clearest water. The lowest NEP (< 0.02 g O2 m-2 15 min-1) was also found at this reef site. Diurnal variations in the effective yields were inversely related to PAR and reef productivity in all seasons and study sites. Results suggest that corals in near shore patch reefs might benefit from shading by turbid water or by higher chlorophyll a or particle (food) concentrations in the water column, which might help explain higher photosynthetic effective yields, productivity and live coral cover observed in these areas.

CORAL TRIANGLE FISHERIES VULNERABILITY IN A CHANGING CLIMATE: SKIPJACK TUNA THERMAL SPAWNING HABITATS (Abstract ID: 29529)

We investigated projected sea surface temperature (SST) changes and their impacts on Skipjack tuna spawning habitat for the Coral Triangle Region (CTR, 12°S-22°N and 94°E-163°E). A comprehensive Skill Validation Assessment found the 5 best performing models for SST of 36 CMIP5 models that were then used as a multi-model aggregate. Monthly 1° SST multi-model aggregate projections under RCP 8.5 show that significant increases in SST as high as 2.8°C (mean value) will likely occur in the CTR by the end of the century. To these estimates of SST change, we applied three parameterizations of Skipjack tuna (Katsuwonus pelamis) spawning temperatures. The three spawning temperature parameterizations were: a) a square-wave function (SWF) derived from catch data with boundaries at 26°C and 30°C; b) a symmetric Gaussian function (SYF) derived from the SEAPODYM models, and c) an asymmetric Gaussian function (ASYF), that modifies the SEAPODYM curve in (b) to include the results of relevant physiological experiments. All three parameterizations show similar geographic patterns, with the amount of favorable spawning habitat decreasing throughout the central, equatorial CTR and increasing at higher latitudes. However, each of the three parameterizations shows marked differences in the modeled magnitude of change, with the ASYF showing a region-wide average decline of 66.1% in favorable spawning habitat between 2015 and 2100. These projected changes in tuna spawning habitats are likely to have important local and regional consequences for fisheries, food security, and livelihoods.

MARINE CONSERVATION PRIORITIZATION IN 3D: ACCOUNTING FOR THE THIRD DIMENSION (Abstract ID: 30042)

Spatial conservation prioritization (SCP) is used to identify areas where conservation goals can be achieved more efficiently, and usually carried out in a two dimensional space. In an inherently three dimensional (x,y,z coordinates) space such as the ocean, this approach might not be the most efficient, as it results in the application of one type of management to an area of the ocean all the way from the surface to the bottom (or beyond). In this study we aim to develop a 3D approach which allows explicitly incorporating depth into SCP, so that vertical as well as horizontal spatial prioritization can be accomplished through conservation planning software. This approach has been developed using Marxan as the conservation planning software,by stratifying the ocean in different layers according to depths, and applying different techniques to prepare the input data such as 3D GIS. Its efficiency is assessed by comparing the resulting spatial conservation priorities with a typical 2D conservation planning. Preliminary results indicate that 3D SCP of marine biodiversity features can be more efficient, both in terms of cost and total area needed to achieve conservation objectives. This new approach could potentially allow protecting important biodiversity at specific depths, while allowing uses of the ocean that do not pose a threat to this biodiversity at other depths. Moreover, such a prioritization could prove important in adequately addressing the protection of presently under-represented marine ecosystems in the global MPA system such as pelagic and deep-ocean ecosystems.

MULTIPL DRIVING FACTORS EXPLAIN SPATIAL AND TEMPORAL VARIABILITY IN CORAL CALCIFICATION RATES ON THE BERMUDA PLATFORM (Abstract ID: 27898)

Experimental studies have shown that coral calcification rates are dependent on light, nutrients, food availability, temperature and seawater &Omega$_{ar}$, but the relative importance of each parameter in natural settings remains uncertain. In this study we applied a Calcein dye as time indicators within the skeleton of coral colonies across the northern Bermuda coral reef platform and evaluated the correlation between seasonal average growth rates with temperature, light and seawater &Omega$_{ar}$ in an effort to decipher the relative importance of each parameter. We also placed small coral colonies in chambers and measured the instantaneous rate of calcification under light and dark treatments. The results showed that skeletal growth, whether hourly or seasonal, appeared highly sensitive to &Omega$_{ar}$. Using short-term light and dark incubations we show, however, how the co-variance of light and &Omega$_{ar}$ can lead to the false conclusion that calcification is more sensitive to &Omega$_{ar}$. For the seasonal data, we assessed the impact of the observed average differences in temperature (4.0℃), light (5.1 mol photons $m^{-2}$ $d^{-1}$) and &Omega$_{ar}$ (0.16 units) on coral calcification rates based on established relationships derived from laboratory studies and found that they could account for approximately 44&percent, 52&percent and 5&percent, respectively, of the observed seasonal change of 81±14 mmolCaCO3 $m^{-2}$ $d^{-1}$.

STRESS RESPONSE OF GASTRODERMAL PRIMARY CELL CULTURE FROM THE TEMPERATE SYMBIOTIC CNIDARIAN, *ANEMONIA VIRIDIS*(Abstract ID: 28345)

Development of cnidarian primary cell culture would allow progress on the environmental and biomedical fields. Primary cell cultures from tentacles of the temperate symbiotic sea anemone, *Anemonia viridis*, have been recently made available in our laboratory. Cnidarian primary cell cultures represent a new biological model relevant to investigate molecular and cellular processes involved in the establishment and maintenance of the cnidarian-dinoflagellate symbiosis and to evaluate the effect and the responses of environmental stresses. We characterized *A.viridis*primary cell cultures by measuring cell growth rate and cell viability during maintenance and propagation of 31-day cultures. Primary cell cultures exhibited a maximal cell growth rate (15 fold increase of cells) during the first two weeks followed by a decrease till the end of the kinetics. Cell viability was constant and high (around 80%) until the end of 31-day culture. Molecular analyses of the expression of tissue specific markers, i.e. markers of epidermal or gastrodermal cell layer and undifferentiated cells, allowed us to confirm the establishment of *A. viridis* differentiated cultured cells from gastrodermal origin. The cellular responses to environmental stresses and to symbiosis constraints were then investigated by this in vitro tool. The effect of thermal and oxidative ($H_2O_2$) stresses on cell viability, cell growth and on the expression of stress markers during a 15-day culture confirms the intrinsic phenotypic plasticity of the gastrodermal cnidarian cells.

MECHANISMS FACILITATING THE TROPICALISATION OF TEMPERATE ALGAL FORESTS IN JAPAN AND AUSTRALIA (Abstract ID: 29122)

The southeastern coasts of Japan and Australia are climate change hotspots, where ocean warming is occurring 2-3 times faster than the global average and leading to the range expansion of tropical species into temperate regions. These changes are profoundly altering ecological communities, causing communities to shift from economically important kelp forests to turf and/or coral-dominated systems. Here, we investigate the role of herbivory in mediating these observed changes. In eastern Australia, we use a ten-year (2002-2012) video dataset encompassing a 0.6°C increase in sea surface temperature to quantify patterns of kelp-herbivore interactions in a tropical-temperate transition zone. We found a marked increase in herbivory as kelp abundance declined from 70% reef coverage in 2002 to full disappearance from 2010 and onwards. During this time, fish communities from sites where kelp disappeared became increasingly dominated by tropical and herbivorous species. Fish surveys and experimental feeding assays in both Japan and Australia identified a small number of species capable of direct consumption of temperate algae. However, subtropical grazing surgeonfish increased most notably in sites where kelp has disappeared, suggesting this functional group plays a pivotal role in maintaining communities denuded from kelps, presumably via the consumption of kelp recruits. Our results indicate that range expansion of herbivorous fish pose a significant threat to kelp dominated ecosystems and the economically important communities they support.

DIFFERENT RATES OF RECOVERY ON CORAL FECUNDITY AND SETTLEMENT SUCCESS ON SINGAPORE REEFS (Abstract ID: 28584)

Coral replenishment is a keystone process for reef resilience, particularly in recovery from localized disturbances that cause extensive mortality to adult colonies on a reef. Reef replenishment is dependent on reproductive fecundity as well as successful recruitment, and both processes are known to be highly sensitive to environmental conditions. However, a majority of studies focus on one or the other, with few investigating differences in influential factors. In Singapore coral reefs, recovery following the 2010 mass coral bleaching event was notably more rapid for coral fecundity than for settlement. High levels of inter-specific variation was also observed in recovery rates of coral fecundity, and these were associated with differential responses to key water quality parameters. Recovery of settlement intensity was severely lagged, with noticeable settlement of other taxa only in 2015, being previously dominated by pocilloporids. Recent settlement success is shown to be associated with improvements in water clarity, which was not a significant factor for fecundity. This provides an increased understanding of the long term impacts to reefs following habitat alteration. Sustainable resource management for successful reef replenishment must therefore identify and address both sets of bottlenecks.

IMPACT OF TEMPERATURE AND PH PREDICTED FOR THE 22TH CENTURY ON ENERGY METABOLISMS AND SHELL GROWTH OF THE GIANT CLAM *TRIDACNA MAXIMA* (Abstract ID: 28237 | Poster ID: 367)

One of the most emblematic organisms of the Polynesian lagoons is the giant clam, *Tridacna maxima*. Used for food and art since millenniums it takes on a strong patrimonial value for the Polynesian society. Otherwise, giant clam populations support since a couple of years the emerging, but promising, economy of live specimens production for the aquarium trade. Such as many other reef organisms, giant clams are today confronted to the effects of global change and can suffer from unexplained mass mortalities events putatively induced by abnormally high seawater temperature. Despite its strong interest, its response to the two most alarming threats linked to global change (i.e., ocean warming and ocean acidification) is still poorly known. To partly address this lack we conducted a series of experiments aiming to reproduce temperature and pH predicted to occurred in the French Polynesia lagoon waters at the horizon of the 22th century (RCP 4.5). In this purpose 96 giant clams were randomly distributed in 16 40 L tanks and exposed for 2 month to the following conditions: i) 29.2°C, pH 8.2 (control); ii) 30.7°C, pH 8.2 (thermal stress only); iii) 29.2°C, pH 7.8 (acidification stress only); iv) 30.7°C, pH 7.8 (thermal and acidification stress). To quantify their responses to each treatment, respiration rates and shell growth were measured at the individual level. At the microscopical scale the effects on the shell microstructure were evaluated by scanning electron microscopy. The data are currently under acquisition and will be presented.

RECURRENT BLEACHING INDUCING THERMOTOLERANCE INCREASES: A DIVE INTO THE HOLOBIONT ADAPTABILITY THROUGH (META)GENOMIC AND EPIGENOMIC MECHANISMS (Abstract ID: 28242)

Coral reefs worldwide are declining under the pressure of global warming. This alarming state is mainly due to coral bleaching and the subsequently induced mortalities. However, in some particular cases of low human-impacted reefs, coral thermotolerance is seemingly increasing in response to recurrent thermal bleaching episodes. It is known that coral's resistance to thermal stress is the result of individual capacities of both holobiont partners, as well as their reciprocal interactions. Yet, the underlying mechanisms remain to be deciphered. In an effort to better characterize them, we conducted a multiscale integrative study, combining genome-wide transcriptomic, (meta)genomic and epigenomic approaches on coral samples from the same colony of *Pocillopora damicornis* (Indonesia). Coral nubbins were subjected to one, two or three ecologically realistic episodes of thermal stress inducing bleaching. After each consecutive bleaching event followed by a year of resilience, we observed a clear and significant increase in thermotolerance. This phenotypic change was associated with a drastic increase of the plasticity at the transcriptomic level (RNA-seq approaches). This transcriptome remodeling was correlated with the observation of genomic (copy number variations) and epigenomic (methylome) variations. Our results suggest that rapid adaptation of corals to heat stress is possible and that molecular markers for thermotolerance could be developed.

ANNUAL HOLOTHURIAN-MICROORGANISM INTERACTIONS UNDER DIFFERENT IPCC *P*CO2-TEMPERATURE SCENARIOS (Abstract ID: 29255)

*Holothuria atra*, one of the most abundant Holothurian species on tropical Indo-Pacific reefs, has the ability to turnover carbonate sediments, potentially contributing to the calcium carbonate budget by changes in total alkalinity and alkalinity derived from the production of Total Ammonia Nitrogen (TAN). Sediment microbes also have the potential to alter sea water chemistry through the dissolution and recycling of nitrogen. We tested the relative roles of microbes and sea cucumber (SC) on seawater chemistry under present day and projected representative carbon pathways (RCP4.5 & RCP8.5) in conditions appropriate to southern GBR for winter and summer. Our results showed that over winter, the animals had no significant impact on sediment decalcification; with physical and/or microbial bioerosion leading to elevated rates of sediment dissolution under RCP8.5 warming and acidification. Likewise, SC had no influence on TAN uptake that was significantly greater by night irrespective of scenario. During summer, there were trends for greater decalcification under RCP8.5, during nighttime and in the presence of SC, however, these were non-significant. TAN production significantly increased in the presence of SC by day and by night, and a greater TAN uptake was shown in their absence during nighttime. These results suggest that on an annual basis, regardless the effects on TAN production by SC, the main driver for calcification/decalcification in future reefs will be changes in the abundance and composition of the communities of microorganisms within the sediments.

MODELING SPATIAL DISTRIBUTIONS OF MULTIPLE ESA SPECIES USING A MULTIVARIATE BAYESIAN FRAMEWORK (Abstract ID: 28868 | Poster ID: 697)

Management decisions for species and place-based conservation increasingly reference probabilistic spatial models of species distributions. For coral species listed under the U.S. Endangered Species Act (ESA), the best available scientific data needs to be utilized, yet different field surveys can vary widely in spatial and temporal effort, and ESA species can be quite rare. We predict joint spatial distributions of multiple Atlantic/Caribbean coral species including ESA species using generalized joint attribute models, a multivariate Bayesian framework. This approach uses inference and prediction for jointly distributed responses that account for a lack of independent occurrence of different species, accommodate multiple types of input data, and account for varying effort and zero inflation. We show spatial models for multiple coral species of abundance and partial mortality using data from multiple discrete surveys, including NOAA's National Coral Reef Monitoring Program, in the Dry Tortugas FL, the US Virgin Islands, and Flower Garden Banks National Marine Sanctuary. Predictive model maps show joint distributions for abundance and partial mortality of corals as related to environmental predictors derived from high-resolution bathymetry, as well as with thermal stressors and wave energy. Increased information on species distributions and environmental drivers can help guide conservation actions, restoration planning (e.g. selection of potential outplanting sites) and identify locations of potential species vulnerabilities to environmental stressors.

COLD WAR IN THE TROPICS: ALLELOPATHIC INTERACTIONS BETWEEN THE BROWN ALGAL GENUS LOBOPHORA (DICTYOTALES, PHAEOPHYCEAE) AND SCLERACTINIAN CORALS (Abstract ID: 29313 | Poster ID: 281)

The brown algal genus Lobophora is an important benthic component of tropical coral reefs. Members of this genus are commonly observed in close contact with scleractinian corals and have been considered responsible for negative effects on the latter. Allelopathy has been recently suggested as a mechanism by which Lobophora may outcompete corals in damaged reefs. We performed in situ bioassays testing the allelopathy of crude extracts and isolated compounds of several Lobophora species, naturally associated or not with corals, against four scleractinian corals in New Caledonia. Our results showed that, regardless of their natural association with corals, organic extracts from species of the genus Lobophora are intrinsically capable of bleaching some coral species upon direct contact. Additionally, three new C21 polyunsaturated alcohols named lobophorenols A-C were isolated and identified. Significant allelopathic effects against Acropora muricata were identified for these compounds. In situ observations in New Caledonia, however, indicated that while allelopathic interactions are likely to occur at the macroalgal-coral interface, Lobophora spp. rarely bleached their coral hosts. These findings are important toward our understanding of the importance of allelopathy versus other processes such as herbivory in the interaction between macroalgae and corals in reef ecosystems.

ENERGETIC RESOURCE ALLOCATION FOR REPRODUCTION IN TWO MEDITERRANEAN GORGONIANS WITH DIFFERENT REPRODUCTIVE STRATEGIES: SURFACE VERSUS INTERNAL BROODERS (Abstract ID: 27839)

The present study investigates the energetic investment in reproduction and the potential energetic allocation from parental colonies to larvae for two gorgonians characterized by different reproductive strategies: Corallium rubrum (internal brooder) and Paramuricea clavata (external brooder). Quantification of sexual products and biochemical composition (lipid content and free fatty acid (FFA) content and composition) were used to examine the parental energetic investment and demand in reproduction. Results showed that the energetic cost is mainly due to the reproductive activity (i.e. gametogenesis and spawning). The two species displayed different life history strategies (with C. rubrum investing less energy in reproduction than P. clavata) and sensitivity to environmental conditions (being P. clavata more sensitive than C. rubrum). The quality of energetic reserves transferred from maternal colonies to larvae was analysed by comparing their FFA composition. C. rubrum showed a similar FFA composition in maternal colonies and larvae, whereas P. clavata transfers low amounts of energy to oocytes. FFA composition suggests that C. rubrum larvae have the highest dispersal and/or crawling behaviour capacity compared to P. clavata. This shows how FFA analyses can get insight into the activity rates, the dispersal and recruitment capability of different gorgonian species. Observed differences in energetic investments may affect the recovery dynamics of these species after major disturbances, with C. rubrum strategy mainly focused on resistance, while P. clavata on resilience.

UNRAVELING INSHORE-OFFSHORE MACROBENTHIC DIVERSITY PATTERNS IN RED SEA CORAL REEFS (SAUDI ARABIA) REVEALED BY BARCODING TOOLS (Abstract ID: 28994)

Understanding patterns and processes that drive the structure of coral reefs communities is essential for biodiversity conservation. Cross-shelf biodiversity gradients (inshore-offshore) have been described for fish, corals, and macroalgae as a response to stressors including sedimentation and pollution. However, the influence of such gradients on cryptic invertebrates, such as small crustaceans, mollusks, and echinoderms, which represent the vast majority of coral reef diversity, is largely unknown. The high diversity, small size and lack of taxonomists have been limiting our knowledge about these cryptic assemblages. Besides, taxonomy based on their morphology is difficult and time-consuming with many species yet to be described. This study undertakes a quantitative survey of invertebrate communities (>2mm) collected using a standardized approach (Autonomous Reef Monitoring Structures (ARMS) across an inshore to offshore gradient on the Saudi Arabian coast of the Red Sea. DNA barcoding of the mitochondrial COI gene was used to supplement morphological identifications. Preliminary results showed that most of the COI sequences do not match any reference barcodes in public libraries (GenBank and BOLD). In addition, the rarefaction curves did not plateau, suggesting that this study was unable to fully characterize the diversity in the region. Community composition changed from inshore to offshore and was significantly correlated with the type of substrate. Inshore reefs are inhabited by taxonomical groups that differ substantially from the remaining reefs sampled.

IMPROVING THE FISH-BE MODEL TO INFORM MARINE PROTECTED AREA NETWORK DESIGN (Abstract ID: 28923 | Poster ID: 649)

Numerous guidelines and tools have been developed to provide guidance in designing networks of marine protected areas (MPA). Some of these tools have been able to include other objectives apart from biodiversity conservation (i.e. minimizing loss or maximizing representation of species and habitats), such as connectivity, fisheries management, and threats management. However, these tools are either not spatially explicit or have only integrated and modeled a few spatial attributes. Here we present an initial version of the spatially explicit Fisheries Information for Sustainable Harvest – Bioeconomic model, which can quantify fish standing stock biomass given varying levels of habitat quality and complexity, larval connectivity, fishing pressure, and sedimentation. This new version is a fish population model with a spatial domain composed of a uniform sized grid with cells. The model runs simultaneously in each cell, with the standing stock biomass documented at each time step for each cell and the entire grid. The model can be used to map and visualize potential benefits of MPAs on fisheries productivity, and guide the design of networks by identifying the size and locations of MPAs. Moreover, the tool can also be used for marine spatial planning as decision-makers and resource managers can use it for developing different scenarios on the effects of various and combinations of threats and other resource-use activities on fisheries productivity.

ASSESSING FUNCTIONAL DIVERSITY: FROM TRAITS TO MULTIDIMENSIONAL INDICES (Abstract ID: 28355 | Poster ID: 507)

Trait-based approaches are increasingly applied in community ecology to assess spatial patterns and temporal trends of functional diversity to ultimately understand how human impacts affect ecosystem functioning. Several methodological frameworks have been proposed to compute the diversity of traits values present in a species assemblage and the similarity of traits values between several assemblages. However, methodological choices could have deep implications on the results since some approaches have biases (e.g. functional dendrogram) and because indices have different properties (e.g. accounting for relative biomass of species or only for their traits values). Here we present user-oriented guidelines for each of the three steps to compute functional diversity: (1) selecting a set of traits and measuring them in a set of species assemblages, (2) building a multidimensional space of high quality to place all the species according to their respective traits values, (3a) computing complementary indices describing the facets of the distributions of species and of their biomass in this space and/or (3b) computing complementary indices of functional dissimilarity between assemblages. For each of the two last steps, we list a set of R packages and functions already available.

INTEGRATED WATERSHED MANAGEMENT AND GREEN INFRASTRUCTURE IN PUERTO RICO (Abstract ID: 29400)

Land-based sources of pollution (LBSPs) represent a significant threat to coastal ecosystems in Puerto Rico. This oral presentation for the ICRS' session #73B: Partnerships for Achieving Effective Resource Outcomes on Coral Reefs – Partnerships with and Among Communities and Stakeholders will describe how to develop effective integrated watershed conservation management plans and effective local restoration efforts led by the non-profit organization Protectores de Cuencas, Inc. (PDC) utilizing low cost green infrastructure. This session will showcase a list of green infrastructure demonstration projects implemented in Guánica, Vieques, Cabo Rojo, Yauco, Culebra and the Northeast Reserves within the archipelago of Puerto Rico. The presentation will be given by PDC's Director, Roberto Viqueira. The session will last approximately 30 minutes. Roberto's presentation will promote integrated watershed management as an effective approach for Puerto Rico and the Caribbean region, as well as provide concrete restora-

tion solutions to LBSPs for marine and coastal ecosystem protection.

ECOLOGY OF HYBRIDISING ANGELFISHES: LOW ABUNDANCE AND NICHE OVERLAP PROMOTE HYBRIDISATION (Abstract ID: 29097)

Hybridisation has traditionally been considered rare in Coral reef fishes. However, recent studies have revealed that hybridisation is common. The angelfishes (Pomacanthidae) have the greatest proportion (~30%) of hybridising species with 26 species reported to hybridise. The aim of this study is to test the theory that low abundance and niche overlap are important factors promoting hybridisation. This theory has been developed based on terrestrial studies and here we test its generality in the marine environment by examining hybridising angelfishes at Christmas Island (Indian Ocean). We studied three species of pygmy angelfish (Centropyge flavissima, C. eibli and C. vroliki) and their hybrids to address three objectives: (1) determine temporal and spatial patterns in abundance and whether these patterns are linked to environmental factors; (2) to test for overlapping patterns in habitat use; (3) to test for overlapping patterns in diet. C. flavissima was abundant, whereas C. eibli, C. vrolikii and all hybrid combinations were consistently rare. All parent species and hybrids used overlapping habitats and achieved highest abundance at sites with a high reef aspect (vertical reef walls), high cover of turf algae and low wave exposure. Parent species and their hybrids also had similar diets that were comprised of a mix of green, red and brown algae. Thus, rarity of parent species and niche overlap help promote hybridisation in angelfishes at Christmas Island. This study provides empirical support that hybridisation in reef fishes conforms to terrestrial-based theories.

COMPARISONS OF SYMBIOTIC DINOFLAGELLTE COMPOSITIONS OF CORALS IN THE UPPER GULF OF THAILAND AND IN CORAL HATCHERY: IMPLICATION FOR CORAL TRANSPLANTATION PLAN (Abstract ID: 30095 | Poster ID: 492)

Symbiotic dinoflagellates (Symbiodinium) in corals in the upper Gulf of Thailand and in the coral hatchery were investigated for establishing suitable coral transplantation plan. We performed genotyping of symbiotic algae of 5 coral species (three Acropora species, Pocillopora damicornis, and Platygyra sinensis), which have been propagated through sexual reproduction in the hatchery and used for coral transplantation in our research area. The results showed that clades C and D were dominant in all coral species examined in this study, and the compositions of these clades showed some variations among species and among coral specimens in the natural reefs and the coral hatchery. Considering the general notion that clade D is more tolerant to heat stress than clade C, selecting cultured juvenile corals possessing clade D in the hatchery may be better for future coral transplantation.

EFFECT OF LOWER PH ON EARLY DEVELOPMENT AND SETTLEMENT OF CORALS, ACROPORA MILLEPORA AND POCILLOPORA DAMICORNIS (Abstract ID: 29969 | Poster ID: 379)

The effects of low pH on the early development and settlement of two coral species, Acropora millepora and Pocillopora damicornis were investigated. Three different pH treatments (pH = 7.6, 7.9, and 8.1) were used. The results showed that the lower pH levels caused significant decreases of fertilization rates of A. millepora. The low pH also led to abnormalities of embryonic and larval developments of both coral species. In addition, there were significant differences in the settlement rates of A. millepora and P. damicornis larvae between pH treatments ($p < 0.05$). The decrease in pH levels caused a strong decline in larval settlement rates. At pH 7.6 and 7.9, all larvae were unable to complete metamorphosis, and metamorphosis delay was observed. From this study, strong negative effects of pH reduction on coral larvae were observed.

CORAL TRANSCRIPTOME RESPONSES TO THE LUNAR CYCLE (Abstract ID: 27967)

The lunar cycle controls the timing of broadcast spawning in reef building corals, with most species spawning on a specific evening or two following a full moon. Very little is known about how corals perceive the lunar cycle and translate this information into precise reproductive timing. To increase our understanding of this process we undertook a long term analysis of transcriptome dynamics over the lunar month preceding spawning in Acropora humilis. Corals were sampled under two different regimens. In the first corals were transplanted to flow through tanks with a normal daily light cycle, and an artificial lunar cycle from a broad spectrum light. The second set were collected from the field. Samples were taken at noon and at midnight at multiple points of the lunar cycle. RNA was isolated from samples, libraries generated, and NGS sequencing performed. Analysis of the results indicates that many biological processes change over the course of the lunar month, including skeletal deposition, energy metabolism, and mRNA translation. There are also effects on genes associated with circadian clocks and neurohormones. It is possible that shifting cycles of clock genes may allow corals to interpret lunar phases and contribute to controlling reproductive timing.

COMPARATIVE STUDY ON CORAL REEF RELATED FISHERY RESOURCES AT THE AREAS OF VIETNAM REPRESENTATIVE FOR WESTERN SOUTH CHINA SEA AND THE EASTERN GULF OF THAILAND (Abstract ID: 28032)

Coral reef related fishery resources were studied at 4 reef areas during 2010 - 2014, using brainstorming consultations with local experienced fishermen. The calculated yields per square kilometer per year ranged greatly among areas, lowest in Ninh Hai waters (19 tons) to highest in Tho Chu islands (200 tons). Studied reefs supported important fisheries with the calculated revenues ranging between 500 - 800 thousands USD per area. Collection of juveniles for cage culture also contributed high revenue for fishermen, around 1 and 1,5 millions USD from lobster juvenile in Ninh Hai waters and Nha Trang bay respectively, and approximately 600.000 USD from grouper juvenile in Phu Quoc islands. The calculation suggested a discussion about uncertainty in making reliable yield estimation, considering reef area calculation and fishing grounds.In addition, the recorded data indicated differentiae of reef resources at the regional and areal scale. The resources in areas of the Gulf of Thailand were characterized by dominance of fin fish in which fusiliers contributed around 50% of total production and diversity of deep water mollusks. Meanwhile, resources in the western South China Sea varied among areas, considering the presence of lobster and Tripneustes sea urchin, both of which were absent in the eastern Gulf of Thailand. Sustainability of reef fisheries in study areas was also concerned with consideration about serious reduction of predator species and over-exploitation of some other resources under continuous pressures of over-capacity, taking account of recent development of night diving for fishing in almost reef areas and illegal fishing at remote reefs

HIGH-THROUGHPUT METABOLOMICS IDENTIFIES SPECIES- AND HABITAT-SPECIFIC METABOLITES IN CORALS (Abstract ID: 28925)

Untargeted metabolomics such as Liquid Chromatograhy-Mass Spectrometry (LC-MS) has the potential to rapidly and quantitatively fingerprint biological states and identify key metabolites in biological processes yet it has rarely been applied to corals. Here, we first quantify variation from multiple experimental sources such as extraction procedures and within colony variation demonstrating the reproducibility of LC-MS coral metabolomics. LC-MS was then used to compare the metabolomes of the shallow-water scleractinian Acropora palmata and 4 species of deepwater coral including a scleractinian, an

octocoral, and two anthipatharians. As expected, clear species-specific differences were detected. The largest difference was between shallow and deepwater taxa likely due to the presence of Symbiodinium sp. in A. palmata. To evaluate the potential of LC-MS to detect ecologically relevant, within-species differences, colonies of Callogorgia delta were collected near and far from areas of natural hydrocarbon seepage in the deep Gulf of Mexico. Colonies growing near seeps had d13C and d15N stable isotope values reflecting input of seep derived organics and the metabolome of seep-influenced colonies differed significantly from those that were not seep-influenced. Characterization of metabolites driving species and habitat differences is underway. These experiments lay the groundwork for joint analyses of metabolomic, proteomic and transcriptomic data that may yield unprecedented insights into the molecular stress response of corals.

THE GENETIC BASIS OF CORAL IMMUNITY AND DISEASE RESISTANCE (Abstract ID: 28089)

The global rise in coral epizootics pose a serious threat to coral reefs, yet little is known about the genetic basis of coral immunity and disease resistance. Here we use transcriptome-wide RNAseq data to profile the immune response of endangered Caribbean staghorn coral *Acropora cervicornis* infected with White Band Disease (WBD), and then compare disease resistant and susceptible staghorn corals to identify the genetic underpinnings of disease resistance. WBD infected corals exhibited significant changes in gene expression across 4% of the coral transcriptome, primarily at genes associated with macrophage-mediated pathogen recognition, phagocytosis, apoptosis and the allene oxide pathway. The strong up-regulation of genes in the allene oxide pathway suggests its importance in coral immunity. Comparisons between disease resistant and susceptible corals identified constitutively expressed genes underlying disease resistance that are independent from the immune response associated with disease exposure. Genes involved in RNA interference-mediated gene silencing, including Argonaute, were up-regulated in resistant corals, whereas heat shock proteins (HSPs) were down-regulated. Up-regulation of Argonaute proteins indicates that post-transcriptional gene regulation plays a key role in coral disease resistance, whereas the down-regulation of HSPs in disease resistant staghorn corals may confer a dual benefit of disease and thermal resilience.

EXPLORATION AND CHARACTERIZATION OF MESOPHOTIC REEFS OF THE FLOWER GARDEN BANKS NATIONAL MARINE SANCTUARY AND NEIGHBORING BANKS IN THE NORTHWEST GULF OF MEXICO (Abstract ID: 29419)

The Flower Garden Banks National Marine Sanctuary (FGBNMS) and adjacent banks in the Northwest Gulf of Mexico (NWGOM) exhibit unique and extensive shelf-edge coral communities. Using remotely operated vehicle (ROV)-based high definition imaging, we conducted 299 stratified random quantitative 100 m phototransects to characterize mesophotic reef habitats and fish communities on East and West Bank within FGBNMS as well as McGrail, Bright, and Geyer Banks lying east of the sanctuary. Benthic community composition differed significantly among habitat types across vertical zones. While Scleractinian corals comprised 66-75% of benthic cover on coral caps of East and West Bank, these shallower habitats account for only ~1% of the total FGBNMS area. Mesophotic communities (46-104 m) in the FGBNMS and adjacent banks were dominated by Scleractinians (14 species), black corals (*Antipathidae*, *Aphanipathidae*), and gorgonians-*Plexauridae*, *Ellisellidae*, *Primnoidae*). Extensive macroalgal overgrowth was observed at both McGrail and Bright Banks from *Sargassum spp.* and*Codium sp.* , respectively. Habitat partitioning among grouper and snapper families was distinct with few species occupying both shallow and mesophotic depths within FGBNMS. The results of this study and others indicate that mesophotic coral habitats in the NWGOM are more extensive and ecologically important than previously known, particularly with respect to supporting biologically diverse faunal assemblages and commercially important fish communities.

REGENERATION IN CORALLIMORPHARIA (Abstract ID: 28833)

Corallimorpharia species, in the phylum Cnidaria, regenerate after fragmentation in approximately 14 days. They are closely related to Scleractinia, but are easily maintained in the laboratory and possess the potential to be a model for aspects of coral physiology and immunity. Our goal is to choose a corallimorpharian species and the conditions that allow for the fastest regeneration to be used in future research. This project examined the impact of intrinsic and extrinsic factors on regeneration. Intrinsic factors included the comparison of 3 species, representing 3 different genera, as well as small (<5 $cm^2$) versus large (>5 $cm^2$) initial polyp size. Extrinsic factors included light intensity (50–100, 150–200 and, 250–300 $\mu mole/m^2/s$) and feeding (starved or fed 1, or 2x/week). Individuals were fragmented and the surface area was measured over time using ImageJ to obtain a regeneration rate for each treatment. Zooxanthellae density was measured with the use of a haemocytometer. As there is a lack of studies describing the cellular processes during coral regeneration, the process of regeneration using light microscopy was also described over a 2-week period following fragmentation. This work will create a basis for future research on experimental pathology and immunology of coral disease, effects of environmental impacts on regeneration and regeneration mechanisms.

INTERRELATION AMONG FOOD WEBS IN MANGROVE CREEK, SEAGRASS BED AND ADJACENT REEF LAGOON IN ISHIGAKI ISLAND, JAPAN (Abstract ID: 28606 | Poster ID: 428)

The organic carbon source derived from mangrove and seagrass bed is an important food source in the aquatic food web of coastal ecosystems. The inter-link between mangrove and seagrass as well as their roles in coastal aquatic food web depend on the ecosystem structure and the morphology of the coast. At Fukido estuary, Ishigaki Island, southern Japan, both mangrove creek and seagrass are conspicuous and often connected to the adjacent reef lagoon by tidal cycles. The distance between each habitat is less than 500 m, therefore the food source is usually mixed due to organisms' migration during ontogenesis in their life cycle and tidal force. To elucidate the main source of food derived from mangrove or seagrass area and transfer to higher tropic level, we analyzed the natural stable isotopes of carbon and nitrogen and their ratios in primary producers and consumers collected from mangrove and seagrass area. The isotopic evidence showed that the primary producers from mangrove has $\delta^{13}C$ values of -28.3 to -24.4 ‰, compared to the -21.9 to -9.9 ‰ values of samples collected in seagrass bed. The stable isotope signatures of consumers showed that their diets derived mainly from mangrove than seagrass area. $\delta^{13}C$ signal showed that juvenile reef fishes depended more on mangrove for food and adult fishes depended more on reef lagoon. This result showed that mangrove area is an important nursery for reef fishes.

'REEF RECOVERY PLANS' FOR THE GREAT BARRIER REEF MARINE PARK-MANAGING LOCAL PRESSURES IN A GLOBAL CONTEXT (Abstract ID: 28971)

The Great Barrier Reef is in decline and the outlook for the ecosystem has been assessed as 'poor'. These declines are driven by a range of pressures, primarily climate change, degraded water quality, coastal development and some fishing activities. These pressures operate at a range of scales from global to local. The Great Barrier Reef Marine Park Authority is working with industries and communities to develop 'Reef Recovery Plans' to address local pressures at a local scale. These plans are intended to complement the catchment-based 'Water Quality Improvement Plans' to deliver a holistic catchment to Reef approach to local scale problems. The local pressures to be addressed include crown-of-thorns starfish outbreaks, localised unsustainable fishing, anchor damage, and marine debris. There is also a focus on protection and restoration of coastal ecosystems that support healthy marine environments. Reef Recovery Plans will include a mixture of regulatory mechanisms (such as Marine Protected Areas and fisheries management), and a voluntary, co-operative stewardship approach. This approach necessitates active partnership between Traditional Owners, government (at all levels), industry (especially tourism, fishing, and ports), and the community (recreational users, conservation). We expect that effectively addressing catchment and marine pressures at the local scale will help maintain the resilience of the ecosystem in the face of global pressures.

THE REEF RESILIENCE NETWORK: TRAINING MANAGERS IN MMA DESIGN FOR FISHERIES AND BIODIVERSITY OBJECTIVES (Abstract ID: 29834)

The Reef Resilience Network connects coral reef managers and practitioners with information, experts, and resources to innovate, accelerate, and leverage solutions for improved global coral reef health and restoration of reef fisheries. More specifically, the Network provides: access to the latest science and management strategies; platforms for managers, practitioners, and experts to share ideas, experiences, and expertise; and training combined with seed funding to launch necessary education, monitoring, and threat abatement projects. In partnership with experts an online and in person training has been developed and piloted to build capacity for coral reef and coral reef fisheries managers to design and implement MMAs for fisheries and biodiversity objectives. The training includes information on design criteria and activities to help managers put scientific concepts into practice for their site. Skill building in communication and facilitation of stakeholders is also provided in order to increase the participant abilities to effectively implement the complex process of MMA designation on the ground. This presentation will provide an overview of the online training lessons, in-person training agenda and lessons learned.

CHARACTERIZATION OF MESOPHOTIC BENTHIC COMMUNITIES IN THE NORTHWESTERN HAWAIIAN ISLANDS (Abstract ID: 28927 | Poster ID: 328)

Historical surveys to characterize the marine biodiversity of the Northwestern Hawaiian Islands (NWHI) have largely focused on shallow (<30 m) or deep (>300 m) waters, with intermediate depths being largely ignored. This intermediate zone hosts mesophotic coral ecosystems (MCEs), which are notoriously undersurveyed worldwide and particularly in remote locations like the NWHI. Since 2012, annual expeditions have focused on systematically characterizing the mesophotic (50-90 m) biodiversity in the NWHI using mixed-gas technical diving. As part of these efforts, the bethic flora and fauna was surveyed using photoquadrat images taken along belt-transects, in combination with specimen collections that were identified by taxonomic experts. Benthic communities were largely dominated by macroalgae and crustose coralline algae, with hermatypic corals and other invertebrates generally covering less than 2% of substrates. Additionally, benthic communities in the NWHI exhibited latitudinal patterns, with linear decreases in coral cover and linear increases in macroalgal cover along a latitudinal gradient (23-28º N). Finally, benthic communities were almost exclusively composed of species that are native to the Hawaiian Archipelago, with the featherduster worm (Sabellastarte spactabilis) being the only non-indigenous species recorded among the over 200 benthic species documented during our surveys. These results underscore the importance of protecting the unique biodiversity of this region using the highest conservation measures available.

POTENTIAL ROLE OF DIMETHYLSULFONIOPROPIONATE IN BLACK BAND DISEASE ETIOLOGY AND PERSISTENCE (Abstract ID: 29784)

Dimethylsulfoniopropionate (DMSP), an abundant source of sulfur and carbon in the marine environment, can be metabolized by bacterial genera found in coral microbial communities. DMSP is produced by the coral holobiont, and may be involved in coral health and disease. To determine the potential role of DMSP in black band disease (BBD), four BBD metagenomes were generated and analyzed for genes associated with DMSP metabolism, revealing more than 2000 sequences associated with the major degradation pathways demethylation and bacterial cleavage. The number of sequences associated with the bacterial cleavage genes dddD and dddL was ~1.5 fold greater than that of the demethylase gene dmdA, suggesting that bacterial cleavage and its products 3-hydroxypropionate (3HP) and acrylate may be more functionally significant than demethylation. However, two metagenomes had a greater number of dmdA related sequences when compared to dddD and dddL, suggesting variation across BBD communities. The number of dddD related sequences was consistently higher than dddL, indicating that 3HP may be more important in community metabolism than acrylate as it is further metabolized to produce acetate, a commonly utilized energy source by many heterotrophic bacteria. This could contribute to BB-disease persistence. The presence of genes related to both pathways suggests that co-metabolism of DMSP is occurring in BBD, possibly influencing microbial community structure. Thus DMSP production by the coral host may be an important factor in initiation and maintenance of the BBD community.

SETTLEMENT PATTERNS AND PREFERENCES OF ALGAL-ASSOCIATED FISH RECRUITS (Abstract ID: 28390 | Poster ID: 203)

Coral reefs are in global decline, with live coral cover decreasing and macroalgal cover increasing in many regions. How these changes in benthic communities may affect the replenishment of key fish groups is not known. Naïve Siganid and Pomacentrid larvae were placed in a large circular aquarium and exposed to four different treatments. In the first treatment, the larva could choose to settle among live coral, dead coral, coral rubble and macroalgae. If macroalgae was preferred, the larva could choose between different macroalgae species, followed by increasing height and density of Sargassum. Siganus canaliculatus and S. spinus preferred to settle in macroalgae and Sargassum thalli of greater density more frequently than other habitats, however, increased height of Sargassum thalli did not significantly influence settlement preferences. In contrast, Pomacentrus adelus and P. wardi did not show any settlement preferences for different benthic substrates or macroalgae species. However, P. adelus and P. wardi are often observed hiding under rocks in macroalgal beds (pers. observation) and when given a choice in an aquarium, rocks of greater surface area was preferred more frequently than smaller-sized rocks. Consequently, the availability of dense Sargassum and hard substratum structures promote settlement of siganids and pomacentrids respectively. This study highlights the importance of macroalgae species and habitat features in influencing settlement preferences and distributions of algal-associated fish larvae.

RESTRICTED GROUPER REPRODUCTIVE MIGRATIONS SUPPORT COMMUNITY-BASED MANAGEMENT (Abstract ID: 28025)

Conservation commonly requires trade-offs between social and ecological goals. For tropical small-scale fisheries, spatial scales of socially appropriate management are generally small - the median no-take Locally Managed Marine Area (LMMA) area throughout the Pacific is less than 1 $km^2$. This is of particular concern for large coral reef fishes, such as many species of grouper, which migrate to aggregations to spawn. Current data suggest that the catchment areas (i.e. total area from which individuals are drawn) of such aggregations are at spatial scales that preclude effective community-based management with no-take LMMAs. We used acoustic telemetry and tag-returns to examine reproductive migrations and catchment areas of the grouper *Epinephelus fuscoguttatus*, at a spawning aggregation in Papua New Guinea. Protection of the resultant catchment area of approximately 16 $km^2$using a no-take LMMA is socially untenable here, and throughout much of the Pacific region. However, we found that spawning migrations were skewed towards shorter distances. Consequently, expanding the current 0.2 $km^2$ no-take LMMA to 1-2 $km^2$ would protect approximately 30-50% of the spawning population throughout the non-spawning season. Contrasting with current knowledge, our results demonstrate that species with moderate reproductive migrations can be managed at scales congruous with spatially-restricted management tools.

EXCEPTIONAL THREATENED CORAL POPULATIONS IN A MARGINAL REEF ENVIRONMENT ON THE SOUTHEAST FLORIDA REEF TRACT (Abstract ID: 29982 | Poster ID: 318)

The southeast Florida Reef Tract (se FRT) spans approximately 170 km of southeast Florida coastline from Miami (25.5°) to St. Lucie River (27.25°) consisting of a diverse coral reef community. Over 5.5 million people reside within 35 km of the reefs with a large portion being on the coast. Consequently the reefs have been impacted by a variety of anthropogenic stressors including altered hydrology, land-based sources of pollution, coastal construction, ship groundings and anchoring, and treated sewage effluent. Many previous studies have documented the regional decline of corals along the se FRT and

NOAA has listed seven coral species as threatened under the Endangered Species Act. Recent regional mapping has uncovered some previously-unknown, exceptional corals residing on nearshore hard-bottom habitats shallower than 10 m close to anthropogenic threats. Thirty-five locations of dense Acropora cervicornis were found exceeding over 156,000 m², only seven of which were previously reported, thus tripling the amount of known area. This is the largest amount reported in the continental United States. Additionally, 115 live stony corals greater than 2 m were identified (8 larger than 4 m), only a few of which were previously known. The majority of corals were Orbicella sp. (80%). Corals were found between 4.6 m and 8.8 m ($\bar{x}$ = 6.4 m) depth predominantly in the nearshore hard-bottom habitats. Most were spatially clustered into discrete areas along the coast. Assessments are underway and condition data will be presented for both populations.

COMBINED EFFECTS OF PCO2 AND IRRADIANCE ON THE ENERGY RESERVES AND CALCIFICATION OF A REEF BUILDING CORAL (Abstract ID: 29018)

Ocean acidification (OA) from increased concentrations of pCO2 in seawater is predicted to reduce calcification rates in reef corals, and may affect the storage and metabolism of physiologically important energy reserves (lipids, carbohydrates, proteins). Irradiance levels affect the bioenergetics of reef corals, and the effects of OA are modulated by light availability. However, the interactive effects of OA and irradiance on coral biomass energy reserves are not well understood. This study used fragments of the reef coral *Pocillopora damicornis* from Kane'ohe Bay, Hawai'i, to test for light (400 vs. 800 umol photons m-2 s-1) and pCO2 (435 vs. 961 uatm) effects on calcification, symbiont and chlorophyll densities, and the composition (lipids, carbohydrates, protein) and energy content (kJ) of coral biomass. Fragments (N = 168) from seven adult coral colonies were exposed to treatments in 24 flow-through aquaria (n = 6 replicate tanks/treatment) for 32 d. Results revealed no effect of pCO2 or irradiance on net calcification or symbiont density. Carbohydrates/gdw increased under high light, but high pCO2 reduced lipids/gdw and biomass energy (kJ/gdw) and protein/cm2 was reduced under high light and high pCO2. These findings suggest OA will interact with irradiance to affect the composition and energetic content of coral biomass in this ecotype of *P. damicornis*. However, under ecologically relevant irradiances *P. damicornis* may be resistant to the OA-driven reduction in calcification reported for other reef corals.

MARINE CONSERVATION FINANCE: IMPROVING THE AMOUNT, EFFICACY, AND EFFICIENCY OF INVESTMENT INTO CORAL REEF MANAGEMENT (Abstract ID: 28947)

The global conservation funding gap is estimated at $7 trillion USD and growing. For management of marine environments, funding is inadequate in terms of the size, duration, and diversity of revenue. Through critical policy analysis and semi-structured interviews, at the global scale and with Great Barrier Reef case studies, this research crosses disciplines and sectors to set the foundation of the "new and emerging field" of marine conservation finance. Case studies include 1) effective marine offsets for the Great Barrier Reef World Heritage Area, 2) a Great Barrier Reef sustainable agricultural loan fund that achieves water quality outcomes and private profits, and 3) a global assessment of opportunities and challenges to develop marine impact investments – models that generate net positive marine outcomes alongside financial returns. Results indicate that innovative finance mechanisms can be employed for marine conservation, but specialized capacity and transition capital need to be developed. Strategic consideration of finance – at the beginning of a conservation planning process and with the engagement of stakeholders – is a critical catalyst to achieving marine conservation outcomes. http://www.marineconservationfinance.com

THE EFFECTIVENESS OF AN MPA NETWORK IN MANAGING THE WEST HAWAI'I AQUARIUM FISHERY (Abstract ID: 28241 | Poster ID: 267)

The commercial collecting of marine organisms for the aquarium trade has been a controversial activity in West Hawai'i for over 30 years. In January 2000, a network of nine Fish Replenishment Areas (FRAs) was established in West Hawai'i to address declines of aquarium-collected reef fishes and associated user conflict. The FRAs, which prohibit aquarium collecting, were designated with substantial community input and together with already established protected areas, comprise 35.2% of the coastline. Further management actions have followed over the succeeding years culminating most recently in new rules limiting aquarium collecting to only 40 permitted fish species, size/bag limits on three heavily targeted species and the addition of a new FRA in South Kona. Coupled with an extensive ongoing monitoring program, the West Hawai'i aquarium fishery is one of the most intensively managed and studied fisheries in Hawai'i. Nonetheless, in recent years distortion and misinformation, oftentimes deliberate and purposeful, have increased regarding the fishery and its impacts on West Hawai' reef fish populations. Drawing on coral reef monitoring data and other relevant scientific information, this talk will attempt to address some of the mythology surrounding the aquarium fishery and provide a more reality-based view of aquarium collecting and the effectiveness of the FRA network.

NITROGEN ISOTOPES IN CORAL SKELETON-BOUND ORGANIC MATTER: INFLUENCES IN THE MODERN OCEAN AND APPLICATION TO FOSSIL TAHITI CORALS FROM THE LAST DEGLACIATION (Abstract ID: 28864)

The isotopic composition of skeleton-bound organic nitrogen in shallow-water scleractinian corals (hereafter, CS-d15N) is an emerging tool for studying the reef nitrogen cycle in the past. We have developed a sensitive and precise method for measuring CS-d15N at seasonal resolution (Wang et al., 2015). Many coral reefs receive their primary nitrogen sources from the open ocean, and the CS-d15N of these corals may provide information on past changes of the open ocean regional and global nitrogen cycle. In this study, we measured CS-d15N in modern shallow-water scleractinian corals from 8 sites proximal to the open ocean. A broad range in CS-d15N (of ~10‰) is measured across these sites, with a strong correlation between CS-d15N and the d15N of the deep nitrate supply to the surface waters near the reefs. While CS-d15N can be affected by other N sources as well and can vary in response to local reef conditions as well as coral/symbiont changes, this survey indicates that, when considering corals proximal to the open ocean, the d15N of the deep nitrate supply to surface waters drives most of the CS-d15N variation across the global ocean. Thus, CS-d15N is a promising proxy for reconstructing the open ocean nitrogen cycle in the past. With this new tool, we have measured CS-d15N in fossil Tahiti corals (with U-Th ages of 14.3 ka, 13.3 ka, 11.8 ka and 8.4 ka) collected during the Expedition 310 of International Ocean Discovery Program. The implications of these results for the regional nitrogen cycle as well as the deglacial changes in Southern Ocean processes will be discussed.

HOW CORALS GOT BONES -- COMPARATIVE GENOMICS HIGHLIGHTS THE EVOLUTION OF CORAL CALCIFICATON (Abstract ID: 28763 | Poster ID: 23)

The massive calcium carbonate skeletons of reef-building corals form the large structures that provide an essential habitat for a variety of marine species. Here, we set out to understand how the non-calcifying ancestor of contemporary corals evolved to become a foundation species of an entire ecosystem and to identify genes essential for the calcification process. For this purpose, we assembled and annotated the genomes of the two Corallimorpharia Amplexidiscus fenestrafer and Discosoma sp., and compared them to the genomes of the non-calcifying anemones Nematostella vectensis and Aiptasia pallida, as well as the calcifying corals Stylophora pistillata and Acropora digitifera. Phylogenetic analysis using 1021 single copy genes confirmed that Corallimorpharia is a sister group of Scleractinia, thereby rejecting the "naked coral" hypothesis and allowing the use of this order as closest non-calcifying relatives of reef building corals in subsequent analyses. Ortholog analyses across the six genomes highlighted the expansion of several gene families involved in calcium ion binding, CARD domain binding, carbonate dehydratase activity and transmembrane receptor protein tyrosine phosphatase activity in Scleractinia. Phylogenetic tracing of calcification genes across the six genomes highlighted different evolutionary origins of these genes, including recruitment and adaptation of existing orthologs as well as gene duplications and neofunctionalization in the coral lineage.

CORAL OPTICS AND THE USE OF PULSE AMPLITUDE MODULATED (PAM) FLUOROMETRY (Abstract ID: 29320)

Pulse amplitude modulated (PAM) fluorometry is widely used in photobiological studies of corals. PAM is easy to use and provides numerous photosynthetic parameters to assess coral ecophysiology. Essentially, PAM instruments measure chlorophyll a fluorescence that originates from Symbiodinium harboured within the host tissue. Recent studies of coral optics have revealed that both coral tissue and skeleton strongly scatter light and that such light scattering differs between coral species. Light scattering by coral tissues can affect the irradiance that Symbiodinium receives within tissues and might thus also affect the intensity of fluorescence detected by the PAM. In the present talk, we provide a brief overview on the optical properties of corals and then ask whether coral optics can affect the interpretation of PAM-based photosynthetic parameters. Specifically, we developed Symbiodinium-containing optical phantoms that imitated the optical properties of different corals in order to investigate if variable chlorophyll a fluorescence is affected by light scattering phenomena in coral tissues. Our main findings suggest that PAM-based photosynthetic parameters differ between artificial tissues with different degrees of light scattering but identical Symbiodinium density. These first results have important implications for the use of PAM in studies on coral health, stress and photosynthesis.

CHANGES TO THE EARLY LIFE OF THE SEAHARE APLYSIA DACTYLOMELA WITH OCEAN ACIDIFICATION AND RISING TEMPERATURE. (Abstract ID: 29348)

Changes in the pH of the ocean that are predicted to occur this century due to climate change may have severe consequences for marine organisms by reducing calcification rates, growth and the ability to deal with other environmental stressors. The sea hare Aplysia dactomela is hermaphroditic and produces egg masses throughout the year on the southern Great Barrier Reef that contain thousands of embryos. In a series of experiments, newly produced sea hare egg masses were exposed to seawater with pH ranging from preindustrial to 7.6 in a flow through aquarium system treated with bubbled CO2. In the preindustrial treatment, CO2 was removed from seawater to increase the pH. Following treatments, the newly hatched larvae were also exposed to the pH treatments. In egg masses exposed to pH of 7.6, there were thinner walls, smaller egg cases with and fewer embryos per case and reduced growth of embryos. Hatched larvae demonstrated slower swimming speeds in the pH 7.6 treatment and higher mortality. In a separate series of experiments, egg masses were exposed to elevated temperature treatments and to combined pH and temperature treatments. Elevating the temperature 3°C had no obvious effect on embryo development. Combined treatments resulted in complete mortality of embryos just prior to hatching. This is the first study using Aplysia to evaluate changes in ocean acidification on embryo development of marine invertebrates.

YOU'VE COLLECTED MESSY CROWD-SOURCED DATA – NOW WHAT? LESSONS LEARNED FROM A CONTINUOUSLY EVOLVING, DECADE-LONG MARINE CITIZEN SCIENCE PROJECT. (Abstract ID: 29580 | Poster ID: 732)

Marine ecosystems are undergoing massive transformation due to the effects of multiple human stressors. Action to protect what is left has been slow for many reasons, such as inadequate administrative capacities or stakeholder pushback, but a lack of data often supports inaction. Recent technological advancements and interdisciplinary collaborations have increased what is known. But the ocean is vast, and there are many data gaps. Projects that crowd-source data are increasingly being used to study marine ecosystems, and have the potential to fill some of these gaps. For example, eShark-Thailand (eOceans.org) has >13,000 records (>10,000 hours) submitted by divers on 185 sites, including encounters with sharks, rays, jellyfish, turtles, seahorses, etc. The problem, however, is that these data are messy: sites are not randomly assigned, effort is not standardized, contributors have varying experience, and species identification is not trivial. But, do these issues negate their value? Here, we present insights from a decade of lessons learned, and assert that crowd-sourced data can be valuable, if: the survey and database are compact and statistically robust with validation in mind; strong two-way relationships are made with outreach and field teams; and there is feedback from participants when interpreting results. We further demonstrate the value of these data through a marine spatial planning exercise using eShark-Thailand, where we investigate the hotspots and drivers of elasmobranch diversity and abundance, and overlay threats to delineate priority conservation areas.

OCEAN ACIDIFICATION AND ITS IMPACT ON ECOSYSTEM PRODUCTION IN LAGOON AND OFFSHORE WATERS OF PALAU (Abstract ID: 29429)

Ocean acidification (OA) in offshore and lagoon waters of Palau have been studied from periodical and intermittent samplings in the past two decades (1992-2015). The decreasing trend was found for pH and Omega aragonite both in the offshore and lagoon waters, although the lagoon water was systematically lower by ca. 0.05 in pH and ca. 0.3 in Omega compared to the offshore water. Reef scale productivity was estimated from changes in the total alkalinity and dissolved inorganic carbon differences between the offshore and lagoon waters and compared with the past data. The reef scale calcification seems to be slightly recovering compared to the level found between years 1999 to 2002. The recovering trend of reef scale productivity may be due to the recovery of coral coverage in the reef slope and patch reef communities. From an incubation experiment using Porites cylindrica sampled in the lagoon, we found the calcification rate shows logarithmic response to Omega, and is more severely affected when omega reaches 2.0 which is expected to occur in mid-22nd century in Palau if this OA trend continues.

GROWTH HISTORY RECORDED IN SKELETAL STABLE ISOTOPES IN THE MESOPHOTIC PORITES CORAL FROM THE GULF OF EILAT, RED SEA (Abstract ID: 28673 | Poster ID: 338)

Mesophotic coral ecosystems are found at depth below 30m. Due to its depth, the mesophotic zone is relatively protected from climatic and anthropogenic disturbance at the surface. Under relatively undisturbed conditions, mesophotic coral ecosystems may act as refugia. Owing to its depth, it has been difficult to observe mesophotic coral growth patterns and histories. Here we introduce geochemical approaches recording ocean environment for Porites coral growing from the mesophotic zone. Oxygen isotope provides sea temperature (ST) and salinity variability with distinct seasonal cycles. We used oxygen isotopes in coral carbonate skeleton to discuss coral growth histories in mesophotic zone. Two Porites corals were collected at sea surface and 50m depth from the Gulf of Eilat, the northernmost part of Red Sea. We applied skeletal oxygen and carbon isotopic analysis using stable mass spectrometry. Analytical results were compared with in-situ environmental data to discuss about difference of growth responses. These existed the difference of histograms of oxygen isotope record between predicted from ST and coral skeletons. The histogram of the mesophotic coral oxygen isotope records showed higher frequency of those recorded in summer than winter. This suggested a decrease or cessation of coral growth at mesophotic zone in winter. Usually, sea surface corals cease coral extension below 18°C at high latitude. Comparison of coral growth history between sea surface and mesophotic zone revealed that the temperature threshold of coral growth varied in response to coral water depth.

A 100 YEARS CORAL GROWTH HISTORY IN VOLCANICALLY ACIDIFIED ENVIRONMENTS: ANALOGUES FOR CORAL ACCLIMATION TO FUTURE OCEAN ACIDIFICATION (Abstract ID: 29064)

Experimental and modelling studies are suggesting that the projected ocean acidification due to rising atmospheric carbon dioxide concentrations would have dramatically influenced on the calcification processes of marine organisms. Recent field based observation in volcanically acidified coral reefs have revealed on-going drastic ecological shifts. However, the long-term observation is very limited for the prediction of coral acclimation in future acidified ocean predicted in next century. Tropical shallow water corals could record long-term growth histories in annual bands of their aragonite skeletons as well as marine environmental changes during a few hundreds years. We discovered the large massive Porites corals living around active volcanic island of Satsuma Io-Jima, Japan, providing a unique opportunity to observe marine organism living under extreme

environments of low pH condition accompanied with volcanic gases emission from sea flower. We collected coral cores around the island inside and outside the rim ridges of Kikai caldera. We applied geochemical approaches (δ18O, δ13C, Sr/Ca, Mg/Ca, Ba/Ca, and F/Ca) and x-ray densitometry (calcification rate, skeletal density, and extension rate) to demonstrate the relationship between volcanic and hydrothermal activities and coral growth characteristics during last one hundred years, including submarine volcanic eruption in 1934. Coral extension rate at the site near hydrothermal vent was significantly small, suggesting the influence by low pH water and/or hydrothermal activity. We discuss the possible future analogue of coral acclimation against ocean acidification and marine pollution in natural system.

WATER QUALITY IMPROVEMENT PLANNING AND INVESTMENT PRIORITISATION: A CASE STUDY FROM THE GREAT BARRIER REEF, AUSTRALIA (Abstract ID: 28918)

The Great Barrier Reef (GBR) Australia, is a unique ecosystem from ecological, social and cultural perspectives, and its interdependence with adjacent catchments. The health of the GBR is dependent on the function of the catchment and coastal ecosystems, and the quality of the water that is discharged from rivers and streams, mostly in wet season rainfall events. The adjacent catchment has been significantly modified since European settlement (~1850) through agricultural land uses, and to a lesser extent, coastal development. These changes have resulted in the transport of much greater loads of sediments, nutrients and pesticides to coastal and marine environments. The coastal ecosystems have also been heavily modified or removed, resulting in degraded habitats and disrupted hydrological connectivity. The challenge for natural resource managers is to adopt a whole-of-system approach to management, connecting knowledge of biophysical and socio-economic aspects of the catchments to the coastal and marine ecosystems. We present a case study in the Wet Tropics region in North Queensland of how this understanding has been incorporated into regional water quality planning. We outline the baseline data used for planning at regional scales, summarise the approaches to integrating indicators from the catchment to the reef, and identify priority actions and challenges. The water quality planning outcomes are being used to inform investment in the region, targeted to address declining water quality, possible drivers of crown of thorns starfish outbreaks and GBR ecosystem health.

OCEAN ACIDIFICATION ALTERS MARINE INVERTEBRATE BEHAVIOUR VIA NEURAL IMPAIRMENT (Abstract ID: 29038)

Ocean acidification poses a range of threats to marine invertebrates including reduced growth and calcification. However, the potential effects of rising CO2 on marine invertebrate behaviour are largely unknown. Here we show that projected near-future seawater CO2 levels (~600, ~950 µatm) alter marine invertebrate behaviours. In squid, elevated-CO2 increased activity ~3-fold and altered their behavioural strategies when startled, with more squid choosing escape and inking at elevated-CO2, compared with threat responses at control-CO2. In gastropods, elevated-CO2 impaired escape behaviours during predator-prey interactions. Coral reef conch snails normally leap backwards rapidly when faced with a predator. However, elevated-CO2 halved the number of snails that jumped from the predator, increased their latency to jump and altered their escape trajectory. Elevated-CO2 impaired decision making but did not affect physical escape ability. Antipredator behaviour was fully restored by treatment with gabazine, a GABA receptor antagonist of some invertebrate nervous systems, indicating potential interference of neurotransmitter receptor function by elevated-CO2 in invertebrates, as previously observed in marine fishes. Altered invertebrate and fish behaviour at projected mid- to end-of-century CO2 levels could disrupt species interactions, community structure and food web stability with potentially far-reaching implications for marine ecosystems.

NEMATODES DISTRIBUTION AND COMMUNITY STRUCTURE IN RHIZOPHORA MUCRONATA FOREST, MIDA CREEK- KENYA (Abstract ID: 29416 | Poster ID: 660)

Nematodes are among the most abundant organisms in marine ecosystems where they play a critical role in nutrient cycling, provision of nourishment to the higher organisms in the food web, pests control as well as acting as disease-causing vectors. Despite their importance and significance in marine ecosystem, there is inadequate scientific understanding of the nematodes' status and distribution in most tropical ecosystems. This study determined the distribution and community structure of nematodes in Rhizophora mucronota forest stand at Kirepwe and Dabaso sites of Mida Creek. Three replicates of sediments samples were randomly collected from one site Kirepwe and two sites in Dabaso (Dabaso site 1 and Dabaso site 2) using plastic corers (length= 10cm, diameter= 20mm). The samples were preserved using 5% buffered formalin solution, stained with Rose Bengal (to aid in sorting of the nematodes) and observed under a light microscope. Eighty one (81) genera of nematodes were encountered in the study mostly dominated by Terschellingia (15.3%), Molgolaimus (6.9%) and Paracomesoma (6.6%). Shannon Weiner diversity index were relatively high in the three study sites i.e. 3.31, 3.43 and 3.26 for Kirepwe, Dabaso site 1 and Dabaso site 2, respectively. Nematodes taxa evenness was similarly high in the three sites i.e. 0.50, 0.57 and 0.53 for Kirepwe, Dabaso site 1 and Dabaso site 2, respectively. The results further showed that the three sites had similar nematodes distribution and community structure ($p>0.05$, F-test) suggesting that diversity in mangrove sediments is regulated by mangrove tree species.
Key words: Mangroves, Taxa Diversity, Taxa evenness, Community Structure

SEWAGE POLLUTION: MITIGATION IS KEY FOR CORAL REEF STEWARDSHIP (Abstract ID: 29004)

Coral reefs are in decline worldwide, and land-derived sources of pollution, including sewage, are a major force driving that deterioration. This review presents evidence that sewage discharge occurs in waters surrounding at least 104 of 112 reef geographies. Studies often refer to sewage as a single stressor. However, we show that it is more accurately characterized as a multiple stressor. Many of the individual agents found within sewage, specifically freshwater, inorganic nutrients, pathogens, endocrine disrupters, suspended solids, sediments, and heavy metals, can severely impair coral growth and/or reproduction. These components of sewage may interact with each other to create as yet poorly understood synergisms (e.g., nutrients facilitate pathogen growth), and escalate impacts of other, non-sewage based stressors. Surprisingly few published studies (8) have examined impacts of sewage in the field – but those that have, suggest negative effects on coral reefs. Because sewage discharge proximal to sensitive coral reefs is widespread across the tropics, it is imperative for coral reef-focused institutions to increase investment in threat abatement strategies for mitigating sewage pollution.

WORKING WITH COMMUNICATION AND MESSAGING FOR VOLUNTEERS OLD, MIDDLE OLD, YOUNG AND YOUNGER (Abstract ID: 29868 | Poster ID: 709)

Communications in the digital age are far from straightforward. At the Hawaii Institute of Marine Biology, our Community Education Program volunteers and interns each have differing preferences on how they communicate and get their information. Sometimes these overlap and sometimes not, and at times our audience express strong feelings about some of the platforms (this can be negative or positive in direction). There are also limitations on each of the various communication methodologies. In addition to our volunteer docent program and our communication with teachers, we recently started a High School after school Marine Science Scholars club and noted that our traditional ways of communication were not working well. We show how we have partitioned our digital resources for our various audiences and resources, including a section in websites, blogs as repositories of training and teacher materials, videos to explain more complex behavior, bcc text messaging rather than email for routine communication with the younger generation, QR codes for recruitment brochures, cell phone calls when text will not do, and more.

OPTIMIZATION OF DNA EXTRACTION FOR CHARACTERIZATION OF CORAL-ASSOCIATED MICROBIAL COMMUNITIES (Abstract ID: 28643 | Poster ID: 142)

Previous studies utilizing cultivation-independent methodologies have demonstrated that Bacteria and Archaea may play pivotal roles in coral health. Having robust meth-

odologies to describe the diversity and structure of these communities is imperative for answering questions about coral health status. However, extraction of microbial DNA from some species of coral can be challenging due to the presence of inhibitory chemical compounds. In an effort to identify a robust method for DNA extraction from Bacteria and Archaea specifically, rather than the coral tissue, a study was designed that examined the impact of six different DNA extraction treatments on seven common Caribbean and Pacific coral species. A two-part analysis was conducted: first, nucleic acid yield and PCR amplification efficiency of ribosomal DNA were evaluated after extraction. Second, PCR amplicons produced from DNA extraction treatments with the highest DNA yields and PCR efficiencies were sequenced using Illumina MiSeq and this data was used to examine the microbial community composition associated with each treatment. The results indicate that some DNA extraction treatments (PowerSoil® and PowerPlant ® Pro DNA Isolation Kits) were not suitable for effective extraction and subsequent PCR amplification of the microbial communities from the coral tissues. Other treatments (UltraClean ® Tissue & Cells and PowerBiofilm ® DNA Isolation Kits) resulted in better yields and amplification from *Orbicella faveolata* and *O. annularis* coral species. These results identify two DNA extraction methods that are best suited for the microbial community analysis of some coral species.

## THE EVOLUTION OF THE GREAT BARRIER REEF OVER THE PAST 30 KA - NEW INSIGHTS FROM IODP EXPEDITION 325 (Abstract ID: 28511)

Sediments cored from the shelf edge of the Great Barrier Reef (GBR) during Integrated Ocean Drilling Program (IODP) Expedition 325 constrain the evolution of the GBR over the past 30 ka. This was a period of abrupt and major environmental perturbations, and responses of the GBR to these changes are largely unknown. We investigate the geomorphic, chronostratigraphic and biologic development of the GBR from 30 to 10 ka, using all available multibeam, seismic, C14 and U-Th dating, sedimentologic, and coralgal assemblage data. We define five distinct reef sequences over the past 30 ka, and discuss their chronostratigraphic development and paleoenvironmental settings. We document a highly dynamic system characterized by recurrent growth and demise of reef sequences as sea level fell to the Last Glacial Maximum (LGM) and then flooded across the shelf during the deglaciation. A major reef drowning event before the establishment of the modern GBR was likely caused by poor water quality associated with increased shelf flooding and sediment flux during the rise. As a system of reefs, the GBR has a remarkable capacity to migrate both seawards and landwards, despite major changes in sea level (e.g., meltwater pulses) and sea surface temperatures. This capacity - and the ability to re-seed itself locally - suggests the GBR was more resilient than previously described. Finally, we discuss the broader implications of the Exp. 325 record for understanding global reef demise and resilience, and for constraining relative sea-level changes.

## MAPPING ANTHROPOGENIC AND ENVIRONMENTAL DRIVERS OF HAWAIIAN CORAL REEF ECOSYSTEM STATES (Abstract ID: 29770 | Poster ID: 406)

A major challenge for coral reef management is understanding how a wide range of interacting human and natural drivers cumulatively impact marine ecosystems; yet comprehensive, spatially explicit data on such drivers are often lacking. We quantified and mapped environmental and anthropogenic drivers of coral reef ecosystem states in the main Hawaiian Islands to fill this important data gap. Environmental drivers were derived from climatological ranges and anomalies of remotely sensed sea surface temperature, chlorophyll-a, irradiance and wave energy over long time series. We characterized anthropogenic drivers using empirically derived and modeled datasets to map fishing pressure, sedimentation, nutrients, new development, habitat modification, and invasive species. Some informative spatial patterns emerged, such as highly localized hot spots of land-based sources of pollution across the island chain. In addition, the greatest mapped values of habitat modification, invasive species and commercial and non-commercial boat-based fishing pressure were all on Oahu. The resulting data are available for download and exploration through several user-friendly online mapping services (e.g., SeaSketch, StoryMaps), facilitating their use by scientists and managers interested in how climate, human activity and ecology interact to drive reef diversity, resilience and ecosystem state. Ongoing projects are using these products to investigate relationships between driver intensity and ecosystem condition, which will ultimately support ocean planning and ecosystem management in Hawaiian waters.

## ECOLOGICAL AND SOCIAL BENEFITS OF MARINE RESERVE NETWORK EXPANSION VIA DIFFUSION (Abstract ID: 28931)

Previous studies have shown that the "ad hoc" expansion of marine reserve networks is suboptimal to strategic expansion guided by systematic conservation planning. However, rather than being "ad hoc", the spread of community-based management can be explained by diffusion of innovation theory, which predicts for example that communities are more likely to adopt a conservation "innovation" (such as a marine reserve) if the benefits of doing so are directly observable or communicated by trusted peers. Using the example of marine reserves in the Philippines, we show that reserve system expansion following such a diffusion model may outperform representation-based conservation planning, both in terms of gaining stakeholder support and when assessed against objectives for population persistence. Reserves proximate to one another are more likely to exchange larvae via dispersal, creating synergistic effects that increase reserve efficacy. This is especially important where reserves are too small to support persistent populations within their boundaries, as in the Philippines. Though the existing reserve system is not fully representative of biodiversity features, growth following a diffusion model has resulted in sub-networks of connected reserves, which might help to explain the fisheries benefits observed within very small no-take marine reserves. In contrast, conservation planning that focuses solely on representation, without considering underlying ecological and social processes, could result in perverse outcomes for population persistence and fisheries-dependent livelihoods.

## BIOGEOGRAPHY AND FUNCTIONAL ADAPTATION OF CORAL REEF MICROBES (Abstract ID: 29013)

The microbial communities inhabiting reef ecosystems influence the health and resilience of coral holobionts. Benthic primary producers contribute significantly to reef microbial ecology by manipulating key environmental parameters (i.e., DOM and oxygen availability, pH) that influence the abundance and composition of microbes. The community structure and metabolic potential was investigated for microbes inhabiting coral reefs across an extensive area in the central Pacific. We found that the microbial taxa present correlated strongly with the percent coverage of corals and algae, while the functional capacity of the communities correlated best with geographic location. Based on these findings, we predict that the carbon sources available to microbes primarily determine their community structure. To further investigate this prediction, the response of reef microbes to enrichment with dissolved exudates from three types of benthic primary producers was examined in two-day dark remineralization incubations. A subset of enrichment cultures were subjected to decreased pH in order to evaluate the compounded effect of DOM availability with acidification. Microbial growth rates,

DOC drawdown, and changes to taxonomic composition and functional capacity were measured. Together, these empirical and in situ studies provide greater insight into how microbial players adapt and respond to the shifts in benthic coverage that reefs are succumbing to worldwide.

PALMYRA ATOLL RESEARCH STATION: UNDERSTANDING A NEAR PRISTINE MARINE ENVIRONMENT TO BETTER PROTECT MARINE ECOSYSTEMS GLOBALLY (Abstract ID: 30091)

In-depth assessments of intact marine ecosystems will provide valuable insights to the restoration and management of marine systems globally. Palmyra Atoll National Wildlife Refuge provides a premier location for research into some of the world's most pressing ecological concerns, including coral bleaching and disease, overfishing and other local anthropogenic stressors, invasive species, and climate change. Palmyra is co-owned and co-managed by the U.S. Fish and Wildlife Service (USFWS) and The Nature Conservancy (TNC), and TNC maintains a world-class research facility supporting a collaborative partnership with the Palmyra Atoll Research Consortium (PARC). PARC scientists have published more than 120 peer-reviewed papers over the past 10 years from their work at Palmyra. This presentation will outline Palmyra research and large-scale conservation projects that are informing global conservation management, such as the eradication of introduced rats that has had positive cross-system impacts, and the removal of three reef-polluting shipwrecks. Research at Palmyra continues with holistic food-web modeling, and monitoring of the behavioral ecology of top predators in pelagic, benthic, and terrestrial habitats of the Refuge. We will also highlight opportunities for additional cooperative research projects that can inform marine conservation and resource management for other tropical reef systems throughout the world's oceans.

COLLABORATION BETWEEN RESOURCE AGENCIES AND DOD FURTHERS UNDERWATER INVESTIGATION AND CLEANUP AT FORMER DEFENSE SITES IN VIEQUES AND CULEBRA, PR (Abstract ID: 29395 | Poster ID: 689)

The former Vieques Naval Installation was used for military training from the 1940s until 2003. It is estimated that up to 9,000 acres may contain munitions and munitions-related items. The island of Culebra and adjacent cays were also used by the Department of Defense as an impact range from 1903 until 1975. Approximately 2,660 acres of Culebra and surrounding islands and cays were used in training exercises by various defense agencies. There is an unquantified amount of unexploded ordnance in underwater locations around both islands due to the use of in-water target areas and overshoots of and skips from land-based targets. The investigation and cleanup of Vieques Island, under the jurisdiction of the U.S. Navy, and of Culebra, under the jurisdiction of the U.S. Army Corps of Engineers (USACE) are ongoing. NOAA participates on technical committees led by the Navy and USACE created facilitate the cleanup of underwater areas surrounding these islands. Collaboration allows public safety concerns to be addressed while ensuring the protection of NOAA's trust resources, particularly ESA-listed corals. The creation and required implementation of standard operating procedures (SOPs) for underwater survey and cleanup work is a measure that has proven highly successful in enabling underwater investigations and limited cleanup efforts to proceed while protecting corals and other marine resources. SOPs include avoidance and minimization of impacts to corals and seagrass from vessel operation, in-water survey equipment, intrusive investigations, and removal actions.

SHARING OR COMPETING? ECOLOGICAL NICHES OF JUVENILE SHARKS WITHIN A MUTUAL SHARK NURSERY (Abstract ID: 29437)

According to niche theory, ecologically and morphologically similar species need to segregate in different niches in order to avoid competition and to successfully coexist within the same habitat. Segregation between sympatric species can be achieved by either spatial, temporal, or trophic niche partitioning. Coastal reef sharks often use lagoons as nursery areas for their young, where inter-specific competition may be particularly high due to large numbers of pups. Investigation of competition within shark nurseries at fine spatial scales are lacking, despite its importance for coastal nursery management. At St. Joseph Atoll, Seychelles, two sympatric juvenile shark species, the sicklefin lemon shark, Negaprion acutidens, and the blacktip reef shark, Carchahinus melanopterus, use shallow flats as a communal nursery. Both shark species are viviparous with no maternal care, therefore inexperienced and opportunistic behaviour is assumed to lead to niche overlaps and competition. We investigated spatial and temporal niche partitioning between the species by manual active tracking and GPS loggers. We also quantified dietary overlap using visual and molecular analysis of stomach contents (DNA barcoding), and analysis of stable isotopes (SIA) of red blood and plasma tissues. Preliminary results show various degrees of spatial and trophic segregation between the two species. If niche partition results through the avoidance of competition, or if it is shaped by species-specific food or habitat preferences, remains to be proven.

A COMPLEX ECOSYSTEM MODEL TO EVALUATE ECOSYSTEM SERVICES OF ALTERNATIVE MANAGEMENT SCENARIOS (Abstract ID: 29567)

Ecosystem modelling is increasingly used to explore ecosystem-level effects of changing environmental conditions and management actions. For coral reefs, there has been a push in recent decades toward the use of ecosystem models to evaluate effects of fishing and the efficacy of marine protected areas. However, ecosystem models that integrate physical, biogeochemical, and ecological dynamics, including human interactions, remain underdeveloped. An ecosystem model that does integrate all of these dimensions is the Atlantis model. We developed an Atlantis model of the coral reef ecosystems of Guam Island in the Western Pacific. We applied it to evaluate tradeoffs both from a management standpoint and from a resource users' standpoint. Using a suite of management scenarios prioritized in consultation with local resource managers, we quantified the ecosystem services (e.g. fishery landings, ecological state) in terms of socio-ecological costs and benefits of alternative management scenarios. We then evaluated the same management scenarios, but using performance indicators of the participation in reef fishery (an important social and cultural activity) and in diving (an important economic activity). This approach shows the utility of ecosystem models in evaluating socio-ecological tradeoffs.

PAST, PRESENT, AND FUTURE MESOPHOTIC REEF SHELF ACCRETION POTENTIAL: A CARBONATE BUDGET APPROACH (Abstract ID: 29268)

Heterogeneous geomorphology in mesophotic reefs promotes high biodiversity and refuges for commercially important fish. Yet little data are available to understand the geological history and structural sustainability of the underlying architectural framework supporting these deep systems. To address these concepts, the first mesophotic reef carbonate budget model was used in the U.S. Virgin Islands at four upper mesophotic reef habitats with different structural characteristics. Combining bioerosion and calcification measurements, coral cover and rugosity surveys, and sediment composition analyses showed that coral growth did not always dominate gross carbonate production but all mesophotic reef habitats had positive net carbonate production rates. Rates were within the range measured by other studies for shallow-water reefs throughout the Caribbean but were lower than those estimated from mesophotic sites nine years earlier, suggesting mesophotic reef structure is not completely spared from climate change processes degrading shallow-water reefs. Still, net positive rates imply these mesophotic reefs are able to maintain and build structural complexity. Reef accretion and sea-level models suggest that variable net carbonate production rates were not the main driver of complex, shelf-wide geomorphology. However, assuming relatively continuous accretion rates since the stabilization of present-day sea level, results indicate net carbonate production variability greatly contributed to the habitat-scale structural complexity differences that help maintain high biodiversity.

HERITABLITY OF CO2 TOLERANCE IN A CORAL REEF FISH (Abstract ID: 27974)

Projected future CO2 levels cause behavioural impairment in reef fishes and populations will need to adapt to maintain their performance. To evolve through natural selection a trait must exhibit heritable phenotypic variation. We tested for individual variation in

behavioural tolerance to high CO2 in the spiny damselfish, Acanthochromis polyacanthus, and then used parent-offspring correlations to assess the heritability of this variation in both field and laboratory populations. Adult pairs of A. polyacanthus and their offspring were collected from around Lizard Island and their response to chemical alarm cue (CAC) was tested after four days exposure to high CO2. Parent-offspring correlations were then performed. In the laboratory, breeding pairs of A. polyacanthus were formed based on their relative behavioural tolerance to high CO2. Offspring from these breeding pairs were reared in control and high CO2 treatments for six weeks. Offspring response to CAC was measured at six-weeks and compared to their parents and siblings. Both field and laboratory populations exhibited a close correlation between offspring and their fathers for tolerance to acute-CO2 treatment, indicating strong heritability in behavioural tolerance to high CO2. However, heritable variation was absent in offspring that had been chronically exposed to high CO2. This study uniquely demonstrates heritability in behavioural tolerance to projected future CO2 levels in both laboratory and wild populations, but also the potential for heritability to diminish with chronic exposure to environmental stress.

HOST ENERGETIC AND STABLE ISOTOPE DIFFERENCES ASSOCIATED WITH PARASITISM IN TWO CORAL REEF FISHES (Abstract ID: 29067 | Poster ID: 251)

Parasites dominate coral reef biodiversity, effect host condition and behavior and thus can influence population and ecosystem dynamics. Cymothoid isopods of the genus Anilocra are large, conspicuous parasites of coral reef fishes. French grunt (Haemulon flavolineatum) and brown chromis (Chromis multilineata) are common hosts of Anilocra spp. infection in the Caribbean. To assess effects of Anilocra spp. on energetics of these fishes, we examined relationships between infection and muscle tissue composition and calories, and gut content volume. We also tested effects of A. haemuli on host oxygen consumption. To assess potential ecological effects of infection, we conducted stable carbon and nitrogen isotope analyses of infected and uninfected fish. Infected grunt had reduced muscle condition but similar calorie values and gut volume compared to uninfected fish. Infected chromis had similar muscle condition and caloric values compared to uninfected fish. A. haemuli infection also significantly increased host oxygen consumption while swimming, and increased respiratory demand was not alleviated with parasite removal. French grunt δ13C values reflected seagrass isotope values, but infected fish were significantly enriched in 13C and 15N. Thus infected French grunt feed on different prey, and/or are in poorer condition, compared to uninfected fish. For brown chromis there was no significant effect of infection on 13C and 15N. Our study provides evidence of a host-specific link between parasite-driven physiological and ecological effects involving reef fishes.

A COLLABORATIVE APPROACH ON MARINE PROTECTED AREA NETWORK ESTABLISHMENT IN INDONESIA, A CASE STUDY FROM NUSA PENIDA AND BANDA ISLANDS (Abstract ID: 28124)

The reformation regime in Indonesia raising an opportunity for stakeholders to be more involved on marine conservation effort. In the previous era, the top-down approach by government was dominant where stakeholders participation were excluded. Conflicts appears in protected areas included marine protected areas (MPAs) between community and government related management authority. The government declared new laws in term of coastal and marine resources management included fisheries and marine conservation. Its such as Law No.31, year 2004 regarding Fisheries, and Law No.27, year 2007 regarding coastal and small island resources management. The laws mentioning important of stakeholders participation into fisheries, coastal and marine resources management. In term of providing best practices in Indonesia, the Nusa Penida MPA in Bali and Banda Islands MPAs in Maluku, utilizing the opportunity to develop a collaborative approach on MPA and the network establishment. Its combination between bottom up and top down approach. Stakeholders has a chance to be actively involved on MPAs establishment and management proportionally. The lessons learned are combination between traditional knowledge and scientific datas are the best input on MPA and its network design, in certain stages the collaborative approach take time and need more resources as the result develop a strong support as well as minimilizing conflicts on MPA establishment processes.

IS PRIVATIZATION THE NEW GREEN? TWO NON-GOVERNMENTAL ENFORCED MARINE RESERVES IN CHINA AND TAIWAN (Abstract ID: 28048 | Poster ID: 636)

Marine reserves (MRs) have emerged as a preferred method to protect coral reefs from overfishing and human disturbance. However, due to ineffective enforcement by governments, many MRs have been reduced to mere "paper parks". This is especially true in many Asian countries such as China and Taiwan where compliance is low and resources dedicated to enforcement may be scarce. Privately managed marine reserves (PMMRs) or locally-managed marine reserves (LMMRs) may be effective in areas where government enforcement is lacking. We aimed to determine if PMMRs and LMMRs are a viable alternative strategy to protecting coral reefs. In Taiwan and China, we surveyed and compared the fish and coral coverage in national marine reserves (MRs) to that in areas of coral reef leased to and managed by dive operators and beach-side lodges (PMMRs/LMMRs). Generally, we found higher fish abundance, species number and fish size at sites within PMMRs/LMMRs compared to MRs. However, in China, other human impacts such as marine debris and illegal coral collection in PMMRs were evident. The increasing popularity of social media and mobile phones with cameras has meant that many instances of illegal fishing or human disturbance have been broadcasted quickly. With the use of social media by aware citizens to aid compliance, PMMRs and LMMRs would be an alternative coral reef management strategy in these countries.

UNRAVELING SOFT CORAL EARLY DEVELOPMENT AND ITS MOLECULAR BASES (Abstract ID: 28789)

The early development of the hard coral Acropora millepora has been described at both the morphological and molecular levels, and comparative studies are under way for other Scleractinia. Complementary data on Octocoral embryogenesis are essential for a broader understanding of the different developmental strategies in Cnidaria and their evolution. This pioneer study establishes the morphological and molecular bases of embryogenesis in a soft coral using Lobophytum pauciflorum. Early development in Lobophytum is morphologically unlike development in other studied Scleractinia. Stages between the fertilised egg and the 16-32 cell morula consist of an irregular cell mass without obvious blastomeres. After their appearance successive rounds of cell division follow, first creating smaller blastomeres and with decreasing cell size returning to an irregular mass of cells with a relatively smooth surface. Molecular data are crucial for a full understanding of this process in Lobophytum and its comparison to Anthozoa. Thereto, transcriptome sequencing was carried out on unfertilised eggs, a range of morphologically distinct developmental stages and adult individuals. Using Lobophytum gene predictions as reference, temporal patterns of differential expression were established relative to the adult stage. We further aim to identify the homologs of key Acropora developmental genes in Lobophytum: comparison of expression patterns using in-situ hybridisation should increase understanding of the molecular bases of the broad range of developmental strategies displayed by Anthozoa.

CORALS & CLIMATE ADAPTATION PLANNING: APPLYING CLIMATE-SMART PRINCIPLES FOR RESILIENCE-BASED MANAGEMENT (Abstract ID: 28204)

The Corals & Climate Adaptation Planning (CCAP) Project is a collaborative effort to explore frameworks and methodologies for climate change adaptation planning for coral reefs. Operating under the auspices of the Climate Change Working Group of the U.S. Coral Reef Task Force, its goal is to tailor and explore the utility of a recently-developed Climate-Smart framework for use in resilience-based coral reef management. A first draft of the tailored CCAP framework was explored and critiqued at a stakeholder workshop in Honolulu, Hawaii in July, 2014. Using West Maui as a case study location, special focus was given to the thought process for brainstorming adaptation options and adjusting existing management activities through Climate-Smart design. Based on these workshop discussions, an Adaptation Design Tool has been developed that integrates information on vulnerability, resilience, and adaptation strategies gleaned from the literature and provides a stepwise process for designing place-specific, climate-smart adaptation options for resilience-based management. This presentation will provide an overview of the CCAP Project and associated Adaptation Design Tool, including results of expert consultations with practitioners in Hawaii and Puerto Rico to test the utility of the tool using real-world examples from their existing management plans.

GROWTH, FEEDING PREFERENCES AND SURVIVORSHIP OF CAPTIVE BRED SEA URCHINS, TRIPNEUSTES GRATILLA, AND POSSIBLE USE AS BIOCONTROL FOR INVASIVE ALIEN ALGAE (Abstract ID: 29189)

Over the past 70 years, Kaneohe Bay has seen aggressive spread of alien invasive algae. Native algae and corals are being increasingly replaced with expanding monocultures of alien algae in large areas of the bay. Programs to remove macroalgae from the reef are supplemented with native hatchery-raised urchins being released onto cleared reefs to prevent regrowth. We investigated the survivorship, growth and dietary preferences of these hatchery-raised urchins, to evaluate their likely efficacy as biocontrol agents. When fed ad libitum on single species of algae, urchins grew significantly faster on diets of Graciliaria salicornia and Kappaphycus clade B than on Eucheuma denticulatum, with intermediate growth on Acanthophora spicifera. In choice feeding trials, we find small urchins (22.5 mm test diameter) preferred A. spicifera to all other species of algae. Medium-sized urchins (25 – 43.5 mm TD) fed preferentially on both A. spicifera and E. denticulatum. Large urchins (45mm TD) grazed all algae at high rates, with significant affinities for A. spicifera and K. clade B. Post-transport survivorship of outplanted urchins was measured in paired open and closed cages in three different reef environments (lagoon, reef flat and reef slope). Survivorship in closed cages was highest on the reef flat (75%), and intermediate in the lagoon and on the reef slope (50%). In contrast, open cages showed similar survivorship on the reef flat and in the lagoon, but only 20% of outplanted urchins survived in open cages placed on the reef slope, suggesting predation on the deeper reef slopes.

TOWARDS AN INTEGRATED APPROACH TO CROWN-OF-THORNS STARFISH MANAGEMENT AND RESEARCH ON THE GREAT BARRIER REEF (Abstract ID: 28893 | Poster ID: 622)

Crown of thorns starfish (CoTS) have been a persistent focus of management on Indo-Pacific reefs for the last 50 years. To date the strategies for addressing CoTS have been simple– find locations with high densities and kill as many as possible. Such approaches have had limited success but, with the exception of new methods for killing, management approaches have evolved little. On the GBR, recognition that the urgency and scale of the problem vastly outweighs the resources available is driving a change – a shift to working smarter not just harder. Principles of Integrated Pest Management developed in terrestrial systems have led to the realization that existing CoTS biological and ecological knowledge must be integrated with an understanding of the spatial dynamics of CoTS populations. This integration is key to developing management strategies that increasingly will rely on models to predict population outcomes, their interaction with management, and to assess the effectiveness of alternative management options. Also significant is recognition that CoTS management is not a single problem with a single solution but rather a multi-scalar problem with different objectives and methods being relevant at different spatial scales, and at different times and places. In this presentation we review these developments and present an attempt to integrate across our current understanding of CoTS biology and ecology, and, our management capacity and objectives, to provide a coherent and ecologically-based framework for linking CoTS research and management on the GBR.

NOTHING IN *SYMBIODINIUM* BIOLOGY MAKES SENSE EXCEPT IN THE LIGHT OF CORRECT SPECIES IDENTIFICATION (Abstract ID: 29684)

In light of modern genetic techniques, there is growing awareness that taxonomic designations of *Symbiodinium* do not reflect biological reality. When these hidden species boundaries go undetected they cause spurious conclusions about their biology. Here we begin by describing the extent of this problem. We then give a brief introduction to several analytical techniques that have provided solutions, all of which generally aim to assign individual genotypes to genetically recombining groups prior to further analyses. We then discuss the results of several recent studies that have employed this approach, highlighting how critical errors in interpretation were avoided by first resolving species boundaries. We show that these approaches are an important first step in connectivity studies and highlight the critical role they have played in justifying the taxonomic status of several new species of *Symbiodinium*. Finally, we conclude with an examination of how these observations in *Symbiodinium* might extend to the study of other poorly resolved taxonomic groups, many of which reside on coral reefs.

QUANTIFICATION OF LAND BASED SOURCES OF POLLUTION IN SUPPORT OF CORAL REEF MANAGEMENT: CASE STUDIES FROM TWO U.S. CORAL REEF TASK FORCE PRIORITY WATERSHEDS (Abstract ID: 27984)

The U.S. Coral Reef Task Force has designated three priority watershed sites: Guánica Bay (Puerto Rico), Faga'alu Bay (American Samoa) and West Maui (Hawaii). The goal of these designations is to reduce land-based sources of pollution (LBSP) by facilitating and enhancing coordination, partnerships, and contributions of local and federal agency resources and expertise. By concentrating efforts in selected areas, the aim is to enact geographically specific integrated activities to reduce pollutant loads to coral reef ecosystems. Here, interdisciplinary scientific assessments in two of the priority watersheds (Guánica and Faga'alu) are presented, and the conclusions and management implications are compared. These studies, conducted by NOAA scientists alongside local and academic partners, quantified a variety of pollutant stressors, including sedimentation, nutrients and toxic contaminants, as well as metrics of coral reef ecosystem health. While both ecosystems are threatened by multiple pollution issues, the size and complexity of the Guánica watershed makes the task of managing these threats relatively more difficult than in Faga'alu. The demonstrated differences between these two systems reinforces that management actions to benefit coral systems cannot be "one size fits all" approach and must be tailored to an individual system.

POTENTIAL SYNERGIES OF THE CORAL TRIANGLE MARINE PROTECTED AREA SYSTEM AND MARINE TOURISM (Abstract ID: 27997)

The Coral Triangle countries: Indonesia, Malaysia, Papua New Guinea, Philippines, Solomon Islands, and Timor-Leste, each have evolving systems of marine protected areas (MPAs) at the national and local levels. Now with more than 1,900 MPAs covering 208,152 km2 (1.6% of the combined extended economic zones), the Coral Triangle Initiative for Coral Reefs, Fisheries and Food Security has endorsed a Regional Plan of Action that contains a target of establishing a "Coral Triangle Marine Protected Area System" (CTMPAS)as part of its goal on improving MPA management and expanding coverage to 20% of all critical marine habitats in the region. This presentation highlights the CTMPAS Framework and Action Plan and describes its development and contribution to improved resource management. The MPA System Framework contains guidance for standardizing how MPAs and MPA networks are evaluated for effectiveness, and provides options for scaling-up existing MPAs to networks of MPAs that are ecologically linked, integrated with fisheries management and responsive to climate. The Framework also provides for a link to private sector driven marine tourism as a means of supporting management and enhancing demand for conservation. Incorporation of marine tourism in the management framework provides incentives for the national and regional institutional players in government and the private sector to facilitate the continued sustainable development and implementation of the regional MPA system that focuses largely on improved management,expanded coverage at scale and human economic benefits.

TRADEOFF ANALYSIS FOR BALANCING MULTIPLE OBJECTIVES IN OCEAN MANAGEMENT (Abstract ID: 29556)

Marine conservation and management is a complex multi-objective challenge. Expansion of uses and industries reliant on marine ecosystem services and resources (e.g., fisheries, shipping, energy, aquaculture, coastal development, recreation) is exacerbating inter-sectoral conflicts and threatening conservation and sustainable use objectives. Tradeoff analysis is a decision-making tool that is well-suited to address this problem, because it explicitly accounts for multiple objectives and is adaptive to the location, scope and complexity of the problem. However, its utility remains uncertain or unknown to many scientists and managers, and its applications to marine systems are few. Our aim here is to demystify tradeoff analysis, and operationalize it in the hands of scientists and managers seeking to balance multiple potentially conflicting objectives in ocean management. We outline the framework of tradeoff analysis, then trial the tool with three novel coral reef system case studies: dredging of post-Panamax cruise ship lanes in Bermuda in relation to coral destruction yet enhanced tourism, design of periodically-harvested closures in Melanesia for meeting fisheries and conservation goals, and cost-effective repair of roads in west Maui for reducing sediment flow to adjacent coral reefs. In all cases: the tradeoff analysis steps are simple and tractable, the results reveal solutions that best minimize conflicts and maximize multiple ecosystem services delivery, and the value of the tradeoff analysis over conventional management is substantial.

THE EYES OF THE REEF NETWORK & BLEACHAPALOOZA 2015: HAWAII'S OCEAN COMMUNITY PROVIDES DATA ON EXTENT AND SEVERITY OF CORAL BLEACHING EVENT TO RESOURCE MANAGERS (Abstract ID: 30065)

Hawaii's reefs span an enormous geographical area making it difficult for resource managers to detect the early onset of coral bleaching, disease, Crown-of-Thorn seastars (COTS) and invasive species outbreaks. Reef users are essential in helping managers monitor reefs, providing the critical mass of 'eyes on our reefs' needed to detect and respond to events in an expedient manner. The goal of the Eyes on the Reef (EOR) Network is to inform, engage and train community members, ocean user groups, managers, NGOs and others in identification of coral bleaching, disease or COTS outbreaks and aquatic invasive species. The EOR Network is a broad outreach and education program that helps to provide the critical first tier of Hawaii's Rapid Response Contingency Plan and promote community stewardship of our valuable marine resources. In 2015, NOAA's Coral Reef Watch predictive satellite tools forecasted the most severe bleaching event in Hawaii's history. At the peak of the warm water event on October 3, a statewide effort known as 'Bleachapalooza' was organized to engage concerned ocean users to file reports of coral bleaching to capture the extent and severity of the bleaching event. Prior to the event, in the month of September when bleaching was highly visible, EOR received 66 reports. Bleachapalooza more than doubled that number with a total of 156 reports in October, giving managers a geographically broader and more detailed look at the event than was possible on their own. Citizen science is a critical component to management detection and response to threats to our reefs.

EVALUATING METAPOPULATION PATCH VALUE IN A MULTISPECIES CONTEXT FOR MARINE RESERVE DESIGN (Abstract ID: 29701)

The idea that some patches within a metapopulation can act as sources is key to marine reserve design. Theory dictates that high-value sources should be protected from harvest in order to ensure persistence and higher biomass. However, the nebulous "source" concept actually encompasses a number of distinct and potentially unrelated dynamic processes. To gain clarity in how metapopulation theory can best be applied to reserve design, we evaluated the utility of a suite of 'patch value' metrics that have been proposed as measures of 'source-ness' in metapopulations: self-persistence, self-recruitment, net import, net export, centrality, and deletion value. We calculated each metric for each of six fish species in a metapopulation model that included information on habitat distribution (km2-scale) and ROMS-derived larval connectivity patterns. We then simulated the assembly of reserve networks using each of the metrics as a reserve-selection rule, and calculated the overall biomass and yield of the six species as a measure of reserve success. Overall, we found that networks selected based on deletion value, larval export, and centrality performed well, while self-persistence was not a good predictor of overall metapopulation performance (likely because there were few sites with sufficient larval retention to be self-persistent). Our results emphasize the value of reserve networks, rather than lone reserves, for fishery and conservation success, as well as the challenge of finding reserve configurations that succeed for multiple species with disparate dispersal patterns.

DIVERGENCE IN A SINGLE TRAIT DRIVES INCIPIENT SYMPATRIC SPECIATION IN CORAL REEF FISH (Abstract ID: 30117)

There is growing recognition that ecological adaptation shaped by natural selection may be a major driver of diversification on coral reefs. In theory, speciation-with-gene flow is most plausible when ecologically important traits directly cause assortative mating, but few natural examples are known. Here, we demonstrate the potential for a single trait, color pattern, to drive incipient speciation in a sympatric population of the polymorphic hawkfish, Paracirrhites arcatus. First, we provide data demonstrating color morphs are exploiting alternative ecological niches, driven by disruptive natural selection favoring color patterns that are better camouflaged in contrasting microhabitats. Second, our experiments show that coloration is also important in choosing mates. The combination of ecological isolation and assortative mating is driving reproductive isolation among color morphs. Third, genome-wide sampling revealed divergent patterns of genetic variation across color morphs that correspond well to those expected in models of speciation-with-gene flow. Whereas the majority of the genome is homogenized by gene flow, there is significant divergence in a few functional genes that are likely under selection. Taken together, these results provide evidence that color pattern alone can drive incipient divergence in a single species, despite high gene flow and no geographic isolation. We argue that this may be a common and potentially significant driver of diversification on coral reefs.

HAVE INVASIVE LIONFISH IMPACTED THE PULLEY RIDGE MESOPHOTIC CORAL ECOSYSTEM? (Abstract ID: 29671 | Poster ID: 323)

Mesophotic coral ecosystems are deep fore-reef, low-light adapted, communities often comprised of scleractinian corals, macroalgae and sponges. At a depth of 60-80m, Pulley Ridge represents the deepest coral reef on the US continental shelf extending over 100km along the western edge of the Florida Platform. We surveyed this unique ecosystem using AUVs, ROVs, and technical diving; the reefs consist of at least 25 species of algae (~50% cover), 18 species of scleractinian corals (<1% cover), and over 50 species of sponges (1-2% cover), in addition to more than 80 species of fish. The

percent cover data represent a significant loss of coral and sponges relative to surveys conducted about a decade earlier. The impacts of coral reef stressors (e.g., bleaching, disease, hurricane damage, and acidification) have not been observed on Pulley Ridge, but the invasive lionfish, Pterois volitans, was first reported on these MCEs in 2010. We observed densities as high as 6.8±3.7 lionfish m-2, typically within "grouper holes", as well as active foraging on many species of fish. While direct comparisons of the Pulley Ridge fish populations pre- and post-lionfish need to be interpreted cautiously, there does appear to be a marked decline in several taxa. We hypothesize that the loss of coral and sponge cover, to increases in algae cover, is an indirect effect of lionfish grazing on herbivorous fishes, which releases algae from herbivory to out-compete slower growing corals and sponges.

SUSTAINABLE FINANCING FOR THE BIRD'S HEAD SEASCAPE AREA IN WEST PAPUA (Abstract ID: 29379)

The Bird's Head Seascape (BHS) region is the global epicenter of marine biodiversity where there are about 600 species of hard coral. The number of species is 75% of all hard coral species known to science today, so it is often referred to as the heart of the coral triangle, that is the triangular area of 6 countries that have the highest levels of coral diversity in the world. It is also known as kingdom of fish since more than 1,700 species of fish recorded by scientists. The BHS area is habitat for several endangered charismatic species as well. The wealth of the BHS's resources is a source of livelihood and food security for local residents. Therefore, to avoid the destruction of this area, initiatives to establish Marine Protected Areas in the Bird's Head Seascape has been done, as the result of a cooperation of the 'Bird's Head Consortium ' which is composed of government, local government and environmental NGOs such as CI, TNC, WWF, Starling Resources, and others. This collaboration have produced 12 Marine Protected Area with a total area of 3.6 million hectares spread out across several districts in West Papua and Papua. The main challenge in the management of Marine Protected Areas is 'high costs required' for the management. To answer this challenge, Yayasan Kemitraan Jantung Konservasi Dunia (YKJKD) or Partnership Foundation for the Global Epicentrum Conservation, has been established. YKJDK is designed to assist efforts to fill the shortage of funds management of this area through the establishment of 'trust fund' in the form of 'endowment' (endowment fund) or 'grants' (sinking fund) that locally managed for the longterm conservation purposes.

THE STRONG EL NIÑO, SEA LEVEL DROPS, AND SMELLY REEFS OF 2015–2016 (Abstract ID: 28813)

With El Niño events, come above-normal sea levels in the eastern Pacific and sea level drops in the west. During past strong events, such as that of 1997–1998, when trade winds temporarily stopped and allowed warm surface waters to slosh eastward, sea levels in the tropical northwestern and later the south-central Pacific were more than 30 cm below normal for several months. Such sea level drops exposed shallow corals to air at low tide (which became smelly) for much longer periods than they are normally exposed to. This can contribute to the formation and maintenance of microatolls, but also leads to widespread coral bleaching and death, thereby damaging shallow-water coastal ecosystems. Here we discuss the sea level drops of 2015–2016, associated with the strongest El Niño of the 21st century (so far), and report on the coastal exposure that occurred around Guam in 2015 and is predicted for American Samoa in 2016.

TRANSCRIPTOMIC BASIS OF HEAT STRESS TOLERANCE OF CORALS FROM THE WORLD'S HOTTEST SEA, THE PERSIAN/ARABIAN GULF (Abstract ID: 28723)

Coral communities from the Persian / Arabian Gulf ("The Gulf") survive summer temperatures of up to 35°C on a regular basis. Most corals elsewhere on the planet, including conspecifics of Gulf corals, are already killed at water temperatures above 32°C. Therefore, corals from the Gulf represent ideal models to study the limits of thermal tolerance in reef corals. Gene expression forms an integral part of the organismal response to challenging environmental conditions, the altered expression patterns can result from changes in both, the constitutional expression and the short-term regulation of stress-response genes. We have selected Porites lobata as a model to study gene expression of Gulf corals as this species 1) has a cosmopolitan distribution, 2) represents a habitat-forming species in the Gulf and 3) is suitable for long-term culture in experimental aquarium systems. Here, we present the results of our analysis of the transcriptome of Porites lobata from Sadiyaat reef and the changes in gene expression associated with the exposure to different environmental stressors.

A MULTI-TRACER APPROACH FOR IDENTIFYING SEWAGE POLLUTION HOTSPOTS ON A HAWAIIAN CORAL REEF (Abstract ID: 29644)

Hawai'i's coral reefs are deteriorating as a result of multiple stressors, with sewage being one of the most devastating ones. Puakō, a coastal community on Hawai'i Island, is one location of particular concern. It has some of the state's richest coral reefs, but coral cover has decreased 50% in the last 40 years, which is assumed to be associated with the high density of cesspools. However, data linking sewage pollution and reef deterioration are lacking. Our study used dye tracer releases, measurements of sewage indicators (fecal indicator bacteria, nutrient concentrations, δ 15N in macroalgae), and mapping tools to identify sewage pollution hotspots in near-shore waters at Puakō. Wastewater from homes reached shoreline waters within 6 hours to 3 days. Shoreline nutrient concentrations were two times higher than those in upland groundwater. Additionally, fecal indicator bacteria levels were high and variable along the shoreline, and much of the δδ15N macroalgal values were within the sewage range. To visualize sewage pollution hot spots, sewage indicator data layers were combined and used with mapping tools. Our study documented that sewage pollution is entering Puakō's nearshore waters, and highlights the need for a multi-tracer approach and mapping tools to identify sewage pollution hot spots for appropriate management actions.

DEEP SEA GAZING: MAKING SHIP-BASED RESEARCH ABOARD RV FALKOR RELEVANT AND ACCESSIBLE (Abstract ID: 29187)

Schmidt Ocean Institute (SOI) is a private, non-profit operating foundation established to advance the understanding of the world's oceans through technological advancement, intelligent observation and analysis, and open sharing of information. Scientists compete for the right to go to sea on our research vessel Falkor where they can take advantage of a wide range of modern scientific utilities, such as broadband Internet, high performance computing, robotic systems, live video streaming, and state of the art scientific instruments and labs. SOI is one of the only research programs that make their entire underwater vehicle dive series available online, creating a collection of video data that enables anyone to follow the deep sea research operations in real time. We encourage students and teachers to take advantage of our programs and materials in classrooms. Telepresence-enabled research is an important component of Falkor cruises, and SOI supported several projects focusing on coral reef research in 2015. In this presentation, we will discuss the methods we used to make oceanographic research accessible to the public, including an image tagging citizen science project conducted in partnership with the Australian Centre for Field Robotics. Intelligent utilization of several robotic platforms, high performance computing system, and broadband Internet enabled real-time robot tracking, image tagging, and an array of outreach activities that helped scientists on board to engage the public in interactive exploration of the ocean in its fascinating detail.

WORKING WITH FISHERS TO EVALUATE THE EFFECTS OF EXPERIMENTAL REMOVAL OF INTRODUCED ROI (CEPHALOPHOLIS ARGUS) ON REEF FISH POPULATIONS IN WEST HAWAI'I (Abstract ID: 29930)

Prior research showing that the introduced peacock grouper, locally known as roi, (Cephalopholis argus) consumed ~ 8 million fish/year from the reefs of west Hawai`i has raised concerns from fishermen and has inspired grassroots removal efforts statewide. A lack of scientific evidence corroborating the effects of roi on native prey fishes has led to mistrust and even threats from fishers towards reef managers. To resolve this disagreement, we worked with local spearfishers to implement a Before-After-Control-Impact experiment designed to detect changes in native fish communities after removal of roi at Puakō, Hawai`i. In April 2011, researchers and local spearfishers reduced roi populations by >90% on a 1.2 ha patch reef and surveyed fish populations twice a year for four years. Our findings indicate a significant decrease in roi abundance but no effect on native fish populations. A slight increase in small prey fishes (<15cm) was observed initially, but did not translate into an increase in overall fish biomass. Information was shared early and often at fishing tournaments and community events to increase mutual understanding between the fishing and management community, and fishers were active participants in multiple research projects linked to invasive fish removal activities, illustrating the benefits of honest and frequent communication to improve management-driven research effectiveness.

BIODIVERSITY OF CULTURABLE BACTERIAL COMMUNITY ASSOCIATED WITH THE DISEASED CORALS FROM NORTH JAVA SEA COASTAL WATERS INDONESIA (Abstract ID: 28917)

Coral reefs are experiencing a recent period of severe decline due to emerging coral diseases. However, little is known about how coral diseases are caused. Our objective were to investigate the general insights into the diversity of the bacterial community associated with diseased corals. To achieve these objectives, sampling was conducted at 2 different reefs condition along Java Sea namely Panjang Island,(heavily impacted agricultural areas)and Karimunjawa Archipelago (relatively pristine area). Coral disease rapid assessment were conducted in dry season of 2015. The prevalence of coral disease on the reef building corals was calculated as the mean percentage of coral colonies affected by disease per 50m2 transect quadrat. While culture collection of 34 bacteria associated with coral diseases was established by plating on Zobell's 2214E. Early assessment on prevalence study conducted at those site locations showed that the prevalence of coral disease was very high for all diseases observed on all reefs in the Panjang Island (74.37±5.29%, mean±SE) and Karimunjawa 27.86 ± 2.7 % SE (mean ± SE). The most common diseases found on each locations, White Plague and Brown Band, were selected for further studies. Polyphasic identification of bacteria associated with diseased coral White Plague showed that these isolates were closely related to two major groups of bacteria: Bacillaceae and Vibrioceae. While following partial sequencings WP strains of the 16S rDNA shown that Brown Band strains belonged to two major groups of bacteria: members of the Pseudomoneae and Bacillaceae.

BLOGGING 201: I'VE GOT A BLOG. NOW WHAT? (Abstract ID: 29222)

Blogs can play a key role in interfacing with the public. They can be used to create communities, share research findings, gain participants in citizen science initiatives, and even help drum up financial support. Starting a blog is easier than ever, with step by step instructions offered by major blog hosting sites such as Wordpress, however, advice for what comes next is harder to find. It is especially difficult to locate reliable information about best practices for scientists seeking to use blogs as outreach tools. Christie Wilcox, lead editor of Science Blogging: The Essential Guide, shares the best tips from the book to help you take your blog to the next level.

NUTRIENT SUPPLY TO THE GREAT BARRIER REEF (Abstract ID: 28984)

The nutrient supply driving pelagic and benthic productivity over the whole Great Barrier Reef and Lagoon system is quantified using a shelf scale 3D hydrodynamic, sediment and biogeochemical model. The (eReefs) model is based on the CSIRO Environmental Modelling Suite augmented with key tropical marine processes modules including coral and seagrass growth, carbon chemistry, Trichodesmium nitrogen fixation, phytoplankton pigment synthesis and a spectral optical model for accurate representation of the in-water light field. Nutrient forcing at the ocean boundary was derived from climatology, along the coast from 22 major river systems and atmospheric supply was included via rain. The model was validated against observations over a 4 year hind-cast simulation and reproduced the observed nutrient climatology, spatial gradients in ocean colour chlorophyll and in situ sensor and water quality observations. Results from the 3D model show the dynamic nature of episodic (< 1 week) subsurface upwelling events along the shelf edge that channel nutrient rich water through gaps in the reef to boosting local productivity. Results are consistent with sparse continuous nutrient observations from moorings and gliders and the model provides significant insight into the interpretation of these observations and the design of observing programs in complex reef topography. Budget analysis for subregions of the shelf quantify the primary nutrient sources in wet- and dry-seasons and identify the relative impact of coastal, ocean and atmospheric supply relevant to water quality management of the reef.

THE ESSENTIAL ROLE OF PLANNING FOR HUMAN DIMENSIONS OF LARGE MARINE PROTECTED AREAS (Abstract ID: 29970)

A new era of large-scale marine conservation has begun. Since 2000, more than 14 Large-Scale Marine Protected Areas (LSMPAs) have been declared - each more than 250,000 $km^2$ in size and totaling more than 7.2 million $km^2$. Due to their sheer size, complex socio-political realities, and distinct local cultural perspectives and economic needs, successfully implementing and managing LSMPAs is challenging. Given the rapid and recent growth in designation of LSMPAs and the potential challenges associated with creation and ongoing management, it was both timely and important to convene a "think tank" of, amongst other constituents, scholars and practitioners, advocates and critics to explore the human dimensions (HD) of LSMPAs. This global meeting held February 8-10, 2016: 1) evaluated existing human dimensions knowledge related to LSMPAs, 2) developed practical recommendations and identify best management practices regarding human dimensions considerations in LSMPAs, 3) produced a shared human dimensions research agenda for LSMPAs, and 4) launched an ongoing collaborative relationship among human dimensions researchers and Big Ocean, a learning network of LSMPA managers. The overarching goal of this collaboration is to be proactive in identifying solutions to overcome human dimensions challenges in LSMPAs. It is likely that overarching themes such as equity and transparency will be tenets based on HD research findings and experience. This presentation will highlight the outcomes of this meeting and how it has begun to influence LMPA planning and implementation.

INTRAGENOMIC VARIATION IN SYMBIODINIUM CORRELATES NEGATIVELY WITH PHOTOSYNTHETIC EFFICIENCY AND HOST PERFORMANCE (Abstract ID: 28849)

Reef-building corals are nutritionally dependent on the symbiotic alga Symbiodinium. The coral host may therefore select for high-performing clonal symbiont lineages, resulting in host-symbiont co-evolution. Yet somatic genetic variation between Symbiodinium clones may affect host performance, particularly under sub-optimal conditions. Applying quantitative PCR (qPCR) to Pocillopora damicornis colonies from Lord Howe Island (AUS), we estimated the relative abundance of Symbiodinium cells with homogeneous ITS2 sequence copies of type C100, and intragenomically variable (IGV) cells with at least two distinct ITS2 sequences including types C100 and C109. We then analysed the physical status and photosynthetic performance of each colony at both ambient and elevated temperature (25 and 29 °C) in a closed-system oxygen flux chamber. The proportion of IGV Symbiodinium was negatively correlated with net photosynthesis and photosynthetic efficiency, and under thermal stress, colonies dominated by IGV cells could only meet respiratory demands at high irradiance (> 250 μmol photons m-2 s-1). IGV Symbiodinium were also estimated to be 50% larger by volume, occurred at lower density, and had higher chlorophyll c2:a ratios than the homogeneous cells. While it is unclear whether their mixed rDNA arrays result from incomplete concerted evolution or recombination, the associated reduction in performance suggests a possible deleterious effect of IGV. It also demonstrates that the beneficial capacity of symbionts can vary within populations, with potential implications for host fitness.

DO CONSERVATION-FOCUSED DIVE BRIEFINGS REDUCE DIVER DAMAGE TO CORALS? (Abstract ID: 29940)

Diving tourism is generally considered "eco-friendly", but many coral reefs are dived intensively and are in danger of decline. Guam receives over a million tourists annually, and its coral reefs support about 300,000 dives each year. Dive boats frequent the same sites repeatedly, where divers damage corals by kicking, grabbing, bumping, entangling gear, and stirring up sediment. When reefs are dived intensively, these small but repetitive injuries to corals accumulate, and can result in delayed healing and tissue loss associated with algal overgrowth, disease, and predation. The effects of careless and uninformed diving practices on reefs could be mitigated through diver education with a focus on coral conservation. In this study, we deliver dive briefings containing varying levels of coral conservation information to divers on Guam, then observe and compare divers' coral contact rates during their dives. We also compare divers' contact rates with predictive factors such as camera use, experience, gender, and nationality to predict which divers cause the most damage and would most likely benefit from conservation-focused briefings. Benthic surveys will be conducted at intensively dived sites and similar undived sites to compare coral health and community structure. The results of this study will be used to support efforts of local agencies to legislate "eco-friendly" diving practices. They will also be presented at a workshop for local dive operators, who will be encouraged to include conservation material in briefings to promote long-term sustainable dive tourism on Guam.

PRODUCTIVITY-DRIVEN SHIFTS IN CORAL REEF BENTHIC COMMUNITIES: WHEN IS THERE TOO MUCH OF A GOOD THING? (Abstract ID: 28863)

Changes in primary productivity have pronounced effects on coral reefs. In some instances, evidence suggests a positive effect of increased pelagic productivity and associated particulate food availability on the cover of calcifying benthic organisms (e.g. hard corals, crustose coralline algae). In contrast, extreme levels of primary productivity can often lead to undesirable regime shifts where fleshy macroalgae dominate. Identifying the conditions under which increases in primary productivity switches from being beneficial to reef-calcifiers versus leading to their demise is a research priority. Using a series of unpopulated Pacific reefs and by combining high-resolution in situ oceanographic measurements, benthic community surveys, isotopic analyses, and statistical modeling, we explore the effects of changing levels of primary productivity on benthic community structure. We show increases in particulate food supply driven by local oceanographic processes, such as internal waves and downwelling, can correlate with higher heterotrophy in hard corals and their overall dominance as benthic competitors. The relationship between nutrients and coral dominance has a limit; at the extreme, these same oceanographic processes of nutrient delivery operating at similar intra-island spatial scales can elevate primary productivity to such a degree that corals lose the battle for space on the reef floor, resulting in stable regime shifts to fleshy macroalgae. Here we discuss at what point along the primary productivity axis these dramatic shifts in benthic organisation occur.

IMPACTS OF 6 YEARS OF HERBIVORE PROTECTION AT KAHEKILI HERBIVORE FISHERIES MANAGEMENT AREA (KHFMA), MAUI (Abstract ID: 28384)

In response to concerns about declining coral cover and recurring macroalgal blooms, the State of Hawaii established the KHFMA in 2009. Within the KHFMA, herbivorous fishes and sea urchins are protected, but other fishing is allowed. We conducted surveys at KHFMA and comparison sites around Maui since 19 months before closure, and covering 6 years of herbivore protection. Over that period, mean parrotfish and surgeonfish biomass increased within the KHFMA, by 139% and 28% respectively. Most of those gains have been of small-to-medium species, whereas large-bodied species have not recovered, likely due to low-level poaching on what are preferred fishery targets in Hawaii. Nevertheless, coincident with rises in herbivore biomass, crustose coralline algal (CCA) cover has increased from ~2% before closure to ~ 15% in 2015. Biomass of unprotected families did not change in the KHFMA, and there were no similar changes in parrotfish or CCA at 12 comparison sites around Maui. In spite of positive signs, it is unclear how effective the KHFMA might eventually be for its ultimate goal of coral recovery. Coral cover declined from 39.6% to 32.9% between 2008 and 2012, with nearly all losses occurring prior to herbivore biomass increasing. Coral cover subsequently increased to 35.4% by early 2015. However, a severe bleaching event later in the year eroded most of those gains. Looking forward, the likelihood of bleaching recurrence suggests that critical role of herbivore management at KHFMA may be in increasing resilience to and recovery from those events.

MULTI-YEAR SURVEYING OF CORAL REEFS USING AUTONOMOUS UNDERWATER VEHICLES (Abstract ID: 29139)

This talk will present insights gained from the operation of an Australia-wide benthic observing program designed to deliver precisely navigated, time series imagery of the seafloor using Autonomous Underwater Vehicles (AUVs). This initiative makes extensive use of AUVs to collect high-resolution stereo imagery, multibeam sonar, in-situ hyperspectral and water column measurements on an annual or semi-annual basis at sites around Australia, spanning the full latitudinal range of the continent from tropical reefs in the north to temperate regions in the south. We present results of a multi-year survey of reefs impacted by a significant bleaching event, illustrating how the observations provided by the repeat surveys have allowed changes in structural complexity, mortality and growth of individual coral colonies to be tracked through time. We also demonstrate how a small AUV with minimal support infrastructure can be used to generate detailed 3D models covering over 10,000 m2 of reef crest at millimeter resolution. This particular area was subsequently impacted by a cyclone and we will show how this data can be used to document changes in species distributions following a major disturbance event. Finally we will present the outcomes of a multi-vehicle deployment used to collect data across a large coral lagoon, capitalising on the availability of ship time to simultaneously deploy multiple autonomous platforms collecting visual and water column data.

SIX DEGREES OF BLEACHING: A WEIGHTED LINK REMOVAL MODEL FOR THE CORAL-SYMBIONT MUTUALISM NETWORK (Abstract ID: 28128)

Network analysis and modeling provide a valuable tool for describing the complex interaction between corals and their symbionts. Scleractinian corals and their symbionts can be mapped as a bipartite network. This network consists of nodes of coral species and *Symbiodinium* OTU that are connected by links that represent a mutualistic interaction occurring between them. We present a bleaching simulation model for this network, where we remove links based on calculated temperature thresholds of the mutualistic interactions. The bleaching simulation model iteratively increases the environmental temperature of the network and removes links once their temperature threshold is met. We compared the bleaching simulation model for the global network and networks composed of nodes found in specific oceans to a null model network with randomly assigned weights. The null model started bleaching earlier than the other networks, and then slowed so that all corals were bleached 2°C later than the others. There were significant differences in bleaching rates among ocean basins, with the Pacific network bleaching the fastest. Incorporating specific host and symbiont thermal tolerances into the link weight affects the performance of the network under a bleaching scenario. Network structure affects bleaching resistance, as evidenced in the differences in bleaching behavior among oceans. Differences in network topology play an important role in determining resilience of the coral-symbiont network when faced with increasing sea surface temperatures due to global climate change.

CORAL REHABILITATION IN SOUTH SULAWESI: HIGH CORAL GROWTH ON SIMPLE MODULAR STRUCTURES (Abstract ID: 27801)

Coral rehabilitation is an important conservation approach in the face of continuing destructive fishing practices in the Coral Triangle, even in Marine Protected Areas. Indonesia, the site of our pilot project, has protected ~32% of its reef habitat; however, much reef habitat is too damaged or disturbed to set aside as MPAs, thus necessitating rehabilitation. We present a pilot coral rehabilitation at Pulau Badi, Spermonde Islands, South Sulawesi. The rehabilitation consists of modular hexagonal frames ('spiders') of epoxy-and-sand-coated rebar secured in the substratum by legs. Coral fragments from

storm and fishing damage (and some from small nursery areas) are secured to the spiders with cable ties. The units allow stabilization of the bottom while providing open water flow around the corals. Approximately 10000 spiders were deployed over 16000 square meters, primarily in long stretches damaged by blast fishing but also in small gaps created by cyanide fishing or other damage. Live coral (primarily acroporid) cover increased from 20% two months after establishment to 82% nearly a year later. Villagers build and help deploy spiders as a supplemental livelihood to fishing, and community engagement and law enforcement to protect reefs have increased, although cyanide fishing of ornamental fishes inhabiting the rehabilitation has become a problem. Currently, fragment supply does not limit rehabilitation but the future goal is to deploy nursery-raised and/or stress tolerant species and to expand the rehabilitation to other sites in the Spermonde Islands.

LARGE-SCALE, MULTI-DIRECTIONAL LARVAL CONNECTIVITY AMONG GROUPER POPULATIONS IN THE GREAT BARRIER REEF MARINE PARK (Abstract ID: 29092)

Larval dispersal is the key process by which populations of most marine fishes and invertebrates are connected and replenished. Advances in larval tagging and genetics have increased our capacity to track larval dispersal, assess population connectivity, and quantify larval exchange among no-take marine reserves and fished areas. Recent studies have demonstrated that reserves can be a significant source of recruits for populations up to 40 km away, but the scale and direction of larval connectivity across larger seascapes remain unknown. We applied genetic parentage analysis to resolve larval dispersal patterns for two exploited coral reef groupers (Plectropomus maculatus and P. leopardus) within and among regional clusters of reefs separated by 60 – 220 km within the southern Great Barrier Reef Marine Park, Australia. A total of 86 juvenile Plectropomus spp. were genetically assigned to their parents on reefs within the study area. We identified both short-distance (200 m to 50 km) larval dispersal trajectories within regions, and long-distance (50 km to 254 km), multi-directional larval dispersal trajectories among regions. Larval exchange between reserve and non-reserve reefs indicated substantial mixing among management zones and the provision of recruitment subsidies from reserves to fished areas. Our findings suggest that both local-scale self-replenishment and regional-scale connectivity contribute to the maintenance of grouper populations in the Great Barrier Reef Marine Park.

BASELINES AND DRIVERS OF CORAL DISEASE IN THE WORLD'S OLDEST MARINE PARK (Abstract ID: 28997)

Disease prevalence within a population or community provides an important indicator of ecosystem health; however, its efficacy as an indicator depends on knowledge of baseline levels of disease typical of healthy communities. Here we use Bayesian hierarchical modelling to analyze a 12-year dataset of coral disease prevalence at 42 sites spanning cross-shelf gradients in terrigenous and human influences along 1200 km of the Great Barrier Reef (GBR). Analyses of satellite-derived sea surface temperatures, water quality metrics and wave heights indicate that overall, thermal and water quality stress was relatively mild at study sites from 2004-2015, but with localized cyclone waves. This long-term dataset of coral disease prevalence within a 45-year-old Marine Park provides a unique opportunity to identify baseline levels of disease that characterize comparatively healthy coral reef communities in the absence of extreme environmental stress events. Using median expected prevalence values as baselines, the 95th percentile of posteriors to denote unlikely levels, and the 95th percentile of the data to denote extreme levels of disease, we compare baselines and outbreak thresholds for five common diseases on the GBR. Analyses of 21 model-selected, biophysical covariates that most strongly influence disease prevalence unravel factors potentially driving these patterns. Identification of empirically-derived, shelf-specific disease thresholds signifying moderate and severe disease risk are critical for informed management of factors driving deteriorating coral health.

INFLUENCE OF NURSERY HABITAT ON THE ABUNDANCE OF A CORAL REEF FISH (Abstract ID: 27834)

The availability of suitable habitat can have a profound effect on the abundance of coral reef fish, particularly those that are habitat specialists. Habitat requirements are however likely to vary with ontogeny, some species associating with specific nursery habitats, and the importance of nursery relative to adult habitats for shaping future abundances remains unclear. Moreover, populations may be influenced by supply of new recruits and any assessment of habitat importance should also consider the effects of supply. We conducted surveys at 16 sites, spanning 200km of the Ningaloo coast, to identify habitat preferences of juvenile, sub-adult and adult damselfish Pomacentrus moluccensis. We then combine information on habitat preferences at different life history stages with six years of information on juvenile abundance and habitat availability to assess the relative importance of habitat and juvenile supply to P. moluccensis populations. Our results show that juvenile habitat at the time of settlement (corymbose corals) is the strongest predictor of future sub-adult and adult P. moluccensis abundance, whilst availability of adult/ sub-adult habitat (branching corals), and changes in juvenile abundance were both poor predictors of future abundance. These findings provide empirical evidence of the value of nursery habitats relative to supply of juveniles and emphasize the importance of identifying and protecting these habitats for the conservation of coral reef fish.

INTRASPECIFIC VARIABILITY IN LIFE HISTORY TRAITS OF FISHES BETWEEN SHALLOW CORAL REEFS AND MESOPHOTIC CORAL ECOSYSTEMS IN THE CENTRAL PACIFIC OCEAN (Abstract ID: 28258)

Many inhabitants of mesophotic coral ecosystems (MCEs), such as reef fishes, represent a lower depth distribution of their species as they are also found occupying shallow coral reefs in relatively close geographic proximity. Research on fishes associated with MCEs is sparse; hence there is a critical lack of knowledge of how reef fish found at mesophotic depths may vary from their shallow reef complements. We investigated intraspecific variability in growth, reproductive potential and energy partitioning of three Hawaiian endemics collected from shallow, photic reefs and MCEs throughout the Hawaian Archipelago and Johnston Atoll: the detritivorous goldring surgeonfish Ctenochaetus strigosus, and the planktivorous threespot chromis Chromis verater and Hawaiian dascyllus Dascyllus albisella. The von Bertalanffy growth function was used to establish species-specific growth models using otolith-derived ages, and energy investment towards reproduction and body condition was quantified using the gonado-somatic index and Fulton's condition index. Body condition was higher for all species in shallow waters than MCEs; however, variability in reproductive investment between shallow and deep populations differed between species. For all species, fishes from shallow waters reached larger asymptotic lengths than their conspecifics. This ongoing study addresses the life history of coral reef fish, a key component of both shallow and mesophotic reef communities, while providing structure for the development of conservation and fisheries management tools in understudied mesophotic environments.

ENVIRONMENTAL DRIVERS OF ACCLIMATIZATION: EFFECTS OF GRADUAL WARMING VS. REPEATED THERMAL STRESS ON SYMBIONT COMMUNITY STRUCTURE AND FUNCTION IN REEF CORALS (Abstract ID: 29955)

Both bleaching severity and recovery conditions affect the reassembly of algal symbiont communities during recovery, and incremental changes in community composition can result in increased coral thermotolerance. We investigated how symbiont community composition and coral bleaching thresholds were affected by repeated, short-term thermal stress, both with and without gradual warming. We tested the hypotheses that

episodic temperature stress results in stepwise increases in the abundance of thermotolerant symbionts and that this process is accelerated under gradually warming recovery temperatures. Replicate cores from three colonies of the Caribbean coral *Montastraea cavernosa* were distributed randomly into treatments in a crossed factorial design, experiencing either constant temperature (26°C) or gradual warming (1°C every 6 weeks), and either short-term thermal stress (32°C, target ~25% symbiont community loss) or no bleaching. Symbiont community function was tracked using chlorophyll fluorometry, and tissue samples taken periodically were analyzed using actin-based qPCR assays to determine symbiont community composition. All cores were subjected to a final bleaching stress at 32°C to assess thermotolerance. This experiment will elucidate how gradual warming and punctuated bleaching stress affect symbiont community composition and drive changes in coral thermotolerance, and has implications for the response of reef corals to real-world warming scenarios.

PRIORITIZING SUITABLE CORAL RESTORATION SITES THROUGH ASSESSMENT OF EXISTING CORAL MONITORING DATA (Abstract ID: 28793 | Poster ID: 535)

In the face of large scale coral reef decline, restoration efforts are increasing throughout the Florida Reef Tract. The general focus of these efforts is restoring Acropora cervicornis populations. Currently, there is little to no spatially explicit information regarding site prioritization for coral restoration efforts in Florida, where most restoration sites are selected using expert opinion alone. This study is the first step towards using spatially explicit information to guide restoration site selection in Florida. A species distribution modeling approach was taken to spatially prioritize restoration efforts along the Florida Reef Tract. A series of non-parametric species distribution models (SDMs) were constructed using species richness, coral cover, and A. cervicornis data. These SDMs were combined with other spatial data in the conservation software "Zonation" to prioritize restoration sites based on connectivity, species interactions, and health. The results of this work is an interactive tool that can be adjusted to support the unique goals of individual restoration projects.

ASYMMETRIC, LARGE SCALE COMMUNITY RESPONSES TO CLIMATE OSCILLATIONS IN GALAPAGOS SUBTIDAL ECOSYSTEMS (Abstract ID: 29048)

Climate events such as El Nino Southern Oscillations (ENSOs) can drive ecosystems to a tipping point as thresholds are exceeded and a sudden transition to a different state (regime) occurs. We monitored benthic communities and oceanography in Galapagos rocky subtidal ecosystems at 12 sites for 14 to 17 years to test the hypothesis that ENSO's create non-linear effects leading to a regime change. Extensive bleaching of massive (Porites, Pavona) and branching (Pocilloporid) corals occurred during the La Nina phase of the 2006-2008 ENSO and again, during the 2010 to 2011 La Nina in response to unusually large temperature variability (30.0 -14.0 degrees C). Surprisingly, large increases in barnacle (Megabalanus) abundance coincided with coral bleaching during both La Ninas, suggesting higher barnacle recruitment during these productive periods. The asymmetric yin yang of ENSO effects was apparent in the negative impacts on corals via bleaching but positive, bottom-up effects on benthic food webs dependent on the large barnacles. Barnacle abundance on rock walls attained maximum abundances of 60 to 80 % cover at some sites in recent years concomitant with a greater proportion of corals overgrown by barnacles, suggesting a shift to a regime characterized by declining coral populations and increasing barnacles and their predators. Community responses of the most recent 2016 ENSO will be analyzed in the context of these hypotheses.

EVALUATING THE QUALITY OF A LONG TERM CULTIVATION EXPERIMENT OF *OPERCULINA COMPLANATA* BY COMPARISON WITH THE NATURAL LABORATORY APPROACH (Abstract ID: 28635 | Poster ID: 290)

Larger benthic foraminifera contribute largely to the carbonate reef budget and are great tools in biostratigraphy. During the last decades they also got importance as indicator species for ecological monitoring. Even before their advancement as bioindicators, laboratory experiments have been conducted to investigate their biology, ecology and reproduction. While recent studies have focused on the effects of single ecological parameters mostly in short term culture experiments (few days to some weeks), the majority of results still shows growth abnormalities and truncated lifespans even in control groups, indicating some imperfections in the culturing systems, which hardly represent open water conditions. Therefore, to fully understand growth and life span of different species and to improve their use in various fields, long term cultivations attempts must be conducted trying to get the perfect equilibrium between cells and environment. This study presents theoretical growth models of *Operculina complanata* based on a 15 month cultivation experiment with 186 specimens and compares them to first results of the equally long Natural Laboratory Approach both conducted at Sesoko station (Okinawa, Japan). Culturing parameters such as temperature, light intensities, salinity and pH and light-dark duration were continuously adapted according to the measurements in the field. The average cell life time in culture was 77days, 13 Individuals lived more than 200 days, 3 reproduced asexually and one sexually, 14% of the individuals were lost and 22% died within the first month.

FISHING ENDANGERS THE TROPHIC STRUCTURE OF THE CORAL AND SHARK DOMINATED SYSTEM OF THE WOLF AND DARWIN ISLETS (GALAPAGOS): INSIGHTS FROM MODEL SIMULATION (Abstract ID: 27815)

The Galapagos archipelago is known for its great diversity in marine species distributed over distinct biogeographic regions. We hypothesized that these regions not only differ in species and/or their relative abundances, but also in overall biomass and resource productivity with implications for fisheries management and conservation. We thus modeled and compared the trophic structure of the south western Bolivar Channel (BC) upwelling system and the coral dominated northern system of the Darwin and Wolf (DW) islets using the Ecopath with Ecosim approach. Results indicate that the BC very much resembles classical upwelling systems off the coast of Peru with high primary production, low level of maturity, high biomass at lower trophic levels, high energy flow, and sea lions as dominating top predators. The coral reef dominated system (DW), to the contrary, showed a more complex food web structure, a higher degree of system maturity and a concentration of fish biomass in large predators (55%) that were identified as keystone species largely controlling intermediate predators. By using the reference models of both systems to explore the effect of increased fishing pressure, a negative impact was pronounced in the coral DW system, where the increased removal by herbivore controlling fish, would eventually lead to an alternative system state with sea urchins dominating the benthic biomass. We argue that an increase in fishing pressure in the presently still semi-pristine coral and shark dominated northern area of the archipelago (DW), would easily lead to loss of one of the most unique ecosystems of Galapagos and propose strong conservation enforcement for the DW region.

VULNERABILITY OF THE GREAT BARRIER REEF TO GLOBAL AND LOCAL PRESSURES: IMPLICATIONS FOR EFFECTIVE MANAGEMENT AND POLICY DECISIONS IN A WARMING OCEAN (Abstract ID: 29087)

The Great Barrier Reef (GBR) has lost half of its coral cover during the past thirty years, attributed predominantly to storms, crown-of-thorns starfish (COTS) and, to a lesser extent, bleaching. Two questions at the core of GBR management plans are: how vulnerable and resilient will the GBR be to future environmental scenarios, and what will the relative importance be of different local or global disturbances? To answer these questions we use a spatially explicit model of coral cover dynamics (mortality and growth) parameterized by four input functions: warming, storms, water quality and COTS. Using a series of 8 scenarios representing combinations of climate change (based on three AR5 global circulation models) and local stressors, we analyse spatial and temporal trends and uncertainties associated with future impacts. Our results demonstrate that coral resilience will decline in pace with climate change under all three RCPs. Local and regional management actions (land-use management, COTS control, spatial planning) can compensate for this resilience loss on some reefs in the near-term (10 – 20 years), but by 2050 these actions can no longer mitigate the loss imposed by climate change. The implications of these results for management and policy decision problems are discussed, particularly the need to better acknowledge and account for the limits of local scale action when dealing with the global problem of climate change.

HAWAIIAN POCCILOPORA DAMICORNIS BABIES LEAD THE WAY TO REEF RESTORATION (Abstract ID: 28109 | Poster ID: 484)

Innovative techniques for restoring coral reefs have been a continuous conversation among scientists, politicians, and government officials for decades. The ability to develop and implement coral transplantation techniques without harvesting existing reef corals can maintain a reef's ecological value. Monthly collection of planula from colonies of Hawaiian Pocillopora damicornis have been successfully maintained, and settled, and the resulting colonies used as source material for mitigation projects. Frequent asexual planulation (versus sexual propagation) provides an abundant supply of coral to be used in improving reef restoration techniques. P.damicornis planula have the potential to pave the way for other restorative corals by providing further insight for successful transplantation, artificial substrate preferences, re-aggregation of identical genotypes, and threshold tolerances to anthropogenic stressors and climate change. Replicate experiments in large quantities can be used to evaluate reef restoration trade offs such as the cost required to transplant corals onto a reef versus the effort to transplant individual colonies. This plentiful resource holds the potential of becoming the new "lab rat" for reef experimentation while at the same time providing critical source material for reef restoration.

CORAL ISOSCAPES REVEAL VARIED NITROGEN SOURCES AND DYNAMICS IN HONG KONG'S COASTAL ENVIRONMENT (Abstract ID: 29155 | Poster ID: 92)

Hong Kong's marine ecosystem health is under threat due to large inputs of dissolved inorganic nitrogen (DIN) from various sources. We used stable isotope analysis to trace major DIN source(s) affecting corals and examined their spatial and temporal variations in coastal environments. We collected corals along coastlines in a wet and dry season and analyzed the $\delta^{15}N$ signals of their *Symbiodinium* ($\delta^{15}N_s$). Spatially, the mean $\delta^{15}N_s$ value was significantly lower in the Southern zone–SHK (5.6±1.5‰) than Northeastern zones–PS (8.0±1.1‰) and MB (8.8±1.3‰) in the wet season. In the dry season, there was no significant difference in the mean $\delta^{15}N_s$ values among zones. When compared between seasons, the mean $\delta^{15}N_s$ value in SHK in the dry season (6.9±0.7‰) was significantly higher than the wet season. The spatial and seasonal differences in the $\delta^{15}N_s$ values highlighted the influence of the Pearl River (PR), which supplies Hong Kong with a high concentration of $^{14}N$ compared to N derived from oceanic water. The dominance of N from PR could contribute to the low $\delta^{15}N_s$ values in SHK in the wet season as it is in close proximity to PR. The seasonal difference, i.e. higher $\delta^{15}N_s$ values in SHK in the dry than wet season, can be explained by the decreasing influence of PR as the dry season accounts for ~20% of the annual discharge. These data suggested PR has a major influence to the DIN dynamics and its significance is subject to spatial and seasonal changes.

EFFECT OF COMPETITION ON GROWTH AND FITNESS OF *SYMBIODINIUM* POPULATIONS IN CULTURE (Abstract ID: 29175)

According to the resource-ratio hypothesis, autotrophs with a lower minimum nutrient requirement will tend to dominate, as they further reduce nutrient availability to competitors, thus leading to dominance via competitive exclusion. With the use of bioreactors, minimum nitrogen and light requirements for *Symbiodinium* can be quantified and used to predict competitive outcomes among clades that co-occur in host corals. However, competitive outcomes are likely influenced by physical factors such as temperature and light, which can impact metabolic rates. Thus, a species may only be a superior competitor for limiting nutrients within its thermal or irradiance optima. We show that temperature drives different competitive outcomes in mixed cultures of *Symbiodinium* clades D and A. Clade D was always displaced by clade A, but more so at 32˚C (D:A cell ratio = 0.00), than at 26˚C (0.02) after 33 days of competition. In co-dominant populations, a slightly reduced photosynthetic efficiency (YII=0.376) was observed in comparison to pure cultures (YII=0.399). We hypothesis that reduced YII is a consequence of resources being allocated to competition and fewer to beneficial metabolic traits. The cost of hosting competing *Symbiodinium* populations might explain the rarity of mixed *Symbiodinium* populations *in situ*.

EVIDENCE OF REPRODUCTIVE PLASTICITY OF PORITES ASTREOIDES ACROSS A DEPTH GRADIENT IN BERMUDA (Abstract ID: 28378 | Poster ID: 183)

Mesophotic coral reef ecosystems (MCEs) extend to the bottom of the photic zone and are relatively sheltered from anthropogenic and natural disturbances resulting in low reef degradation compared to shallow reef counterparts. MCEs are hypothesized to serve as a refuge for shallow reefs, where larvae may aid the re-population of previously disturbed shallow habitats. This study determines whether upper mesophotic Porites astreoides can function as a reproductive refuge for shallow reef environments by (1) comparing patterns in lunar periodicity, fecundity, and differences in larval sizes between 10 m and 30 m colonies, and (2) testing whether there is a significant difference between larval settlement success in laboratory settings in July and August 2015. Shallow colonies released more larvae than upper mesophotic colonies in July, while the opposite pattern was observed in August. In August, the shallow colonies released significantly larger larvae than the upper mesophotic colonies, however this did not hinder metamorphosis as larval settlement rates did not differ with parental depth. These results indicate that upper mesophotic P. astreoides produce viable larvae that are able to colonize available substrates at similar rates to shallow larvae. In conjunction with vertical connectivity studies, our results suggest that upper mesophotic P. astreoides may be able to serve as a reproductive refuge for shallow water environments.

A CATASTROPHIC CORAL DISEASE OUTBREAK IN HONG KONG THAT MAY BE ASSOCIATED WITH HARMFUL ALGAL BLOOMS (Abstract ID: 29483)

A rare massive outbreak of coral disease took place in March 2015 in Tolo Harbour and Channel, a eutrophied semi-enclosed embayment in northeastern Hong Kong. The disease was first noticed by abnormal extensive protrusion of mesenterial filaments or tentacles from affected coral colony surfaces. Rapid tissue loss quickly followed, with a pattern closely resembled white syndrome. In tissues of diseased lesions, ciliates were observed. Field survey registered a loss of 20.6-51.4% in total coral cover in five locations, three of which were within marine protected areas. Coral communities of closer proximity to water discharge in inner Tolo Harbour were more impacted. *Platygyra* spp., the locally dominant corals, suffered the highest morality when compared to *Acropora* spp., with the latter being generally shown to be more vulnerable to stresses and diseases. Experimentally, healthy coral tissue could be induced to exhibit lesion by exposing to water previously used to incubate diseased corals. Ciliates were always present in the coral lesion even the water was filtrated and autoclaved. Presence of toxin in the water was therefore the likely cause of lesion and the source of this toxin could have been the harmful algal blooms of *Heterocapsa circularisquama* and *Noctiluca scintillans* that broke out a bit earlier. The latter bloom attended the highest density (21500 cells/ml) ever recorded since monitoring started in 1977. There could therefore be a close association between eutrophication, algal bloom and coral diseases. Project supported by RGC GRF 460013.

LINKING LAND AND SEA THROUGH AN ECOLOGICAL-ECONOMIC RECREATION MODEL (Abstract ID: 30134 | Poster ID: 587)

Coastal and marine systems provide key ecosystem goods and services that support human well-being. Despite their importance for Hawaii's economy, many of these services are declining due to land-based stressors, such as nutrient runoff, pollution, and sedimentation. These stressors are expected to worsen with increasing climate change and development, resulting in ecological, cultural, and economic benefits loss. To support an integrated land-sea approach to management and planning in a priority watershed in West Maui, we are building a Bayesian network-based recreation model to link a sedimentation model and land-based sources of pollution with the social and ecological factors that influence recreationists' preferences for snorkeling sites. Employing a discrete choice experiment (DCE), we evaluated preferences and willingness to pay for six coastal site attributes. We are linking non-market economic values with ecological attributes to assess ecological, economic, and cultural gains and losses under different climate change and management scenarios. Preliminary DCE results suggest that recreationists positively value benefits in terms of increased biodiversity and recreation opportunities, as well as reductions in pollution and health risk. Our results are expected to inform strategic planning for integrated ridge to reef management that strengthens both socioeconomic and ecosystem health.

APPLYING SOCIAL SCIENCE TO UNDERSTAND THE WELL-BEING OF REEF-DEPENDENT COMMUNITIES IN MICRONESIA (Abstract ID: 28110)

The importance of social science for generating management-relevant information about the uses and impacts of human activities on coral reef and other coastal resources is now recognized. In recent years, the use of social scientific methods has been expanded to include research that examines how people benefit from natural resource management and conservation intervention, a key objective that increasingly has been adopted by conservation organizations and coastal resource management agencies across all geographical areas. Social scientific methods are being employed to help develop indicators to better understand linkages among changes in biological and physical conditions, ecosystem services, and human well-being. This presentation examines efforts and activities in Micronesia related to the use of social science identifying the most important human well-being indicators for the region, as well as the opportunities and challenges involved in implementing social scientific research. The presentation will also highlight in particular the NOAA Habitat Blueprint focus area in Guam and how social science is being employed in designing socio-ecological research that examines impacts of sedimentation on reefs as critical habitats and on fisheries as a means of livelihood and cultural heritage.

BIOEROSION BY THE SEA URCHINS ON CORALS IN THAILAND (Abstract ID: 30031 | Poster ID: 84)

Sea urchin is one of the most abundant bioeroders in coral reefs in Thailand. In this study, the bioerosion on a staghorn coral Acropora millepora (Ehrenberg, 1834) by the sea urchin Diadema setosum (Leske, 1778) was investigated. Both field surveys and experiments were conducted. From the field surveys at Chon Buri Province in the upper Gulf of Thailand, the highest abundance of sea urchins was approximately 11 individuals m-2. The results from the stomach contents showed that there were significant amounts of calcium carbonate found in the sea urchins' stomachs. In addition, two experiments were conducted to investigate the interaction between sea urchins and corals and the interaction between sea urchin, corals, and algae Cladophora sp. The results of the interaction experiment without algae showed that bioerosion rates of one sea urchin were approximately 0.20 g day-1 and 1.59 cm-2 day-1 in term of CaCO3 and area respectively, which were higher than that of with algae. There were also correlations between the densities of sea urchins, sizes of sea urchins, and the bioerosion rates. However, after the experiments, we found that most corals bioeroded by the sea urchins can recover within 14 days.

EL NIÑO, SURFACE CIRCULATION AND CORAL LARVAL DISPERSAL ACROSS THE WORLD'S GREATEST MARINE BARRIER (Abstract ID: 29457)

Over 5000 km separates the frequently disturbed coral reefs of the Eastern Tropical Pacific (ETP) from western sources of population replenishment. However, the presence of trans-Pacific corals in the ETP implies that some species have, at least historically, breached this 'East Pacific Barrier' (EPB). It has been proposed that increased eastward flow during El Niño facilitates cross-Pacific dispersal into the region. However, direct evidence is lacking in corals. We present output from a biophysical dispersal model, employing the Connectivity Modelling System (CMS), driven by 15 years (1997-2011) of high resolution oceanographic data. The model is parameterised to represent the positively buoyant larvae of a generic broadcast spawning coral with high dispersal potential. No eastward cross-Pacific connections occurred over the modelled period, which encompasses a range of climatic variability, including the extreme 1997-98 El Niño. We infer that ETP populations decimated by this event have therefore likely recovered from local sources. Instead, rare connections between eastern and central Pacific reefs were simulated in a westward direction. Significant complexity in the surface flows transporting larvae mean that generalised upper-ocean circulation patterns are poor descriptors of inter-regional connectivity, complicating assessments of how climate change will impact coral gene flow Pacific-wide. We discuss efforts to incorporate the effects of temperature on larval development in the biophysical model in order to make more accurate projections of future dispersal.

CORAL ZOMBIES: ASSESSMENT OF REPRODUCTIVE CONDITION IN ACROPORA PALMATA ACROSS THE U.S. CARIBBEAN (Abstract ID: 29781)

Reproductive failure in Caribbean Acropora has been identified as a critical factor in their Endangered Species Act (ESA) listing and in preventing the species' recovery. Previous work on Acropora palmata (elkhorn coral) reproductive condition indicates that visually intact and 'apparently healthy' colonies can in fact carry mild to severe reproductive pathologies. A total of 34 sites across the U.S. Caribbean, were surveyed two weeks prior to spawning in 2013, to determine the reproductive condition of A. palmata populations from histological examination of tissue biopsies. The survey included Florida, Puerto Rico, and St. Thomas, St. John and St. Croix in the U. S. Virgin Islands, resulting in biopsies from 327 colonies. The reproductive effort of A. palmata ranged from 0% effort in two Florida reefs and two St. Croix reefs to 100% at one St. John, USVI reef. The Caribbean-wide assessment of the reproductive effort of A. palmata identified populations that are reproductively viable, indicating healthy 'resilient' populations, and those that are impacted. This work has identified key locations where further management actions are needed to promote species recovery and provides the first step in an epidemiological approach to understanding drivers of decline in certain populations, as well as populations warranting heightened protection (resilient populations).

MICROATOLLS AS INDICATORS OF SEA-LEVEL CHANGE ON REEFS (Abstract ID: 28523)

A major outcome of the Great Barrier Reef expedition in 1973, and David Stoddart's research during it, focused on detecting changes in sea level. Together with Terry Scoffin, he described living and fossil microatolls from the Great Barrier Reef and recognised their significance as sea-level indicators. In the four decades since, changes in sea level associated with global climate change have become a focus of considerable concern, particularly in relation to the small reef islands throughout reefal seas. Accurately surveyed and dated Porites microatolls provide considerable insight into past water level changes, especially where their elevations can be compared to living modern equivalents. These long-lived massive corals, up to 9 metres in diameter, preserve a biologically-mediated multi-decadal record of sea-level. The upper surface of fossil microatolls on a reef flat generally lies in a narrow elevation range similar to that observed for their modern, living counterparts. This paper examines the insights that Stoddart provided and assesses how microatoll morphology is likely to respond to future sea-level changes.

ENVIRONMENTAL FACTORS LIMITING FERTILISATION AND LARVAL SUCCESS IN CORALS (Abstract ID: 29181 | Poster ID: 530)

Early life history stages of reef-building corals, specifically fertilisation and larval survival, are susceptible to changes in the chemical and physical properties of seawater. Quantifying how changes in water quality affects these stages is therefore important for understanding and predicting population establishment in novel or changing environments. A review of the literature identified that levels of salinity, temperature, pH, suspended sediment, nutrients, and heavy metals affect coral early life history stages. Using published experimental data, this study quantified the influence of these seawater properties

on coral fertilisation and larval survivorship probabilities. Fertilisation success was highly sensitive to salinity, copper, phosphorous and suspended sediment. Larval survivorship was sensitive to copper, lead and temperature. A combined model was developed, to estimate the joint probability of survival through fertilisation and larval survivorship. This model was able to determine the likelihood of larvae surviving through each stage of development to settlement competency, as well as incorporating real life data from Sydney and Lizard Island in Australia. This combined model could therefore be used to recommend targets for water quality in coastal waterways as well as aid in predicting the potential for species to expand their geographical range in response to climate change.

PRELIMINARY MEASUREMENTS OF CORAL COMMUNITY LIGHT-USE EFFICIENCY IN RESPONSE TO VARIABLE ENVIRONMENTAL CONDITIONS (Abstract ID: 28716)

Primary production is arguably the most important ecological function of corals. Primary production is strongly driven by ambient light levels, confounding interpretation of day-scale productivity measurements. Light-use efficiency (LUE) normalizes primary production by removing the light-engendered variability. Our objective was to determine how environmental conditions affect the LUE of a coral community. We placed a community of*Porites astreoides* inside a flume mesocosm, where we controlled irradiance and flow speed during four trials: (1) control, (2) elevated temperature, (3) elevated nutrients, and (4) elevated CO2. During each trial, we measured daily gross primary production (P) and daily absorbed photosynthetically available radiation (APAR), then calculated LUE as P ÷ APAR. Relative to control conditions, there was no significant change in LUE with elevated temperature or CO2, but LUE did decrease significantly under elevated nutrient conditions. Though it was not explicitly manipulated, there was a statistically significant negative correlation between LUE and salinity, which increased as a by-product of the nutrient treatment methodology. Further research is required to more definitively characterize the effects of larger changes in each of the environmental parameters, but these preliminary data demonstrate the potential utility of applying LUE to evaluate an important aspect of reef ecosystem function.

LOOKING THROUGH A MICROSCOPE BRIGHTLY! TISSUE CHANGES SHED LIGHT INTO PATHOGENESIS OF DISEASE AND ECOLOGICAL PROCESSES IN CORAL REEFS. (Abstract ID: 28218)

Understanding what drives coral reef health and kills animals associated with coral reefs will be critical to maintaining healthy reefs. By revealing morphologic changes at the cellular level such as inflammation or presence of microorganisms, histology has provided important insights into health of various organisms associated with coral reefs in the Pacific. For instance, we now know that the herpesvirus associated with fibropapillomatosis, a tumor disease affecting sea turtles globally, is shed mainly in small tumors, and that only a few affected turtles (superspreaders) are likely responsible for a majority of disease transmission. Skin lesions in surgeonfish, thought to be a normal color variant, have turned out to be pigment cell tumors. A die-off of collector urchins on Oahu was likely associated with viral-like particles infecting inflammatory cells. Finally, histology is beginning to explain various phenomena in coral diseases such as dark spots (overgrowth of fungi), tissue loss (associated with parasitic corals, ciliates, fungi, algae, and cyanobacteria), and growth anomalies. Microscopy might even prove useful in explaining ecological patterns. We have found that dominant Porites, Acropora, and Pocillopora have a high prevalence of tissue-associated bacterial symbionts that could provide competitive advantages and explain their dominance on reefs. Microscopic morphology of corals might also even aid coral taxonomy by revealing tissue structures unique to certain species. Many new discoveries await those willing to peer through the looking glass.

DEALING WITH CORAL REEFS RISK AND DECISION MAKING IN THE FACE OF CLIMATE CHANGE AND DEVELOPMENT NEEDS (Abstract ID: 29465)

New dimensions of environmental resource value and loss will increasingly become a key feature on the government balance sheet in coral reef regions .Forecasting expected losses of critical environmental functions provided by reefs is setting new challenges for scientists.International investors wrestle with the dollar value of risks of frontier tropical ecosystems which affect stakeholder confidence .Efforts to develop “state of the art” techniques to quantify coral reef ecosystem services will be presented plus a critique of how these support decision making. Advances in GIS and satellite imagery illustrate the future opportunities to measure regional ecosystem changes. A series of case histories will illustrate approaches to dealing with risk to marine assets revealing dimensions of resource risk exposure, risk reduction and future liabilities. Our understanding of the role of biodiversity; reef system robustness; recoverability; habitat uniqueness; species life cycles in the sustainability of reef services will be reviewed and reveals fundamental gaps in knowledge. The global efforts being made to place $ values on the world’s natural capital and tropical ecosystem life support services will be summarised. A pioneering approach to environmental due diligence of investments, eco risk assessments will be presented. Insights will be given on the latest techniques for mapping environmental resources and services in integrated GIS systems on the web, which will provide a “reef ecosystem health thermometer” making key services visible to stakeholders.

A NEXT-GENERATION APPROACH TO SPECIES DELIMITATION IN THE SPECIOSE OCTOCORAL GENUS, SINULARIA (Abstract ID: 28271)

Sinularia is a speciose clade (~180 described species) of octocorals that dominates primary substrate in shallow coral reef communities throughout the Indo-Pacific. Like other zooxanthellate corals, Sinularia is highly susceptible to bleaching, and mass mortality events have been recorded throughout its range. Attempts to better understand the ecology of Sinularia-dominated communities are hindered by the difficulty of delineating species. Molecular markers and associated morphological synapomorphies divide the genus into five major clades, but within clades a marked lack of congruence between morphological and molecular characters leads to conflicting evidence for species boundaries. To date it is not clear if this conflict is due to the relative invariability of the mitochondrial markers typically used for species discrimination or to a lack of understanding of the range of intraspecific morphological variability in the genus. To address this issue, we used a RADseq next-generation sequencing approach to delineate species boundaries among 14 putative morphospecies in which molecular identity is often in conflict with morphology. The majority of the specimens analyzed were collected from a single site in the South China Sea (Dongsha Atoll) where a mixed assemblage of Sinularia species covers >80% of the shallow forereef. Delineation of species based on the RADseq data has allowed us to assess the reliability of single-locus mt haplotypes for species discrimination in Sinularia, and to identify genetic clades that exhibit high levels of morphological variability.

POPULATION GENETICS OF HUMPHEAD WRASSE (CHEILINUS UNDULATUS) IN ANAMBAS ISLANDS, INDONESIA BASED ON D-LOOP MITOCHONDRIAL DNA (Abstract ID: 28803)

Overfishing is the main threat of coral reef biodiversity on the planet. One of the threatened species is the humphead wrasse (Cheilinus undulatus) which also known as the napoleon wrasse, is mainly found on coral reefs in the Indo-Pacific region. Listed as an ‘endangered’ species on the IUCN Red List, the major threat to this species is live reef food fish trading (LRFFT) exports to Hong Kong and South China. Anambas, Indonesia has long been a center of export for humphead wrasse and groupers. This trade is primarily composed of wild-caught adult individuals, but over time stocks have become severely overfished and adults in the wild have become nearly impossible to find. Here, we investigate the population of C. undulatus in Anambas and reveal the genetic relationships of adults from captivity with juveniles in the wild through a portion of the mitochondrial DNA region known as the D-loop. In 2013, seven adults of C. undulatus were collected from captivity in Air Sena and Tanjung Patinting and 50 samples of the juveniles were collected from Air Asuk and Batu Belah. Our results show that among 19 haplotypes, haplotype 1 was predominantly found in Air Asuk and Batu Belah. Thus, the remaining juveniles were from haplotypes of the adults from captivity other than in Air Sena and Tanjung Patinting. This haplotype network will provide a better understanding of whether there is a natural semi-closed aquaculture system in Anambas and further for the conservation management of humphead wrasse, particularly in that region.

SPONGE DIVERSITY ON CORAL REEFS: PHYLOGENETIC SIGNAL IN RESPONSES TO PROCESSES THAT DRIVE DIVERSITY PATTERNS (Abstract ID: 30071)

Sponges do not conform with geographic-scale species diversity patterns illustrated by corals and other coral reef organisms: region-wide sponge species diversity is similar among ocean basins, and local diversity is revealed to be similar among locales whenever a variety of sites are sampled. Lack of conformity may reflect the broad range of growth forms, internal morphologies, propagative strategies, chemical characteristics, skeletal properties, and symbiont associations displayed by members of the at least 20 sponge orders that inhabit coral reefs; and the consequently broad range of ecological requirements and vulnerabilities of sponge species. We have been evaluating processes driving diversity patterns by experimental additions of species to sites from

which they were absent, and by monitoring sites through time in sufficient detail that diversity changes can be confidently ascribed to particular abiotic or biotic events. The latter entails time-series volume measurements of every sponge of every species in permanent plots. During the last 30 years, our long-term census plots at four Caribbean sites have experienced temperature anomalies, dense phytoplankton blooms, disease, changes in predator populations, and storms; resulting in data on how over 80 species are influenced by these factors. Simple tallies of number of species do not tell the important stories about sponge diversity. Analyses of phylogenetic signal in responses to environmental challenges reveal a troubling coincidence of beneficial functional roles played on coral reefs and diversity losses.

THE OUR FLORIDA REEFS COMMUNITY PLANNING PROCESS: COLLABORATIVE MANAGEMENT ACTION DESIGN TO INFORM THE CONSERVATION OF SOUTHEAST FLORIDA'S CORAL REEF ECOSYSTEM (Abstract ID: 28859)

The Our Florida Reefs Community Planning Process is an unprecedented opportunity for community engagement in marine resource management in the State of Florida that has brought together local residents, reef users, business owners, visitors and the broader public in southeast Florida to identify actions that should be taken to strengthen coral reef conservation and management in the region. This area, which is inhabited by more than 6 million residents with an additional 30 million tourists visiting each year, lies adjacent to the northern third of the Florida Reef Tract. Our Florida Reefs (OFR) was designed to increase public involvement in the management of southeast Florida's coral reef ecosystems by facilitating a collaborative process with community members to develop recommendations that will become part of a comprehensive management strategy to ensure healthy coral reefs in the future. Community Working Groups consisting of local residents, reef users, business owners, scientists, and representatives from NGOs and local, state, and federal agencies worked together to developed recommended management actions through a 2 year collaborative planning process. The outcomes of OFR will provide the State of Florida with a strategic policy framework for the integrated management of coral resources along its southeast coast. Planning and implementation of OFR is a partnership between Florida Department of Environmental Protection and NOAA's Coral Reef Conservation Program.

ECOLOGICAL AND BIOGEOCHEMICAL IMPACTS OF INTERNAL WAVES ON MESOPHOTIC CORAL ECOSYSTEMS: TESTING EDDY CORRELATION AND ISOTOPE APPROACHES, IRIOMOTE, JAPAN (Abstract ID: 28489)

While mesophotic coral ecosystems (MCE) may be protected or damped from disturbances impacting shallower reefs insufficient information is available on the environmental conditions supporting these 'deep water refugia'. Nutrient inputs and recycling have rarely been quantified over MCE but may differ fundamentally to that of shallow counterparts due to the reduction in light and increasing reliance on oceanic nutrients, leading to increased heterotrophy over autotrophy at species and ecosystem levels and stronger links to oceanic processes. For instance, due to the depth of MCE relative to typical water column density stratification, internal waves may be a highly significant process depending on community aspect and exposure. Preliminary observations of MCE along a continuum of oceanic exposure in Funauki Bay, Iriomote, Japan indicate that ocean-exposed MCE are subject to semi-diurnal temperature oscillations of up to 4 C during summer (range 23 – 29 deg C), while inner MCE occur shallower in more turbid but stable environments. Oceanic exposure along the bay may determine both the distribution and function of spatially extensive, but relatively homogenous, communities dominated by Leptoseris sp. or Acropora ? horrida. Combining bulk and compound-specific stable isotope analyses, depth-specific radioisotope markers such as radiocarbon, and eddy correlation experiments in these habitat promises a useful approach for elucidating the functional importance of internal waves in the development and persistence of MCE at local to regional scales.

SWITCH FROM AUTOTROPHY TO MIXOTROPHY IN SYMBIODINIUM: GLUCOSE MODULATION OF PHOTOSYNTHESIS AND SYMBIOSIS (Abstract ID: 29029)

The mutualistic symbiosis between Symbiodinium and its cnidarian hosts provides the metabolic foundation for biodiverse coral-reef ecosystems, but many details of nutrient exchange between host and alga remain unknown. Here we show that when cultured in the presence of glucose in the light (10 μE) (mixotrophic growth), clonal Symbiodinium strain SSB01 loses pigmentation and photosynthetic activity, whereas little loss of pigmentation occurs during growth on glucose in the dark. Mixotrophic cells also lose thylakoid membranes, accumulate lipids, alter their cell surface, and show little ability to infect either larval or aposymbiotic adult Aiptasia (anemone) hosts (suggesting that algal photosynthesis may be important for uptake or retention by the host). Despite these changes, the alga exhibits rapid growth on glucose in either the light or dark. When bleached cells are returned to medium without glucose, they regain pigmentation, photosynthetic activity, photoautotrophic growth and the ability to infect the host. To elucidate how glucose modulates SSB01 physiology, we used RNA-seq and RT-qPCR to characterize changes in global gene expression during both bleaching and recovery. We found that levels of transcripts for proteins associated with photosynthesis, carbohydrate metabolism, and cell adhesion declined in glucose-bleached cells, suggesting that modulation of transcript abundance upon addition of glucose to photoautotophically-grown cultures reflects certain physiology changes that allow the transition from a photoautotrophic to a mixotrophic life-style.

WAITING FOR RECRUITMENT: RESILIENCE WITHOUT RECOVERY IN THE LAKSHADWEEP ARCHIPELAGO (Abstract ID: 28632)

Determining the resilience of reefs to increasingly severe climatic events will be critical for their effective management. There is growing evidence that resilient reefs are characterized by high levels of herbivory–essential for mediating algal growth–and the availability of stable structure for new coral settlement. After a coral mass mortality in 2010, we monitored 9 shallow reefs in the Lakshadweep to determine if our assessment of their resilience capacity was reflected in recovery five years later. Although most reefs showed high herbivory rates and had suitable recruit settlement structures, recovery was slow across the archipelago. From 2012-2015 coral cover in permanent quadrats increased by a maximum of 1.5% per year. This contrasts with recovery trajectories after the 1998 ENSO mass mortality, where coral cover increased by 7% annually at these reefs, driven primarily by species of Acropora. In contrast, post-2010, coral juveniles were nearly three times less abundant at these reefs. Recovery, where observed, was driven by a single species (Pocillopora verrucosa). This compositional shift can have important consequences for the structural complexity and community assembly in these reefs. Our results suggest that despite having several factors necessary to guarantee resilience, the absence of banner years of coral recruitment post-disturbance may seriously limit current reef recovery trajectories across the Lakshadweep Archipelago. Identifying and protecting potential sources of coral larvae will be critical to translate this high resilience into quick recovery.

GAPS BETWEEN FUTURE DISTRIBUTION OF CORALS AND MARINE USE/SPATIAL PLANNING AROUND JAPANESE ARCHIPELAGO. (Abstract ID: 28499)

After the adoption of the Aichi Target 2010, protected areas are rapidly expanding in Japan. It is also true in coastal areas such as the Pacific side of the northern part of the main island (Sanriku) and Southern islands in Okinawa. However, most of them did not consider the effect of climate change to decide their conservation target. Here we evaluated the potential distribution of the reef-forming coral species, such as Acropora

spicifera and Acropora solitaryensis, which compose coral communities around their northern limits in the Pacific.. We projected future distribution of these species using outputs of statistical models based on future sea surface temperature (SST) data derived from climate models. We also collected data on the use of the coasts, including fisheries right areas and areas with marine leisure activities the latter of which was represented by the number of dive shops. The distributions of the coral species are highly constrained by the lowest SST and would potentially expand to the north within 50 and 100 years. The response curves of presence of the corals to the SST agreed well with the experimental results on the tolerance to SST. A comparison with the present use (diving shops) of the coral reefs showed there were significant differences between the use of the corals for leisure activities and the distribution of the species even in the present situation. Considering the future distribution, potential conflicts between the present fishery use and coral expansion was suggested. We will discuss suitable configurations of proposed marine protected areas considering these dynamics and conflicts under several different conservation targets.

INTENSIVE CORAL REEF RESTORATION TECHNOLOGY BY APPLYING LARVAL SUPPLY BASE (Abstract ID: 28505)

Since 2006, we have developed the useful and efficient technology on active coral reef restoration as the project of Japanese Fisheries Agency at Okinotorishima, the southernmost isolated island of Japan. Firstly, coral mass-culture technology by using sexual reproduction in aquarium was developed from 2006 to 2008 at Okinawa. As the result, the highest survival rate in one year later reached up to 80%. Besides, the mass-cultured juvenile corals grown on ceramic tiles were successfully transported from Okinawa to Okinotorishima, 1,100km away, via a research vessel taking 64 hours. On the other hand, we developed the artificial concrete block designed as a substrate for outplanting juvenile corals and installed them to the unsuitable area for coral such as sandy gravel bottom at Okinotorishima in 2009. Since 2010, field experiment has been carried out in which the transported ceramic tiles with juvenile corals were outplanted on the blocks. The highest survival rate of the coral in the artificial blocks in one year later marked more than 80% in an appropriate experimental condition. The next challenge is to expand restoration scale utilizing larval dispersal ability. Therefore, we are trying to develop of "the larval supply base", functioning as not only nursery for juvenile corals but also larval supply from maturity corals. It is estimated based on our basic test outcome that 100 square meters larval supply bases, stocking 9 mature colonies of the same species per square meter, have a potential for supplying 100 larvae per square meter on 40ha in Okinotorishima.

DISSOLUTION OF CARBONATE SEDIMENT AT SEAGRASS MEADOW ESTIMATED BY TOTAL ALKALINITY FLUX AND PORE WATER PROFILES (Abstract ID: 28915 | Poster ID: 242)

Ocean acidification decreases the pH of seawater and the saturation state of minerals, and Eyre et al. (2014, Nature Climate Change) indicated that carbonate sediment dissolution could be more sensitive to ocean acidification than calcification by reef organisms. Particularly in seagrass-carbonate sediment, it has been suggested that both abundant labile organic matter and wide redox range would increase $pCO_2$ in sediment, and total alkalinity (TA) flux from sediment to water column caused by Mg-calcite dissolution would also increase. Here, we measured sedimentary dissolved oxygen (DO) and carbonate profiles in a seagrass area of Shiraho coral reef, Ishigaki Island, and TA flux at the sediment-water interface was estimated under natural hydrodynamic conditions using eddy covariance (EC). Almost half of the sediment was Mg-calcite derived from foraminifera and its Mg content was 16.4 mol%. Analysis of the sedimentary DO and Oxidation-Reduction Potential (ORP) profiles at night indicated that $O_2$ was depleted deeper than at least 4 mm and sulfate reduction could occur. While pore water TA and dissolved inorganic carbon values increased with depth, pore water saturation state of aragonite was constant at a value of ~ 2.3 during the entire nighttime. On the other hand, the calculated nighttime TA flux from sediment to water column was 0.9–3.2 mmol $m^{-2}$ $hr^{-1}$ though seawater in water column was oversaturated with respect to Mg-calcite. This would be caused by Mg-calcite dissolution and bacterial sulfate reduction.

MARGINAL CORAL REEFS AND CORAL COMMUNITIES IN JAPAN (Abstract ID: 29388)

Japan covers a wide latitudinal range, stretching from subtropical to temperate areas. Coral communities and reef morphologies show significant changes along the latitudinal gradient, which provides baselines to understand coral reef development patterns and to examine the effect of climate change on coral communities. 1) Unique feature: The highest-latitude coral reefs in the world occur at Tsushima and Iki Islands (34˚N) (Yamano et al., 2012, Geology). These coral reefs are established under extremely low sea surface temperature (SST) and high turbidity setting. Thus defining the end of the distributional range, the reefs serve as baselines for understanding coral reef distribution along SST and turbidity gradients. 2) Historic change: A 80-year record of coral occurrence showed poleward range expansions of four species in response to SST warming (Yamano et al., 2011, GRL). A monitoring program revealed winter SST tolerance of each coral species, which enabled improved reconstruction of the past range expansions based on inter-annual variation of sea surface temperatures (Takao et al., 2015, Coral Reefs). 3) Future projection: It would require consideration of another important issue, ocean acidification. Without consideration of coral adaptation and/or acclimation, in the high CO2 emission scenario, coral habitats will be lost in the 2070s because of higher SST in the south and ocean acidification in the north, whereas the lowered CO2 emission scenario allows coral survive around the southern part of Japan even in the 2090s. This strongly suggests the importance of reducing CO2 emission for conservation of corals (Yara et al., in press).

DAILY FLUORESCENT BAND RECORDED BEHIND BLACK BAND DISEASE (Abstract ID: 28107 | Poster ID: 155)

Coral diseases are growing concern for coral reef conservation as well as predation by starfish and bleaching due to warmer water. Black band disease (BBD) is a first coral disease found in Caribbean Sea and has been spreading many coral reefs worldwide. I found periodical green fluorescent bands as GFP on the surface of dead skeleton after BBD infection. These bands match daily pattern, and are observed exclusively on the light (or upper) side of BBD-affected corals. Fluorescent bands were obvious for encrusting, branching and foliacious *Montipora* corals those are most susceptible corals around Sesoko Island, Japan. Fluorescent bands are translucent, powdery, and some are spot-like form close to polyp structure. Peak band was observed at 535nm when excited at 410nm. Bands are stable in acidic/alkaline solution, in organic solvent, in sodium hypochlorite solution, and still have fluorescence more than a year for dried specimen. Progress rate of BBD was faster in upper (light) side during daytime. Bands are formed during daytime through some chemical changes affected by bacterial activities under the space of BBD.

*ACROPORA TENUIS* LARVAE CAN EXPEL NON-ESSENTIAL*SYMBIODINIUM* STRAINS (Abstract ID: 28542 | Poster ID: 121)

*Acropora* corals must acquire *Symbiodinium* from the surrounding environment during early ontogeny. The genus *Symbiodinium* includes nine phylogenetically distinct groups (clades A-I), and each clade includes numerous types. Recent field observations revealed that naturally settled*Acropora* recruits typically harbor certain members of clades A and D, despite the presence of other *Symbiodinium* in the nearby environment. In contrast, *Acropora* larvae/juveniles can acquire a variety of *Symbiodinium* in the laboratory. Although this disparity between field and laboratory results might be attributed to *Symbiodinium* cell densities around the coral, it remains unclear how corals process accidentally acquired *Symbiodinium*within their tissue. Thus, we supplied *A. tenuis* larvae with three clade A strains (type A1 and type A3, which are often found within natural *Acropora*recruits, and type A2 relative, which is never detected within corals) and then determined the infection rate and density of infected cells within larvae. The infection rate and density of cells infected with types A1 and A3 did not decrease even after the supply of *Symbiodinium* cells was stopped. However, the infection rate and density of cells infected with the type A2 relative declined from 83.3 ± 20.8 to 46.7 ± 5.8% and from 8.2 ± 3.3 to 4.9 ± 0.9 cells/indiv., respectively, within 7 days after removal of *Symbiodinium*. Even in this case, cell division was observed within the larvae. These results suggest that *A. tenuis* can expel non-essential *Symbiodinium* strains.

VARIATION OF KUROSHIO TRANSPORT DURING 1860-2007 AD INFERRED FROM CORAL NITROGEN ISOTOPE SIGNATURE (Abstract ID: 29259 | Poster ID: 97)

The Kuroshio Current supports the tropical reef corals thriving in the temperate areas along the Pacific coast of Japan. We reconstructed the variability of nitrate supply on Kuroshio front due to the current transport over the past 151 years using coral skeletal nitrogen isotopic composition (δ15Ncoral). A 151-year δ15Ncoral record is four times the length of the observational record (1971-present) of Kuroshio transport and could provide a direct comparison with global climate change, such as the Pacific Decadal Oscillation (PDO) index and El-Niño (ENSO), through recent global warming. Coral cores from Porites were collected from Tatsukushi Bay in 2008 on the Pacific coast of Japan, which is located on the northern front of the Kuroshio Current. δ15Ncoral was used as a proxy to record the δ15N of nitrate controlled by the upwelling of subtropical subsurface water, and δ15Ncoral was negatively correlated with observations of the Kuroshio transport (R=-0.69, P<0.001) and the 2-year lagged PDO index (R=-0.63, P<0.005) from 1972 to 2007. The 151-year record of δ15Ncoral suggested that the Kuroshio transport varied in ~25 year cycle, and the amplitude became more stable and the volume was intensified through the 20th century. The Kuroshio transport was intensified by the La Niña state in the early 1900s and by the El-Niño-PDO state after the 1920s. Our results suggested that the variation of Kuroshio transport is relevant to north pacific climate through the 151 years and controls nitrate supply on the Kuroshio front.

THERMAL PERFORMANCE OF THE HIGH LATITUDE CORAL PORITES HERONENSIS: SIGNIFICANCE FOR ITS FUTURE DISTRIBUTION (Abstract ID: 28150 | Poster ID: 312)

A northward shift of hermatypic corals distribution due to the increase in seawater temperature under climate change has been observed in Japan, with further shift predicted in the future. The main factor limiting coral distribution is considered to be the lowest annual seawater temperature. Therefore, it is important to study the physiological response to temperature change of corals living in the vicinity of the northern distribution limit. The present study investigates the thermal performance of a marginal coral,*Porites heronensis*. The corals were incubated under different temperature for 14 days and their metabolims and physiological parameters were measured. The optimal temperature for the growth of the coral *P. heronensis*was showed to be around 21°C, higher than 19°C, the annual average SST observed in Nabeta bay. Critical lower temperature was 12°C with bleaching and high mortality. Bleaching was observed for all corals at 29°C. The results obtained showed that the annual lowest SST in Nabeta bay, 12°C, could limit the growth of *P. heronensis* with bleaching or even high mortality occurring during winter. Increased seawater temperature due to climate change could decrease bleaching occurrence and mortality during winter, resulting in an increase in the population of *P. heronensis* in Nabeta bay. It could also allow a poleward shift of the northern limit of its distribution. However, the annual maximum temperature in Nabeta Bay being 26°C, a future increase of more than 3°C could lead to possible bleaching during summer even in such high latitudes.

SEASONAL VARIATIONS OF SEAWATER PCO2 AND SEA-AIR CO2 FLUXES IN A FRINGING CORAL REEF, NORTHERN SOUTH CHINA SEA (Abstract ID: 28112 | Poster ID: 370)

Evidence based on four field surveys conducted between July 2009 and April 2011 indicates that both sea surface partial pressures of CO2 (pCO2) and sea–air CO2 fluxes at Luhuitou fringing reef in Sanya, Hainan Island, northern South China Sea (SCS) are subject to significant seasonal variations. The diurnal variation of seawater pCO2 ranges from 264 to 579 μatm in summer, which is much larger than that in autumn (152-335 μatm), in winter (84-260 μatm), and in spring (114-228 μatm). The sea-air CO2 flux in summer (~9.6 mmol CO2 m-2 d-1) is also larger than that in other seasons (i.e. ~3 mmol CO2 m-2 d-1 in spring, ~3.5 mmol CO2 m-2 d-1 in autumn, and ~2.7 mmol CO2 m-2 d-1 in winter). The atmospheric pCO2 in this reef shows small diurnal and seasonal variations. The integration of the time-series pCO2 data shows that the reef area is a weak source of atmospheric CO2 at ~0.54 mol CO2 m-2 yr-1. Further analyses indicates that the seasonal variations of the surface seawater pCO2 in Luhuitou fringing reef are mainly affected by seasonally-dependent biological metabolic processes (organic process and inorganic process), and that the organic process play a more important role than the inorganic process. Seasonal sea surface temperature (SST) variations and hydrodynamic processes may also have some influence on seawater pCO2 variation.

THE GROWTH AND CALCIFICATION OF THE CORALLINE ALGA, AMPHIROA SP. (Abstract ID: 30171 | Poster ID: 368)

The calcifying/coralline red algae play critical ecological roles including contributing significantly to primary productivity, enhancing critical structural strength and consolidating reef through calcification, as well as being key to a range of invertebrate settlement and metamorphosis processes in coral reef ecosystems. A new strain was isolated from the South China Sea and its characteristics was investigated. By analyzing structural features and 18s RNA, the strain was identified as Amphiroa sp. It contained biochemically precipitated calcium carbonate as skeletal material with high calcification rate. The growth rate with 3-4 g m-2 d-1 was determined. Additionally, the effects of pH on physiological performance of Amphiroa sp. was also investigated. The results revealed that growth rate was negatively impacted, while the calcification rate was rarely affected by ocean acidification.

BACTERIAL AND EUKARYOTIC COMMUNITIES ASSOCIATED WITH*PALYTHOA TUBERCULOSA* – DIVERSITY AND RELATION TO PALYTOXIN DISTRIBUTION PATTERNS IN JAPAN (Abstract ID: 29177)

The function of coral-associated microorganisms have been broadly studied with relation to nutrient cycles, however, microbial diversity of other reef organisms and the roles of secondary metabolites are still scarce. *Palythoa tuberculosa* (Anthozoa: Zoantharia) is a common reef zoantharian, but lack of information on this species' microbial diversity. It also possesses a large non-peptide toxin, palytoxin (PTX). The origins of PTX and its analogs have not yet been identified, but dinoflagellates and/or bacteria are putative sources. We surveyed the diversity of the microbial communities of *P. tuberculosa* across different seasons to provide baseline information of community composition. In addition, we measured PTX concentrations to investigate correlations between microbial communities and PTX. We sampled four times from Kabira and Teniya, Okinawa, Japan. PTX content was checked in colony tissue. DNA was isolated from gastric cavity water and used for next-generation amplicon sequencing of 16S ribosomal DNA. Preliminary results showed the dominant bacteria was family Endozoicimonaceae at both locations. At Teniya, 35% to 96% of *P. tuberculosahad* PTX while at Kabira only up to 40% of the colonies had PTX. Analyses of the correlation between bacterial communities and PTX levels are still in progress.

ENDOLITHIC BACTERIAL COMMUNITIES AND POTENTIAL FUNCTIONS IN THE CORAL *ISOPORA PALIFERA* (Abstract ID: 29209)

Microbial endoliths, which inhabit interior pores of rocks, skeletons and coral, are ubiquitous in terrestrial and marine environments. Usually, there was a distinct green-pigmented layer within the skeleton of the coral *Isopora palifera*. To characterize diversity of endolithic bacteria, 16S rDNA amplicon pyrosequencing was used to investigate bacterial communities in the green layer of eight *I. palifera* colonies retrieved from two locations and different depths on Green Island, Taiwan. The dominant bacterial group in the green layer belonged to the phylum Chlorobi, green sulphur bacteria being capable of anoxygenic photosynthesis and nitrogen fixation. Specifically,*Prosthecochloris* were prevalent in this green layer. Furthermore, to describe the potential function of

endoliths along different depths, nine metagenomes of endolithic microbes in coral were characterized by whole-genome shotgun sequencing approaches. Results showed that functional traits in coral skeleton along depths were more conserved than bacterial taxa, which indicated potential functional redundancy of endoliths. This is the first study to provide a detailed taxonomic and functional profile of endolithic bacteria in coral, and to determine prevalence of *Prosthecochloris*in the green layer. Finally, we infer that 1) these bacteria may have an important functional role in the coral holobiont in the nutrient-limited coral reef ecosystem; 2) a core functional trait of endoliths in coral shows limited variation in response to environmental heterogeneity.

DISTRIBUTION AND PATTERNS OF POPULATION OUTBREAK OF CROWN-OF-THORNS STARFISH IN JAPAN OVER 100 YEARS IN ASSOCIATION WITH GLOBAL WARMING AND LARVAL DISPERSAL (Abstract ID: 28575)

Population outbreak of the Crown-of-Thorns Starfish (COTS), Acanthaster planci, has been the major threat to the reef ecosystem in the Indo-Pacific region though their cause(s) are still unclear. Here, we reviewed the previous records of COTS outbreaks and occurrence in the Japanese waters over 100 years (1912-2015). Overall, COTS distribution has been extending northwards from the previously northernmost site Amami Ohshima since 1953. Global warming seems to be partly responsible for the increase in the frequency and intensity of population outbreaks in the temperate waters. Genetic homogeneity within Japanese COTS populations indicates that larval dispersal is likely causing northward migration. The patterns of the two major population outbreaks in the 1970s and 2000s were complex but had similar patterns. The western Okinawa main island populations had the highest probability of being the source for secondary outbreaks within Japan. Amami population is also likely to be an important source for outbreaks of the temperate waters. On the other hand, population outbreaks have never been observed at least three regions; Ogasawara, Tokara and Ohsumi Islands. Ogasawara is located approx. 1000km south of the Kuroshio Current so that infestation via larval dispersal from other populations might hardly occur. The latter two regions are, however, located in the middle of Kuroshio Current, implying that there are some key environmental factors that suppress recruitment and/or juvenile survival.

MECHANISM OF ESTABLISHMENT AND MAINTENANCE OF*GONIOPORA STOKESI* POPULATION AROUND OKINAWA, JAPAN (Abstract ID: 28637 | Poster ID: 180)

*Goniopora stokesi* is widely distributed in tropical and subtropical regions throughout the world. This species is commonly found free-living on soft substrates and makes dense populations in isolated environment, probably due to its characteristic manner of asexual reproduction: daughter colonies are formed on the surface of the parent colony and later detach from the parental colony. In 2010, the largest *G. stokesi* population ever reported was found at 30 m depth in Oura Bay in Okinawa Island. This study investigated the population dynamics, its genetic population structure, reproductive strategy and the growth rate of colonies to understand the mechanism of establishment and maintenance of the *G. stokesi* population in Oura Bay. The colony densities in the studied quadrats did not increase, while daughter colonies were produced year round. On the other hand, this species was gonochoric and spawned gametes in late August to early September in Okinawa Island. An analysis of the ITS region of rDNA indicated that the colonies sampled from this population were not clonemates but exhibited no gene flow from another population in Okinawa. These results suggested that this population was maintained via not only asexual reproduction but also sexual one within the population. The growth rates of daughter colonies were similar to those reported for other poritidae species, while the colony size at sexual maturity was smaller than others. These reproductive traits of this species may be effective in establishing and maintaining its population in unstable environment.

REGIONAL-SCALE EROSION OF MODERN CORAL REEF ECOSYSTEMS (Abstract ID: 28778)

Coral reefs serve as natural barriers that protect adjacent shorelines from coastal hazards such as storms, waves and erosion. Projections indicate global degradation of coral reefs due to anthropogenic impacts and climate change will cause a transition to net erosion by mid-century. No studies have quantified the amount of regional-scale accretion or erosion that has occurred since the industrial revolution. Here, we calculate the spatial gains and losses of seafloor elevation and volume for 5 coral reef ecosystems in the Atlantic, Pacific and Caribbean over the last several decades. We show that these reef systems have already transitioned to a net-erosional state. Our most conservative estimates indicate mean seafloor elevation change at these 5 sites ranges from -0.06 to -0.8 m, corresponding to net volume losses ranging from 0.2 Mm3 to 52.8 Mm3 (million cubic meters). Regional-scale loss of seafloor elevation and volume has accelerated the rate of relative sea level rise, and increased current water depths of coral reef ecosystems to levels not expected until near the year 2100. The magnitude of erosion that has already occurred, trajectories for continued coral reef degradation and increasing sea level place these ecosystems and nearby communities at elevated and accelerating risk to coastal hazards. Our results set a new baseline for projecting future impacts to coastal communities resulting from erosion of coral reef systems and associated losses of natural and socio-economic resources.

¬CONSERVING SMALL-SCALE FISHERIES UNDER UNCERTAINTY IN SELF-RECRUITMENT USING SIZE LIMITS (Abstract ID: 29976)

A major challenge in managing for conservation and fishery sustainability at small spatial scales is the unknown amount of external versus self-recruitment, and the applicability of fishery management tools under such conditions. We tested the application of minimum size limits by using empirical data we gathered to create a mixed-recruitment, size-structured integral projection model and simulated harvest to determine the size limit resulting in both increased population abundance and maximum annual harvest for self-recruitment amounts ranging from 0-100% of total recruitment. Over a wide range of life histories, a single 'robust' size limit resulted in increased population abundance and therefore sustainable harvest within 10% of the maximum harvest for every possible recruitment mix. In addition to allowing individuals to reproduce before being harvested, minimum size limits can also be used to rebuild population abundance and maximize sustained fishery harvest when managers have no knowledge about recruitment sources.

EFFORTS OF SMALL-SCALE FISHERS IN CORAL REEF CONSERVATION: CASE ILLUSTRATIONS FROM THAILAND (Abstract ID: 28621)

Coral reefs and small-scale fisheries are closely linked; healthy coral reefs not only provide abundant fishery resources for small-scale fisheries, but also an additional source income for fishers who operate recreational tourism. Maintaining coral reef health could be an important concern to ensure sustainability of their livelihoods. In this study, semi-structured surveys and focus group meetings were conducted to understand the perception of small-scale fishers on importance of coral reefs and their efforts on coral reefs conservation in Ko Samui and Ko Chang, the famous tourism destinations located in the western and the eastern Gulf of Thailand. Although the islands have been influenced with tourism development, small-scale fisheries are still existent. Most of the fishers realized that coral reefs are important for sustaining their livelihoods as their primary sources of food production. Besides, during tourism season, they also gain benefits from tourism-related activities such as providing boats for tourists to diving or fishing sites. They all agreed that coral reefs should be conserved and sustainably utilized. Consequently, many environmental conservation activities have been initiated by local communities attempting to protect coral reefs such as reef cleanup activities, coral reef monitoring volunteers etc. This study could illustrate perception and some efforts of small-scale fishers that enhance abundance of fishery resources and coral reef ecosystem balance.

A TURNAROUND AT SANYA NATIONAL CORAL REEF NATURE RESERVE? (Abstract ID: 28163 | Poster ID: 703)

Located in the South China Sea, Sanya, Hainan province, is China's only seaside tropic resort city where 13 million tourists visited annually. While Sanya's GDP rose by tenfold over a decade, such unprecedented growth also brought pollution, habitat destruction

and other stresses that overwhelm its coral reefs. Since 1980s, researchers noted a plummet of coral coverage from 80 to 12%, with significant declines in distribution and diversity as well. While the central government tried to control such damages through legislation, its ability to influence policy implementation was limited. At the local level, performance of city and provincial government officials was measured by GDP growth and their ability to meet job and tax revenue targets. Hence, enforcement of protection laws was not a priority, even in marine reserves. Recently, however, research and monitoring have gained traction, media reports become less censored, and government priorities have shifted to include environmental protection. Public awareness has increased, and the authorities seem to recognize that conservation is not just good governance, but also good business practice. Summarized here are China's recent efforts in managing the Sanya National Coral Reef Nature Reserve, its only national-level MPA dedicated to coral reef conservation. Through literature research and interviews, we examine the roles played by scientists, journalists and government officials, and how science informs policy making and management. A turnaround is perhaps underway due to renewed prioritization from the central government.

CURRENT STATE AND FUTURE PROSPECTS OF CORAL REEF FISHERIES IN THE SOUTH CHINA SEA (Abstract ID: 28091)

We investigate future economic and ecological trajectories of reef fisheries in the South China Sea (SCS) under combined management and climate change scenarios. We first integrate existing data to assess the current social, economic, and ecological status of SCS reef fisheries. Secondly, we use an ecosystem model to investigate how scenarios of fisheries management and climate change will affect reef fish catch and biomass in the future ( 2045). SCS artisanal and subsistence reef catch was approximately 1.1 million t in 2010, supporting the livelihoods of up to an estimated 3.2 million reef fishers, and providing food for up to approximately 32 million people. Under a scenario of low greenhouse gas emissions and sustainable fisheries management, reef fisheries catch was projected to increase by 20% by 2045 relative to 2015, and by 40% under a status quo management scenario (no new fishing restrictions) and high emissions. The projected number of reef fishers across SCS countries in 2045 can potentially catch 35% and 16% more per fisher under a status quo and sustainable management scenario, respectively. However, the increased catch under a status quo scenario comes at the expense of a large loss in top predators from the reef. Based on these projections, we will analyze the social and economic implications on reef fisheries dependent communities. By assessing the ecological and societal trade-offs associated with potential futures, this study helps to identify what alternative policy pathways SCS countries can take now to progress towards socio-ecologically resilient coral reef fisheries in the long-term.

GENOME-WIDE DNA METHYLATION PROFILING REVEALED COMPLEX ROLES IN ACROPORA MILLEPORA (Abstract ID: 28995)

Eukaryotic cytosine methylation is an ancient trait present in both animals and plants. However, knowledge about DNA methylation in corals is still in its infancy. We show that the coral Acropora millepora has a typical animal gene methylation machinery. We performed bisulphite sequencing and found that DNA methylation only occur at CpG dinucleotides. CpG methylation exhibits similar patterns as in other animals and plants, such as cluster of methylated cytosines and symmetric methylation from both strands, but variations among features were also evident. We confirm the preference of DNA methylation in ubiquitously expressed genes, but also observed complete promoter methylation from a subset of inactive genes that indicates a repressive role on gene expression. In spite of the higher mutability of methylated sites, a comparison of orthologous genes in A. millepora and Acropora digitifera, showed that CpG containing codons were overrepresented at the first codon position (CGN codon) suggesting strong purifying selection. Finally, we compared DNA methylation profile with two other cnidarian species, namely Hydra magnipapillata and Nemetostella vectensis. On average, A. millepora has a higher methylation level than N. vectensis, but less than H. magnipapillata. A distinctive feature of the Hydra methylome is that introns are highly methylated, probably due to their high transposon content, while transposons outside of introns are less methylated. Our results support multiple functions of DNA methylation in coral genomes, which will lead to a deeper understanding of the complex relationships among DNA methylation, transcription plasticity and transposon silencing.

ASSESSING MPA EFFECTIVENESS USING ECOLOGICAL, SOCIAL AND ECONOMIC INDICATORS IN PHILIPPINE COMMUNITIES (Abstract ID: 29220)

The establishment of MPAs in the Philippines has proliferated and has been shown to allow for the recovery of declining coral reef conditions. While this growth of MPAs can be an indication of potential benefits, other studies have showed that many MPAs in the country are not so effective. These concerns highlight the need to better understand processes and standards that go into establishing MPAs, if and how these lead to social and ecological benefits for the community and the MPA, and potential feedbacks. This study used a socio-economic assessment tool (SEAT) and an MPA Effectiveness Assessment Tool (MEAT) to look at the interplay between investments, processes and benefits for various MPA sites. MEAT gauges governance levels in the study sites, while SEAT incorporates resource valuation considerations and livelihood parameters to evaluate benefits derived from effective management. General Additive Mixed Models were used to gauge associations between inputs and outputs from MPA development activities. Investments into MPA establishment were correlated to enhanced productivity of reefs (e.g., increased diversity, and catch of reef-associated organisms). A relatively strong indicator that the MPA translates to increased incomes and employment appears to be the level of revenues garnered by the MPA itself followed by the condition of the management plan. Interestingly, these relationships are non-linear, potentially reflecting the complex political aspects underlying the system. The relations and thresholds between ecological-socio-economic indicators are further explored

CORAL DISTRIBUTION MAPPING OF OKINOTORISHIMA USING TIME-SERIES HIGH RESOLUTION SATELLITE IMAGERY. (Abstract ID: 28544 | Poster ID: 536)

This study was aimed to understand recent coral distribution and their secular changes at Okinotorishima, Tokyo, JAPAN, by utilizing high resolution satellite imagery. Imaginary taken in 2006, 2011, and 2012 were used in this study. For the analytical method of the imagery from 2006, a coral coverage distribution map was made, after clustering using satellite imagery, by superimposing each cluster on existing coverage distribution map made around the same time. For imagery from the rest of the years, the coverage was given automatically according to the relationship between data of each cluster and its coral coverage based on the analysis of 2006. The accuracy of the analysis was verified in comparison with the result of the field survey. It was revealed that the accuracy of the coral coverage was within around ±4~5% from the analyzed value and the one of the coverage change was within around ±5%.

OBSERVING CHANGES IN CARBONATE CHEMISTRY ON CORAL REEFS ACROSS THE PACIFIC (Abstract ID: 28837 | Poster ID: 376)

Many coral reef scientists are researching how ocean acidification is changing seawater chemistry and affecting coral reef ecology. Most research is conducted at limited spatial and temporal scales. In 2005, the Coral Reef Ecosystem Program (CREP) began analyzing seawater samples for dissolved inorganic carbon and total alkalinity to assess changing carbonate chemistry across the Pacific. Since 2013, in concert with an additional suite of oceanographic instrumentation, these two analytes have continued to be collected by CREP at 49 coral reef sites as part of NOAA's National Coral Reef Monitoring Program. CREP's ocean acidification measurements span a spectrum of spatial and temporal scales at islands and atolls ranging from 28 N to 14 S. We will present long-term nearshore, near-reef, and 1 km offshore water chemistry data to reveal differences between islands and elucidate the importance of oceanographic processes (e.g. Equatorial Undercurrent and El Nino Southern Oscillation) on reef chemistry.

Additionally, we will present diurnal water sample data, supported with high-resolution instrument records for reefs in the central, equatorial, and South Pacific. Both of these sampling efforts (e.g. onshore-offshore references and diurnal sampling) enable CREP to calculate reef-level net ecosystem calcification (NEC) and net ecosystem production (NEP) rates. These rates are variable across the Pacific, serve as useful indicators of coral reef ecosystem health, and establish novel datasets for the islands and atolls CREP monitors.

KAI KULEANA KAKOU - UNITING TO CARE FOR WEST HAWAII'S COASTAL AND MARINE COMMUNITIES (Abstract ID: 29912 | Poster ID: 687)

With public and private funding support, eight coastal communities in West Hawai'i met in 2012 to identify shared challenges and opportunities and agreed that mutual support would be of benefit. Since that time, they have grown into the Kai Kuleana Network and are devoted to supporting one another in stewardship, education, and policy initiatives in various stages of development and implementation. Through quarterly participatory meetings, shared values and training objectives have been identified and substantive progress has been made in accomplishing both individual community objectives and broader goals that affect all of West Hawai'i. By sharing knowledge and lessons learned with one another and at larger events, such as the Hawai'i Conservation Conference, network members inspire others, maintain effective communications, accelerate learning and amplify impact to address complex problems faced by coastal and marine communities in West Hawaii – problems that are shared throughout Hawai'i and the Pacific.

RECREATIONAL SPEARFISHING ON CORAL REEFS: AN AUSTRALIAN PERSPECTIVE (Abstract ID: 27785)

Recreational fishing is a growing component of the world's fisheries and is increasingly linked to declines in fish populations. However, due to an absence of past monitoring data, recreational fisheries are poorly understood, difficult to assess and pose governance challenges. We explored historical trends in recreational spearfishing in Australia, as documented in a 58-year chronology of spearfishing magazines. Data were extracted from reported fish captures, advertising, and spearfisher commentary and assessed with regression models and ordination analyses. The proportion of coastal fish captures reported declined by approximately 80%, whereas coral reef and pelagic fish reports increased 1750% and 560%, respectively. Reported catch composition shifted markedly from coastal temperate fishes during the 1950s to 1970s to coral reef and pelagic species in the 1990s to 2000s. The mean weight of reported trophy coral reef fishes also declined significantly over the study period, potentially reflecting their vulnerability to fishing. Interviews with fishers in Australia and the Solomon Islands also provided cross-cultural insight into the reasons why fishers engage in fishing. We found a strong perception that fishing delivers a range of benefits to individuals and societies. These results emphasise the need for regulatory agencies to work closely with fishing communities to observe fisher behaviour, detect shifts in target species or fishing intensity, and to channel the motivations and values of fishers for the benefit of ecosystems and society.

A SEMI-IN SITU EXPERIMENT OF LARVAL DEVELOPMENT OF SCLERACTINIAN CORAL ACROPORA GEMMIFERA IN RESPONSE TO ELEVATED PCO2 (Abstract ID: 29232 | Poster ID: 25)

Here, we investigated the effects of acute exposure to elevated CO2 on skeletogenesis and gene expression in primary polyps of Acropora gemmifera and the variance of metamorphosis using Illumina RNAseq approach. Embryo and juvenile were exposed to 3 targeted pH values (pHT = 8.13, 7.82, and 7.53), which correspond to the designated pCO2 levels (389, 700, and 1214 μatm) that were projected for the pCO2 levels of the present, the end of the present century, and next century. According to the data of skeleton development, compare the proportion of 4-loop-synapticulae period at 6d-28d between groups, there were significant differences ($P<0.05$) between groups pH8.1 and pH7.5 at 11d-28d, pH8.1 and pH7.8 at 15d-21d, and pH7.8 and pH7.5 at 15d-28d. The reference transcriptome consisted of 64556 contigs with mean size of 914 bases and N50 of 1612 bases. We have found 50097 total genes, and 2529 were identified on the basis of sequence similarity to known genes were expressed in A. gemmifera. The gene ontology analysis indicated that the transcription of genes associated with the terms of biological process, cellular component and molecular function. According to the analysis using the Kyoto Encyclopedia of Genes and Genomics (KEGG) database, we identified 22 important genes which were involved in major Organismal Systems, such as mineral absorption, endocrine and other factor regulated calcium reabsorption, vasopressin regulated water reabsorption, proximal tubule bicarbonate reclamation, osteoclast differentiation, gastric acid secretion, etc.

VERTICAL PROFILES OF CALCIUM AND PH IN THE CORAL GASTRIC CAVITY: IMPLICATIONS FOR OCEAN ACIDIFICATION (Abstract ID: 28522)

One hypothesis to explain reductions in coral calcification rates caused by ocean acidification is that elevated seawater CO2 results in increased transport of CO2 into the calcifying fluid, acidifying the fluid and reducing calcification. A major route through which CO2 may enter the calcifying fluid is through the coelenteron or gastric cavity. It is therefore important to understand the processes controlling coelenteron pH, which may partially affect the response of corals to ocean acidification. In this study, pH and Ca2+ microsensors were combined with a reaction-diffusion model to study the dynamics of pH and Ca2+ in the coelenteron of the reef corals Turbinaria reniformis and Acropora millepora. Our study showed that Ca2+ concentrations linearly decreased from the mouth to the base of coelenteron due to calcification. Based on these profiles, instantaneous calcification rates could be estimated, but lower than the rates derived by buoyant weight measurements. In contrast, the H+ concentration remained relatively constant over much of the coelenteron cavity before it increased sharply towards the base of the coelenteron, indicative of proton-pumping from the calcification fluid below. The resulting H+ gradient between the coelenteron cavity and the calcification site was >10 times higher than previously predicted. Consequently, the energy required to export protons from the calcifying fluid was estimated to be ~3 times higher than previously calculated. Our numerical simulation reveals that ocean acidification (OA) decreases the pH at the base of coelenteron, and this pH decline is greatly amplified by the deeper coelenteron and high calcification rates.

PRELIMINARY RESULTS OF WHOLE GENOME SEQUENCING ANALYSIS OF *ACANTHASTER PLANCI* IN JAPAN, HAWAII AND THAILAND. (Abstract ID: 28570 | Poster ID: 73)

Sea level fluctuations associated with Pleistocene glaciation have great genetic impacts on marine species that seldom experience vicariance. Previous studies using morphological data and partial mitochondrial genes indicated Pleistocene vicariance caused allopatric speciation between the Indian and Pacific Oceans in marine species. However, impacts on the whole genome are still unclear. Here we present preliminary results of whole genome comparisons of *Acanthaster planci*, whose sudden population outbreaks have been one of the largest issues in conservation of coral reefs in the Indo-Pacific region, to examine the impacts of Pleistocene vicariance at a whole genome level. We collected specimens from Phuket in Thailand (Indian Ocean species), Miyazaki in Japan (Pacific species) and Hawaii (genetically distinct Pacific species). Heterozygosity was highest in Miyazaki and followed by Phuket and Hawaii, implying the isolated population in Hawaii has lower genetic diversity. Estimated whole genome sizes ranged from 400 to 450 Mbp. While the similarity of the whole mitochondrial genome sequence was about 91% between Indian and Pacific species that between two Pacific species was 99%. On the other hand, a rough estimate of whole genome sequence similarity between Indian and Pacific species was 98% and that between Miyazaki and Hawaii was 99%. These results suggest, as predicted by smaller effective population size of the mitochondrial genome, neutral mitochondrial genes had experienced much stronger genetic drift than nuclear genes.

TEMPERATURE VARIATION AND CORAL COMMUNITY STRUCTURE OF MESOPHOTIC REEF ECOSYSTEM IN PALAU (Abstract ID: 28514)

Tropical mesophotic reef ecosystems are receiving attention in recent years among coral reef researchers due to their potential as refugia for shallow coral reef ecosystems. Light has been shown to be a limiting factor of coral community in mesophotic reefs while temperature was suggested as not a significant abiotic factor. In light of the prediction of severe El Nino event for 2015/16, seawater temperature variation and its effects on coral community in mesophotic reefs can fill the critical gap in knowledge in the physical-biological link between mesophotic reefs and their shallow counterparts. An ongoing seawater temperature monitoring in several mesophotic reef ecosystems in Palau has been carried out since year 2014. Temperature loggers are being deployed at every 5-m depth interval up to 40 m depth in the outer reefs in Palau. Temperatures as low as 19 to 22 degree Celsius have been recorded in depths between 30 to 40 meters with daily fluctuation ranged from 8 to 10 degree Celsius. Extent of cool water pulsing was recorded as shallow as 15 m depth. Seasonal upwelling occurred at higher frequency between January to June resulted in bigger daily and monthly temperature fluctuations in deep water compared to other months. This indicates that corals in mesophotic reefs in Palau are constantly being subjected to big temperature variations. Additional information such as reef community, hydrodynamic processes, light availability, nutrient flux is needed to provide comprehensive baseline data of mesophotic reefs in Palau.

IDENTIFY TYPE AND DISTRIBUTION OF REEF SHARKS SPECIES IN MEKO WATER, DISTRICT OF EAST FLORES, EAST NUSA TENGGARA (Abstract ID: 29480 | Poster ID: 273)

Adonara Island is one of big islands in District of East Flores that has total an approximately 519.64 km2 of land area. Based on shark bycatch survey in January 2015 by WWF Indonesia, it is known that 71.31% of shark species is caught accidentally. Meko Water is the highest area for shark bycatch level than other areas. The purpose of this research was to collect data and information about types, distribution and habitat of shark species in Meko Water, East Flores. We conducted underwater visual census with long swim in for 4 different depths (5, 10, 15 and 20 m) for 40 minutes (10 minutes in each depth). Location determination was based on multilevel methods with total of 20 dive sites that were divided into 3 different clusters (semi hotspot, hotspot and control zone). There were 2 species of sharks that were found in Meko Water; blacktip reef sharks (Carcharinus melanopterus) with 86 sightings (82.69%) and whitetip reef sharks (Triaenodon obesus) with 18 sightings (17.31%). The average size of blacktip was 100 cm with range of 50-150 cm and whitetip was 103 cm with range of 70-120 cm. The highest sighting of sharks was found in fringing reef (75%) in control zone as many as 39 sightings. The result of this research will used to be a basic information for formulate the recommendation for shark fisheries management in East Flores District. Keywords: shark species, distribution, sightings, Meko Water, East Flores

EFFECTIVENESS AND PRODUCTIVITY HAND LINES WITH DIFFERENT BRANCH LINE AROUND PORTABLE FISH AGGREGATING DEVICE (Abstract ID: 27871 | Poster ID: 264)

This research used portable FADs, hand line with a length of branch line to be 0.9 m; 1.2 m; and 1.5 m. The purpose of this research to prove influenced of the length of branch line on technical performance. This research was used experimental fishing methods in around of portable FADs area. The fishing location at Indian Ocean on 8°07.615' S - 106°24.89' E and 8°21.03' S - 106°26.89' E for 6 days and grouped period into morning and afternoon. The catch was 176 fishes with weight 379.7 kg, they were 104 yellowfin tuna (254.7 kg), 68 skipjack tuna (116.1 kg ) and 4 dolphinfish (8.9 kg). Hand line with branch line 1.5 m produced at most yellowfin tuna, as many as 70 fishes with weight 141.3 kg, or an average individual weight of 2.83 kg. The result of the analisys of varians F-test was p-value = 0.397 > 0.05; it means there is no influence significantly the length of branch line catches obtained. Key words: FADs portable, hand line, branch line, Indian Ocean

RAPID ASSESSMENT FOR CORAL DISEASE IN SAWU SEA MARINE NATIONAL PARK, INDONESIA (Abstract ID: 29464 | Poster ID: 165)

In November 2014, The Nature Conservancy coordinated a Rapid Ecological Assessment of the Sawu Sea Marine National Park (SSMNP) that included measures of reef health. Health indicators included disease, bleaching, predation, overgrowth. Of 54 surveyed reefs, 52% were badly damaged, 40% in fair condition, and 8% were healthy. We recorded 2,068 scleractinian coral colonies with health problems: 45% suffered predation and lesions caused mainly by bioeroders and fishes, 31% overgrowth by invertebrates (mainly sponges) and algae, 17% stages of bleaching, and 7% disease dominated by white syndromes. Coral diseases included Skeletal Eroding Band, Brown Band, Black Band, Yellow Band, White Syndrome, and Growth Anomalies. Porites, Acropora, Montipora, and Stylophora experienced highest frequencies of disease. Favia and Platygyra, important reef framework corals, were among the top ten most diseased corals. Owing to the significance of corals as indicators for the state of the marine environment, this coral diseases information is crucial for management of coral reef conservation areas within the SSMNP.

DYNAMIC CHANGES IN GENE EXPRESSION DURING EARLY STAGE OF CORAL-ALGAL SYMBIOSIS (Abstract ID: 29403 | Poster ID: 124)

Acroporid juvenile corals contain the different Symbiodinium clade (e.g. clade A , clade D) from adult colonies which contain clade C. Previous study has shown that clade C Symbiodinium hardly increased in juvenile polyps during the first 2 months after inoculation, while clade D spread in polyps in about two weeks. It was unclear why these Symbiodinium increased in juvenile polyps in different timings. It seemed that host corals have different preparation periods to make endosymbiotic relationship with clade C and clade D. In this study, we focus on the early symbiosis stage between coral and two Symbiodinium (clade C and clade D), and investigated molecular mechanisms for the establishment of coral-Symbiodinium endosymbiosis with transcriptome changes by RNA-sequencing (RNA-seq). The result showed that the number of differentially expressed genes (DEG) was increased with increasing of endosymbiotic algae. From this result, we found some enriched biological processes in endosymbiotic juveniles. We present here about candidate genes involving in establishment of endosymbiosis, and the differences in clade C-symbiosis and clade D-symbiosis.

PREDICTED RESPONSES OF CORAL REEFS TO THERMAL STRESS AND ITS APPLICATION TO CORAL REEF MANAGEMENT (Abstract ID: 29199)

Vulnerability of thermal stress to coral reefs such as mass coral bleaching and threaten reefs worldwide. NOAA Coral Reef Temperature Anomaly Database Version 4 (CoRTAD) with weekly data of 4 x 4 km resolution from 1981 was used to develop a tool for assessing bleaching risk assessment for the entire atolls of Maldives. Application of outputs of this tool enabled identifying reef areas that have the highest and lowest risk to bleaching. This study use thermal stress information at selected reefs in Baa atoll Biosphere reserve and assess the reefs using bleaching assessment methodology prepared by Australian Institute of Marine Sciences as standard means of assessing bleaching. This is particularly useful in time of predicted bleaching and compare with proxies of chronic and acute thermal stress. Identification and application of these (acute and chronic) thermal stress areas enabled to put evidence to the theory: corals acclimated to warmer conditions fare better during acute (bleaching) events than corals acclimated to cooler conditions. Policy makers and reef managers can use the outputs of this through identification of reef areas that are resilient and vulnerable to coral bleaching for developing reef management policy and strategy. It can also be used as an advocacy tool for climate change impacts on coral reefs of Maldives and consequential economic impacts.

CHARACTERIZATION OF AMMONIUM TRANSPORTERS IN*SYMBIODINIUM MICROADRIATICUM* (Abstract ID: 29068)

Nitrogen is a limiting factor for growth in oligotrophic environments of tropical seas. Accordingly, many marine organisms acquired the ability to fix nitrogen from inorganic sources. Corals, as well as *Symbiodinium*, their dinoflagellate symbionts, are able to utilize ammonium as an inorganic nitrogen source. In a recent study of *Symbiodinium* genomes, we revealed an unexpected abundance and diversity of ammonium transporter (AMT) genes across this genus. Phylogenetic analysis of those genes indicated homology to yeast and bacterial ammonium transporters; protein sequence analysis of cloned cDNAs verified the conservation of residues essential for AMT function. These findings suggest that *Symbiodinium* might have evolved an excess of AMTs in response to nitrogen limitation *in hospite*.*Symbiodinium* reside within a specialized intracellular organelle, termed symbiosome, which provides an acidic microenvironment with a pH of 4-6, as opposed to a pH of 8.1 typical of seawater. In order to determine if AMTs evolved in response to symbiosis, we aim to perform functional analysis of these transporters in yeast mutants to determine their specificity, affinity, and

pH-dependent activity. We also expect to see an increase in *Symbiodinium* growth rates as a response to controlled culture experiments using decreased pH and limited ammonium concentration. We believe that the evolution of functional AMTs at different pH conditions is a key aspect in maintaining a symbiotic lifestyle.

THE IMPACT OF HEAVY METALS CONTENT TO GROWTH OF CORALS PORITES LUTEA BASED ON ANNUALLY-BANDED AT TUNDA ISLAND, BANTEN BAY (Abstract ID: 29208 | Poster ID: 390)

In order to assess pollutants and the impacts of environmental change at Tunda Island, heavy metal concentrations of Cr, Sr, Fe, Zn, and Pb were traced through analysis of coral skeletal growth bands in cores of the massive coral Porites lutea. Core sections were examined using x radioagraphy and samples extracted from annual growth bands. Samples of coral skeleton were analyzed using neutron activation analysis and atomic absorption spectrometry to detect metal concentrational in annual growth bands. Results indicated that corals on the windward side of the island incorporated metal concentrations (Cr, Sr, Fe, Zn, Pb) in 1940 and metal levels were still detectable up to 2014. On the leeward side of the islands accumulation of heavy metals in the coral skeleton began in 1969 and was still evident up to 2014. The concentration of heavy metal pollutant in corals from the windward and leeward reefs showed a significant decline over time, while the concentration of strontium remained relatively stable. Anthropogenic influences on the Java mainland are likely responsible for heavy metal pollution in seawaters around the island. Results from this study show that the coral P. lutea accumulates heavy metals in its skeleton and this ability makes it a useful proxy for monitoring and recording environmental pollution at the study site. Keywords: heavy metals, P. lutea, annually growth bands, Tunda Island

BLEACHING IN PALAEOZOIC CORALS? (Abstract ID: 27867 | Poster ID: 235)

Recent scleractinian corals owe their bioconstructing abilities to symbiosis with dinoflagellates. These algae do not fossilize, hence the reasoning for the photosymbiosis is indirect. In scleractinians photosymbiosis usually correlates with high integration of large sized colonies and small sizes of polyps. The oldest known presumably photosymbiotic scleractinians are Triassic (~245 Myr). Earlier Palaeozoic reefs were built by other corals: Tabulata and Rugosa (subclasses extinct at the end of Permian, ~252 Myr). Palaeozoic bioconstructions containing corals first appeared in the Ordovician (~450 Myr). It has been evidenced that tabulate corals posessed photosymbionts as early as in the Silurian (~430 Myr), but Ordovician specimens from Estonia suggest even earlier photosymbiosis. Reefal structures were several times in severe decline during their history. It has been hypothesized that the cause of these events were expulsions of zooxanthellae (possibly similar to bleaching). The aim of this study is to test this hypothesis. One of such collapses of reefal systems was the Late Devonian (~375 Myr) extinction event. Tabulate faunas from the Late Devonian of the Holy Cross Mts (Central Poland) are investigated here. The analyzed pre-extinction faunas have moderately integrated colonies, with small individuals and moderately large colonies, suggesting photosymbiosis. Post extinction corals have larger individuals, small colonies, and variable integration levels, being possibly aposymbiotic. These observations may evidence change in photosymbionts, similar to recent bleaching.

EARLY-MIOCENE REEFS IN THE SIAMANÁ FORMATION, LA GUAJIRA – NE COLOMBIA (Abstract ID: 29726 | Poster ID: 6)

We studied two reef sites (Arroyo Ekieps and Arroyo Uitpa) in the Siamaná Formation in the Guajira Peninsula, Northern Colombia. Our preliminary results indicate that: i) The reefs are composed by 28 species of zooxanthellate corals, included in 16 genera and 12 families commonly associated to shallow environments and to patch and fringing reefs. There are four species of Montastraea and Porites, three species of Astrocoenia, two species each of Agathiphyllia, Diploastrea, Siderastrea, one species each of Acropora, Alveopora, Antiguastrea, Astreopora, Colpophyllia, Goniastrea, Goniopora, Heliopora, Millepora, Stylophora and one specimen of the Caryophylliidae family. Arroyo Ekieps has a higher richness (25 species) than Arroyo Uitpa (9 species). ii) There were low levels of siliciclastic input in Arroyo Uitpa and no significant input in Arroyo Ekieps. iii) The presence of larger archaiasinids , Miogypsina sp. and Amphistegina ssp. suggest an early Miocene age for both sites. iv) Raup-Crick Similarity Index shows a high similarity to early-Miocene reefs in Mexico, Florida and Venezuela. Further research effort will be focused on dating more precisely both sites of the Siamaná Formation.

VARIABILITY OF TUNA PREY ITEMS ALONG THE COAST OF SOUTHERN MINDANAO, PHILIPPINES (Abstract ID: 29246 | Poster ID: 274)

Tuna and its allies are migratory and are among the large predators in the marine pelagic environment. The abundance and distribution of tuna stocks are not limited to the actual extraction site but is dependent on the availability of their prey items. To supplement visual inspection of partially digested prey from the gut, molecular tools must be used to identify degraded prey items to give insights on the migration pattern of tuna in Mindanao. In this study, we report the identification of tuna prey from the gut contents of Yellowfin tuna landed in Sarangani and Zamboanga using COI DNA barcodes. A total of 69 guts were obtained from the public markets. Initial results revealed that prey items of Yellowfin tuna differ in the 2 landing sites in Philippines. In Sarangani, tuna prey was primarily several small tuna species, Thunnus albacares (33.4%) , Thunnus atlanticus (11.1%), Thunnus obesus (11.1%), Thunnus tonggol (11.1%) and Thunnus Maccoyii (11.1%), Pinktail triggerfish (Melichthys vidua, 11.1 %) and Duckbill barracudina (Magnisudis atlantica, 11.1%) while in Zamboanga, it is Bigeye cigarfish (Cubiceps pauciradiatus, 60.0%), and small Yellowfin tuna (Thunnus albacares, 40.0%). However, predator-prey relationships in tuna must be interpreted with caution as it may be influenced by the use of bait and/or the catching practices in each site.

USING 3D SCANNING TO QUANTIFY CORAL MORPHOLOGY (Abstract ID: 28681)

Scleractinian coral species exhibit a diverse range of morphologies, some of which vary significantly across environmental gradients such as light and wave energy. Morphology determines two key coral traits: surface area and volume. Surface area relates to a colony's capacity for photosynthesis, heterotrophy and reproduction. Colony volume relates to mechanical damage thresholds and resource acquisition. Therefore, morphology is a fundamental determinant of the ecological success of corals; driving species coexistence, competition and community structure. However, due to technological limitations, morphology is typically categorised (e.g., branching, tabular) and research based on quantitative measurements of morphology is slow, expensive, inaccurate and/or restricted by portability. Here we present results using handheld 3D laser scanning to quantitatively measure morphological traits across a range of morphologies. Specifically, we compare how surface area, volume and planar area, relate to morphological groups and attempt to collapse colony morphology into a few continuous axes of individual level variation in morphology. Of these, surface area to volume ratios stand out as a key trait for comparing how growth form categories can be arranged on a quantitative continuum. We propose a hypothesis on how surface area to volume ratios may explain differences in coral demographic rates, highlighting the potential advantages of moving towards a quantitative framework of coral morphology.

CONSERVATION GENETICS APPROACHES TO ASEXUAL CORAL RESTORATION ACTIVITIES (Abstract ID: 27914)

The elucidations of the present population structure and genetic diversity are of fundamental importance in establishment effective conservation measures of coral reefs. Coral reefs have various values, but have been decreasing around the world by both global climate change and local anthropogenic effects. In the past decade, coral transplantation has been recognized as a prime management tool for restoration. Asexually method of transplantation has been conducted in many places of the world. However, there has been concern about adverse effects of transplantation for the purpose of restoration, such as loss of genetic diversity, break down local genetic structures and genetic introgression. To compare genetic diversity between cultured and wild population, we studied with *Acropora tenuis*through the Nansei Islands, Japan by using 13 microsatellite markers. For wild population, we assessed the population structure and genetic diversity of 298

colonies from 15 localities. We found that *A. tenuis* did not propagate by asexual way in the wild. The genetic diversity was not significantly different among populations even in possibly peripheral distribution. In addition, our results show that there are at least two major populations of *A. tenuis* in the Nansei Is. For cultured population, we studied 155 colonies from 3 coral farms in Okinawajima Island, Japan. The genetic diversity of each farm is compared with that of wild populations. We believe that accurate evaluations using genetic tools will be valuable for successful restoration of coral reefs.

SIZE-STRUCTURAL SHIFTS REVEAL INTENSITY OF EXPLOITATION IN CORAL REEF FISHERIES (Abstract ID: 29832)

Fisheries represent a considerable threat to coral reef resources because fishers typically target large-bodied species. Although species occupying higher trophic groups are known to suffer a majority of the exploitative effects, changes in composition among lower trophic groups may be significant. Using size-based biomass spectra analysis, we investigate the effects of fishing on the size-structure of fish assemblages and determine if patterns of exploitation vary across trophic groups. Our analyses reveal striking evidence for the effects exploitation can have on fish assemblages. When examining biomass spectra across the entire assemblage we found consistent evidence of "size-specific exploitation", a process by which large-bodied individuals experience disproportionate reductions within the top predatory trophic group. However, when assemblages were analyzed among trophic groups, two additional forms of exploitation were realized; "size-biased exploitation", in which all sizes are exploited with a bias toward greater proportional effect on larger-bodied individuals, and "size-neutral exploitation", in which proportional exploitation is equivalent across all size classes. Importantly, the breadth of size classes and trophic groups that showed evidence of exploitation related positively to local human population density and diversity of fishing methods employed. Our findings highlight the complexity of coral reef fisheries and that the effects of exploitation are realized across multiple trophic groups and not solely restricted to large-bodied top-predators.

AN OUTBREAK OF A SESSILE SEA CUCUMBER REDUCES POST-SETTLEMENT SURVIVORSHIP OF CORAL RECRUITS (Abstract ID: 28561)

An outbreak of sessile sea cucumbers, Ocnus Sanya, occurred on the degraded Luhuitou coral reef in Sanya Bay, Hainan, China. This study explored the pattern of distribution of O. Sanya on the reef, and the impacts of high abundance of O. Sanya on post-settlement mortality of Pocillopora damicornis recruits. The average density of O. Sanya reached 2000 individuals m-2 on hard substrate in 4m depth, which is significant higher than those on 2m and 6m depth, and the average coverage on hard substrate ranged from 11.95 to 23.69% between 2m and 6m depth. With O. Sanya (821.5 ± 160.9 individuals m-2, mean ± SD) on the surface, the tiles had 19.7% more surface sediment than those without sea cucumbers. The settled P. damicornis recruits showed significant higher mortalities on the terracotta tiles with O. Sanya than the control tiles after 3 weeks, in which the average survivorships of recruits with low and high O. Sanya density (649.3 ± 207.3 and 1126 ± 250 individuals m-2 respectively, mean ± SD) were only half and one third of that of recruits on control tiles. The higher O. Sanya density resulted in lower survivorship of coral recruits on tiles, although was not significant. These results suggested that the outbreak of O. Sanya hinders coral recruits recovery, and will deteriorate the sediment stress on coral recruits.

MODEL SUGGESTS CORAL POPULATION RECOVERY AFTER REMOVAL OF ANTHROPOGENIC DISTURBANCE (LUHUITOU, HAINAN, SOUTH CHINA SEA) (Abstract ID: 28108 | Poster ID: 531)

Luhuitou reef is a fringing reef at Hainan Island, South China Sea. Coral communities suffered dramatic decline over the past 50 years under chronic anthropogenic disturbances. Since the establishment of a marine reserve in the 1990s, the frequency and intensity of disturbances declined. Massive Porites dominate in the current coral communities. A matrix population model was based on size-frequency data from field work and projected population trajectories over 100 years under no disturbance and random disturbances. The model reflects a largely open population of massive Porites, with low local recruitment and preponderance of imported recruitment. Under no further disturbance, the population of massive Porites will grow and its size structure will change from predominance of small size classes to large size classes. Therewith, total Porites cover will increase. Even under random disturbances between 10 and 20 years, the Porites population could remain viable, albeit at lower space cover. The models suggest recovery at Luhuitou following the removal of chronic anthropogenic disturbance. Extending the area of coral reef reserve to protect the open coral community and the path of connectivity is advisable and imperative in the conservation of Hainan's coral reefs.

MICROBIOME DYNAMICS IN EARLY LIFE STAGES OF SCLERACTINIAN CORAL ACROPORA GEMMIFERA (Abstract ID: 28288 | Poster ID: 145)

Reef-building coral health highly depends on associated microbes, but little is known how they are developed at different coral developmental stages. Here, we conduct a case study to elucidate the establishment of coral associated microbes through coral life cycle. The microbiota of scleractinian coral *Acropora gemmifera* at various developmental stages were explored by high-throughput 16S rDNA sequencing analysis. Our results show that microbial communities in eggs are highly similar to parental adults, suggesting host coral can vertically transmit microbes to its offspring. Such new finding broadens our understanding of vertical transmission of associated microbes in corals. Microbial community structures were shifted differently from eggs to juveniles. Such variations may be related to coral development and environmental factors. Some specific microbes were accumulated at certain developmental stage. For example, the phylum *Cyanobacteria* was particularly abundant at juveniles and its abundance in 6-day-old juvenile was higher than that in 31-day-old. In contrast, the genus*Ruegeria* affiliating to *Rosebacter* clade was all detected through the life cycle. In conclusion, coral eggs can obtain associated microbes by vertical transmission, but the microbial community structures varied more during the coral offspring development from eggs to juveniles.

CORAL MICROBIOMES AND HEAT STRESS – TESTING THE PROBIOTIC HYPOTHESIS IN A LONG-TERM RECIPROCAL TRANSPLANTATION EXPERIMENT (Abstract ID: 28016)

Ocean warming is an immediate threat to coral reef ecosystems worldwide, and it remains unknown to what extent the coral-associated microbial community may contribute to coral resilience. To begin to address this question, we used a long-term reciprocal transplantation experiment of Acropora hyacinthus between two thermally distinct backreef pools on Ofu Island, American Samoa. Native coral colonies in the two pools had different microbial communities. Moreover, after 17 months of transplantation, microbiomes of non-native corals transplanted into each pool adjusted to the new environmental conditions and were not significantly different from native corals in the same pool. In short-term heat stress experiments, the microbial community responded within 20 hours for corals that had been transplanted to a more stable, cooler environment. But

colonies living in the warmer, more variable environment for 17 months bleached less and maintained their original microbial communities. The robust and stable microbiome of the highly variable pool was characterized by a consistent set of microbial taxa across all control and heat treatments that were not (or only rarely) present in the susceptible corals transplanted to the more stable, cooler pool. Overall, our data provide evidence for a community of microbes associated with heat resistance patterns of corals across variable habitats. Whether these microbial differences influence thermal resilience, or are influenced by it, remains to be determined.

ASYMMETRICAL MESOPREDATOR RELEASE: MORAY EELS INCONSPICUOUSLY PREDOMINATE HEAVILY FISHED REEFS (Abstract ID: 29640 | Poster ID: 253)

Populations of apex predators have declined globally due to human activities. In the absence of sufficient top-down control, mid-level predators can increase drastically in number (termed "mesopredator release"), which may lead to a trophic cascade that severely impacts the bottom-level prey populations in an ecosystem. On densely populated, accessible coastlines of the Main Hawaiian Islands, few large piscivorous fish remain. Nonetheless, these habitats are not functionally devoid of apex predators; rather, on heavily fished reefs, fishermen act as a top predator in the system. However, prey selectivities of humans differ from that of the natural predator assemblage, exerting high levels of top-down control on some targeted fishes and little pressure on non-target species, such as moray eels. Due to their cryptic nature, moray eels are underestimated in visual fish surveys. Consequently, almost no accurate data is available on eel abundances over space or time. Here, we developed a novel eel surveying technique that involves chum deployment on a defined transect to obtain a more accurate eel density estimate. We use this method to then examine how the eel biomass density relative to other reef fishes changes across a gradient of fishing intensity. We hypothesize that the reduction and replacement of natural apex predators with human predators has led to an asymmetrical release of moray eels from top-down control in heavily fished areas.

REDUCED METABOLISM, LIMITED STAMINA: ECOLOGICAL IMPLICATIONS OF ELEVATED CO2 ON A KEY GRAZER (Abstract ID: 30062 | Poster ID: 381)

Ocean acidification has been identified as a threat to coral reef communities in subtropical and tropical regions. Studies have indicated that fish may have positive, negative, or neutral physiological responses to elevated CO2, and these responses are likely species-specific. More recently, research has indicated that elevated CO2 has a pronounced effect on the behavior (e.g., predator evasion) of many coral reef fish. Very little research has addressed how grazers, key to coral reef health, may respond to acidified seawater predicted to occur as the climate changes. The purpose of this experiment was to assess the feeding behavior, swimming performance, and metabolic responses of parrotfish exposed to CO2-acidified seawater. To do this, striped parrotfish (Scarus iserti) were acclimated to ambient sea water at 8.2 pH, seawater manipulated to a pH of 7.9, and seawater manipulated to a pH of 7.6 over a 24 hour period and held in these conditions for 14 days. Parrotfish exposed to a pH of 7.6 experienced lower metabolic rates while processing food relative to fish in ambient seawater. Fish chased until exhaustion traveled shorter distances and fatigued more quickly in CO2-acidified seawater relative to control conditions. Ocean acidification may impair digestion, thereby, limiting growth and reproduction in striped parrotfish. In combination with elevated mortality due to inability to escape predators, parrotfish may have a reduced capacity to manage algal growth on coral reefs.

INCREASING THE RESILIENCE OF CORAL REEFS AND INFRASTRUCTURE TO CLIMATE CHANGE THREATS IN BARBADOS BY IDENTIFYING, CHARACTERIZNG AND ADDRESSING LOCAL STRESSORS (Abstract ID: 29830 | Poster ID: 459)

Coral reefs of islands nations are threatened by climate change and land-based anthropogenic pollution. Preserving and enhancing the resiliency of these coral reefs to climate change is paramount as a conservation measure and to reduce coastal hazards. A more resilient coastal zone is an important component of sustaining the overall economic and social health of Barbados. The Barbados Coastal Zone Management Unit is presently executing the Coastal Risk Assessment and Management Program (CRMP). The goals of the Ecosystem Based Adaptation Pilot Project, one aspect of the CRMP, include: 1) identify and characterizing land and marine based sources of stress that impact fringing reefs, 2) completing a coral nursery pilot project to support fringing reef restoration, and 3) develop a future hierarchical-management strategy to mitigate the major factors that degrade the resiliency of the fringing reefs. During the field program we collected specific parameters to be used as "markers for management effectiveness." The various factors affecting coral reef resiliency will be discussed as well as the two primary processes: eutrophication and chemical pollution. The sources of nutrients (sewage vs. agriculture) driving the eutrophication were characterized spatially and over time. Numerical modeling tools were used to investigate the potential benefits of future reef restoration efforts on wave energy dissipation, reductions in beach erosion, and storm damage mitigation. Coupling pollution forensics with coral aquaculture and restoration is a strategy to increase coastal resiliency.

ANALYZING DISTRIBUTION OF CORAL RECRUITS USING FLUORESCENCE IMAGING (Abstract ID: 28151)

Coral recruitment is a fundamental process that influences coral population dynamics as well as reef community structure. Formation of new juvenile colonies is essential for recovery and indicates good conditions for development and growth of coral reefs. To date, coral recruitment success rates are poorly described; therefore developing an effective survey method for coral recruits distribution analysis is essential. Due to the fact that corals and their symbiotic algae both contain florescence pigments, (chlorophyll-a and fluorescent proteins), we used the FluorIS- Fluorescence Imaging System, to develop a non-invasive method to identify coral recruits in situ during daytime. In this study we tested the efficiency and accuracy of this method by monitoring twenty random quadrats for ten months. Our results show that this low cost, easy to use method, reduces errors in identification formed by other fluorescent organisms (e.g. algae, sponges and worms) and/or surveyor errors. Using this time series we positively identified coral recruits as small as 0.2 cm in diameter and were able to record their settlement, growth and mortality. World's coral reefs are declining and at risk of collapse as a result of local and global stressors. Understanding physiology and survival of coral recruits will improve future predictions of their ability to resist, respond and recover under stress.

EFFECTS OF ELEVATED $PCO_2$ ON PHOTOSYNTHESIS IN TROPICAL MACROALGAE (Abstract ID: 29736 | Poster ID: 284)

As ocean pH decreases due to increasing atmospheric anthropogenic CO2, the levels of pCO2 and HCO3- available in seawater for photosynthesis increases. Little is known about how photosynthesis in macroalgal species will be affected. Different species may have varying responses due to species-specific inorganic carbon uptake mechanisms. We hypothesize that elevated pCO2 will increase photosynthetic rates of tropical macroalgae that are undersaturated by current DIC levels (~2 mM), or that possess ineffective carbon concentrating mechanisms. We studied eight species of calcifying and fleshy tropical macroalgae chosen for their ecological significance on coral reefs. All species were collected from the same shallow (~5 m) patch reef site along the Florida Reef Tract. Photosynthetic rates were determined at three pH levels (7.8, 8.1 and 8.4) to determine the effects of CO2 availability on DIC uptake. At each pH level, photosynthesis was determined across a range of irradiances to examine the energetic requirements of DIC uptake. To discern inorganic carbon uptake mechanisms, we measured photosynthetic rates in the presence and absence of inhibitors of internal and external carbonic anhydrase (AZ and EZ). We found that species had varying responses to elevated pCO2, but that the majority showed an increase in photosynthetic rates at lower pH. Some, but not all species showed a reliance on CA to promote photosynthesis. Our results suggest that species-specific inorganic carbon uptake mechanisms likely play a role in macroalgal responses to elevated pCO2.
