# ABSTRACT BOOK

## 13TH INTERNATIONAL

# Coral Reef Symposium

## 19–24 JUNE 2016 • HONOLULU, HAWAI'I

This program is produced for information and to provide assistance on site at the meeting. It contains the most up-to-date scientific program information through 25 May 2016. All changes received after the printing of the program will be updated on the conference website and will be included in the meeting mobile app. Additional information also can be found on the conference website.

TOWARDS DEVELOPING A FRAMEWORK FOR REEF RESILIENCE: A GREAT BARRIER REEF CASE STUDY (Abstract ID: 29211)

The resilience of the Great Barrier Reef to a changing climate is predicted to vary greatly across the 344,400 km2 and 2,900 individual reefs that make up the world heritage site. Resilience-based management allows responsive adaptation to this challenge. Understanding the capacity of the reef to resist and recover from a broad range of threats and disturbances it faces is crucial for long-term protection. The science of resilience has increasingly become the focus for measuring and managing reef health, however there are still significant gaps when it comes to how to operationalise resilience-based management. The Great Barrier Reef Foundation is convening experts in reef science, conservation and management to develop a globally applicable Reef Resilience Framework. The approach in developing the framework is integrative, collaborative and practical – it recognises the complexity of the ecosystem, is underpinned by the adaptive management principle and is cognisant of the need for communities as well as the ecosystems to adapt to climate change. The framework is intended to provide a mechanism to drive action towards building reef resilience and support resilience planning. It will aid in the assessment and prioritisation of key threats and support decision-making, particularly in relation to the implementation of effective management solutions designed to enhance ecosystem resilience.

DIFFERENT GROWTH STRATEGIES FOR THE CORAL SPECIES SETTLED ON NEW MODEL MANUFACTURED OF SEMI-ARTIFICIAL SUBSTRATES, RED SEA, EGYPT (Abstract ID: 28593 | Poster ID: 179)

Growth and development of recognized coral recruits settled on the artificial model surface was recorded over two years at Hurghada, Red Sea. One soft and several hard recruits were recorded on the models surface. Different strategies of recruit development were performed. Accordingly, month of first species observed, number of polyps, species development with seasonal monitoring of the dimensional changes, seasonal variation in percentage of area development and increase in circumference of each species over the two years was carried out. This indicated a species specific pattern of development that differs significantly among coral families. These differences in the growth pattern of coral species are most probably related to the strategy used by each of the species to achieve its maximum growth and establishment of the colony to the substrate at the same time. Most common development pattern recorded follows the polynomial type, which indicated that the growth in the colonies dose not depend on the arrival of new recruits to the site but on the availability of certain parameters which may include food, illumination and temperature. So in most cases the asexual reproduction is the common type of reproduction until colonies reach certain size (or age) or develop mature enough individuals that are able to produce gametes.

HEAT SHOCK PROTEIN GENE HSP70 AS AN INDICATOR FOR DETERMINING THERMAL STRESS RESPONSE IN STYLOPHORA PISTILLATA FROM GULF OF SUEZ, RED SEA (Abstract ID: 28371)

The branching coral Stylophora pistillata is one of the most abundant hermatypic corals along the coasts of the Red Sea. It has been used for many years as a model species for coral biological studies. To examine thermal stress and any mutation would occur in Stylophora pistillata, we identified full-length sequence of Hsp 70 in samples of control and other samples after exposure to 26°C for 24h and 31°C for 72h. Relative quantification of gene expression level was measured for Hsp 70 in all thermal stressed colonies. Molecular modeling of Hsp 70 protein was made based on the ATP bound open conformation. After submission the sequence of Hsp 70 gene from Stylophora pistillata, GenBank assigned accession KP330265 for this sequence. Gene expression increased at 26°C for 48h than of 24h. It decreased at 72h in contrast expression of gene at 29°C. Gene expression decreased in 48h but increased in72h at high thermal stress of 31°C. Molecular modeling demonstrates that even though many amino acid residues of Hsp 70 protein were mutated after exposure to heat stress, the resultant mutants did not lose molecular interactions that might be necessary for protein stabilization and function.

RESILIENCE-BASED MANAGEMENT IN REMOTE ATOLLS OF THE INDIAN OCEAN: AN OPERATIONAL CASE STUDY FROM THE MALDIVES (Abstract ID: 29591)

The Maldives is an archipelago containing approximately 1200 coral reef islands with more than 305 that harbor communities and permanent settlements that are heavily dependent on reef resources. Due to its vulnerability to climate change and its high resource-dependence, an urgent need to incorporate resilience science into conservation planning and local management was identified. Detailed ecological and socio-economic data for coral reefs and local communities were collected and mapped at a national scale. We developed a management framework that explicitly incorporates both ecological and social resilience, variations in human impact, uncertainty, and identifies the necessary interventions required to address multiple objectives in different atolls. The analysis identified atoll areas regularly used by local communities and private sector resorts, areas that present potential conflict between users, and finally ecologically significant areas. Specific locations were designated conservation priorities as they contain both ecological and social values that are not currently addressed by any existing management scheme. Systematic conservation and spatial planning processes were useful in identifying priority areas but are only effective if accompanied with innovative decentralized governance. Specific management actions are planned for each atoll and will be integrated into national policy.

LONG TERM REEF HEALTH MONITORING (2004-2013) AT ABANG WATERS, BATAM CITY, RIAU ISLANDS PROVINCE (Abstract ID: 27786)

Long term reef health that was expressed as coral live cover and others reef benthics cover monitoring at Abang Waters, Batam City, Riau Islands Province. The aims of monitoring observed, whether the reef benthic covers were changed on a temporal and spatial scale. Reef Monitoring in 2013 is a nine (9) years period, since baseline on 2004 at 12 different sites. Reef health monitoring have used Line Intercept Transect (LIT) method, with ten meter transect long and three (3) transects for representated , and they were lied on 5-7 meter depth. Change of coral cover and others benthic on a temporal and spatial scale was analyzed by one-way ANOVA with further tested by Tukey with p=0.05. Result of monitoring shown that average of coral live cover was 50.71%, however live coral cover have been decrease compared in 2010 which their cover 68,62%. On a temporal scale, the result of monitoring have been shown that significant changed to several benthic cover included coral live cover Acoropora (p=0.04), Sponge (p=0.05) and Coral Ruble (p=0.003), whereas on a spatial scale, the all monitoring sites were experienced decrease in coral live cover. The environment factors were predicted by sedimentation loading and sea temperature stress was indicated by coral bleaching event in 2007 and 2010. The nine (9) years monitoring have been done which shown that decreased live coral cover, however not changed reef health condition Key Words: reef health, reef monitoring, coral cover, benthic cover, Abang Islands

DISTINCT BACTERIAL COMMUNITIES OCCUR ON CORALLINE ALGAE THAT INDUCE HIGH CORAL SETTLEMENT. (Abstract ID: 30101)

Coral larvae must undergo a metamorphosis and settlement process in order to succeed in colony formation and contribute to reef growth. Crustose coralline algae (CCA) are known for their capacity to induce a metamorphic/settlement response in corals. CCAs vary in their capacity to induce these responses but the identity and role of their respective bacterial biofilms is not well understood. We set out to characterize the bacterial community of CCA species with different inductive capacities. Acropora millepora coral larvae were exposed to four different CCAs in multiple-choice assays. The bacterial communities of each CCA species were characterized by pyrosequencing of variable regions V1-V3 of the 16S rRNA gene. Two of the CCAs accounted for three quarters of all settlement. Despite all four CCA species sharing some bacterial groups, we found unique bacterial groups associated with the two species with the highest inductive

capacity . This study is the first to implicate roles for these novel bacterial groups in coral settlement. We will discuss our results in terms of the identity of these groups and their possible role in the inductive capacity of the CCA-bacterial community consortia.

THE IMPACT OF PHILIPPINE MPA MANAGEMENT EFFORT ON HUMAN AND SOCIAL CAPITAL AND VICE VERSA: ASSIGNING NON-USE VALUES TO REEFS BEYOND ECONOMIC BENEFITS (Abstract ID: 29294)

Evidence strongly suggests that marine protected areas (MPAs) have the potential to provide ecological and economic benefits while balancing the trade-offs that come with stricter fisheries management measures. However, the effect of MPAs on social and human capital and MPAs' other non-use values in the Philippines has only been minimally explored. This study aims to determine and measure the impact of MPA management efforts on these benefits at the Philippine municipal level. Relying on contingent valuation techniques in the absence of complete data on the impact of MPA management on natural capital, this research aims to show the value that Philippine coastal society has affixed unto reefs beyond their monetary and economic benefits. Using the Management Effectiveness Assessment Tool (MEAT) and the newly developed Socio-Economic Assessment Tool (SEAT), the researchers compiled data on MPA management effort (using the MEAT) and socio-economic benefits derived from the MPA (using the SEAT) from focused group discussions with MPA managers. Taking data from 17 MPAs, it is evident that social and human capital is high and well-distributed among stakeholder communities along the coast; however, based on this study, this impact cannot be directly attributed to management effort as of yet. Our research suggests some revisions to the SEAT (e.g. on its leadership, social cohesion, education and health metrics) and some parameters to consider when assigning value to Philippine coral reefs to improve the social acceptability of protected areas.

PUTTING THE SUCCESS OF BIOERODING SPONGES ON FUTURE REEFS INTO PERSPECTIVE: ENHANCED BIOEROSION VERSUS PHYSIOLOGICAL CONSTRAINTS OF *CLIONA ORIENTALIS* (Abstract ID: 27934)

Excavating sponges –which are one of the major groups of bioeroders on the reef– belong to the perceived winners under future climate scenarios. Ocean warming and acidification have been shown to boost their bioerosion capacity, but it remains unclear whether there are adverse physiological effects of these stressors that may counteract the enhanced bioerosion on the long run. We exposed the aggressive photosymbiotic bioeroder *Cliona orientalis* from the Great Barrier Reef to a prolonged temperature and acidity rise (according to the IPCC predictions for end of the century summer conditions under "business-as-usual" $CO_2$ emissions). Subsequently we monitored the physiological response of the sponge, focusing on changes to its carbon budget and bioerosion efficiency. Temperature stress resulted in extensive bleaching and occasional mortality, suggesting a strong dependence of the sponge on its zooxanthellate symbiont. Increased acidity alone did not have a profound effect on the sponge bioerosion or survival rates. When combined, these stressors led to a significant reduction in the energetic budget of the sponge, synergistically reducing rather than enhancing bioerosion rates. Overall this study points towards an impaired physiology of the sponge under the changed conditions, leading to the hypothesis that although *Cliona orientalis* may be able to survive future summers, its growth and bioerosion capacity will be substantially diminished.

EXAMINING EDGE EFFECTS ALONG THE KUROSHIO CURRENT IN A SCHOOLING REEF PLANKTIVORE (Abstract ID: 29549)

Informed management in the face of rising anthropogenic pressure has become a priority for the sustainability of coastal fisheries in the Coral Triangle. Depauperate information on pelagic larval duration and behavior presents a particular challenge to understanding the scale of movement in many target reef species, particularly at the boundaries of species' ranges. In such cases, genetic analyses can illuminate dispersal patterns. Schooling, reef-associated caesionids are heavily impacted in regions with high artisanal fishing pressure. We collected tissue samples of *Caesio cuning* from five localities in the apex of the species' distribution to examine genetic connectivity along ~2000km of the Kuroshio Current from the Philippines to the northern extent of the species range in the Ryukyu Islands. Individual samples were barcoded and genotyped via RAD tags and the subsampled genomes were mined for a panel of SNPs to examine (1) levels and direction of gene flow between and among sites in the Philippines and Japan and (2) whether significant decreases in effective population size ($N_e$) at the limits of the species range can be detected. Characterizing genetic signatures from sites proximal to strong ocean currents and from the core to the periphery of the species range provides us with a clearer understanding of connectivity in *C. cuning* populations, helping to inform optimal management strategy for this species.

COMPARATIVE ANALYSIS OF FORAGING BEHAVIOR REVEALS HIGH FUNCTIONAL DIVERSITY AMONG CARIBBEAN PARROTFISHES (Abstract ID: 30085)

Herbivorous fish and sea urchins play a critical role in the resilience of coral reefs by limiting harmful algae. The principal herbivores on many reefs are a diverse group of fishes, which are responsible for different ecological processes (e.g., provisioning of space for coral recruitment, bioerosion, the removal of macroalgae, etc.), and which have complementary impacts on benthic communities. Classifying herbivorous fishes into distinct functional groups based on their predicted impacts on reef ecosystems can inform resilience-based management strategies. We analyzed the behavior, diets, and bite mechanics of parrotfishes in the Florida Keys to document ecological diversity among the dominant herbivores on many Caribbean reefs, and to classify these species into functional groups. We found that in contrast to Pacific reefs, where most parrotfishes are categorized as scrapers and excavators, parrotfishes on Caribbean reefs include representatives of four major herbivore functional groups: scrapers, excavators, macroalgae browsers, and grazers. While fishes in different functional groups clearly have different impacts on benthic communities, we also found that species in the same functional group tended to select different habitats, feed from different substrates, and forage over different spatial scales, suggesting high levels of complementarity within functional groups, and implying that most species play a unique role in the ecosystem. By identifying key functional differences among parrotfishes, our results can inform management of Caribbean reef ecosystems.

CAN CLIMATE ADAPTATION PORTFOLIOS MITIGATE RISK IN THE FACE OF UNCERTAIN IMPACTS OF GLOBAL CHANGE? (Abstract ID: 28746)

Marine conservation and management often focus on the preservation of 'pristine' areas in hopes that these areas will be robust to disturbance and repopulate degraded sites. However, as climate change occurs, the utility of any given site may shift tremendously such that now 'pristine' sites morph into ecological or evolutionary sinks. Given our poor capacity to anticipate the future, what is the best strategy for enabling successful coral reef adaptation to global change? One possible solution is constructing reserve portfolios that protect a diversity of coral species and provide raw evolutionary material across space. Such a portfolio of reserves may have the highest likelihood of capturing key sites and promoting geographic range shifts, physiological acclimatization, and adaptation via natural selection. We report a synthesis of coral traits a graphically outline a meta-community model that will quantify the costs and benefits of building reef adaptation portfolios relative to other conservation approaches, including the preservation of pristine locations. We suggest that diverse conservation portfolios are the key to promoting adaptation in the face of the irreducible uncertainties of global change. By designing management actions to enable billions of match-mismatch tests, nature can draw from these diverse portfolios to pick the winners of ecological reorganization and evolutionary adaptation.

ECOSYSTEM APPROACH TO FISHERIES ASSESSMENT FOR A CORAL REEFS BASED MARINE CONSERVATION AREA IN TROPICAL SPHERE (Abstract ID:

29756)

Ecosystem approach to fisheries management (EAFM) has been suggested as the better option for managing the fisheries in Indonesia since the deliberation of Coral Triangle Initiative in which Indonesia is considered as the member of the initiative. Since that, EAFM in Indonesia has been improving from developing EAFM indicators for ecosystem approach to fisheries assessment (EAFA) methodology to the implementation of EAFM in a number of fisheries units, including in the MPA-based fisheries unit i.e. Gili Matra Marine Conservation Area of West Nusa Tenggara, Indonesia. This paper contributes to the experience of assessing EAFM Indicators using flag model based methodology. Results of the assessment show that relatively good condition has been achieved for the EAFM domain of fisheries resources, habitat, and economics, while for the fishing technology, social and institutional domain, the results are moderately good. A tactical decision approach suggested by Gavaris (2009) is used for taking some management actions to improve the fisheries performance at the Gili Matra MCA.

ECOLOGY OF A TISSUE LOSS DISEASE OUTBREAK IN ACROPORIDS ON THE REEFS OF PALMYRA ATOLL, LINE ISLANDS (Abstract ID: 28935)

Disease outbreaks are a global problem on coral reefs including reefs in remote regions. Before we can predict and respond to disease events we must first understand the ecology and pathogenesis of these diseases. In 2011, we documented an outbreak of an acute tissue loss disease on acroporids in the remote region of Palmyra Atoll, Line Islands. Disease prevalence averaged 1.5% on the reef with surveys in prior years finding no signs of disease. Disease prevalence was similar the following year (2012) but disease progression had changed from predominantly acute tissue loss lesions (>5cm bare skeleton) to chronic tissue loss lesions (<5cm bare skeleton). The disease was still present in 2014 (10.4% prevalence) with both chronic and acute tissue loss lesions on corals. Aquaria studies showed the disease was transmissible through direct and indirect contact. Thirty-four tagged infected colonies followed for one year all had progressive tissue loss (avg. 42% loss) with a case fatality rate of 55.9%. Four of the remaining live colonies had signs of chronic tissue loss and the other 11 colonies showed no signs of disease. Treatment of lesions with a double band of marine epoxy, mixed with chlorine powder, was found to delay but not stop the disease. Histology revealed necrosis with a minority of colonies showing wound repair suggesting an ongoing active process. The bacterium *Vibrio coralliilyticus* strain OCN014 was isolated from diseased coral and was identified as a potential etiological agent based on laboratory infection trials.

MARINE HABITAT CONSERVATION THROUGH SOCIAL MARKETING CAMPAIGN IN PAPUA, INDONESIA (Abstract ID: 30158 | Poster ID: 658)

Community support in the management of Marine Protected Area (MPA) management is a key for success. Social marketing through Pride campaign program has been implemented in 21 MPAs in Indonesia, Malaysia, and Timor Leste with the total area 171,112 ha. . The campaigns were to support behavior change of fishers to comply with the implementation of No Take Zone (NTZ) of the MPA to prevent the degradation of marine resources and promote sustainable fisheries, food security and biodiversity conservation. After two years of the program, social marketing campaigns succeeded in increasing the average levels of Knowledge, Attitude, Interpersonal Communication and Behavior Change across the campaign sites. The campaigns developed an overarching hypothesis of impact that captured the knowledge, attitude and behavior changes needed to reduce threats and achieve conservation results. These included increasing knowledge and conversations about the location and benefits of the protected area, reducing violations of the NTZ and stabilizing fish biomass and hard coral cover. The existence of NTZ could ensure food security for the people in the greater area. This paper will show the process and success story of the social marketing campaign to conserve marine habitat.

INCORPORATING ECOSYSTEM SERVICES VALUES IN RESILIENCE-BASED MANAGEMENT: THE CASE STUDY OF A REMOTE INDIAN OCEAN ATOLL (Abstract ID: 29349)

Understanding the values of ecosystem services and integrating them into spatial conservation plans can allow policy-makers and managers to make decisions about use of resources. Ecosystem services provide a key link between ecological resilience, which supports ecosystem services, and social resilience, which is supported by ecosystem services. Managing marine areas for ecosystem services can thus promote socio-ecological resilience. However, measuring the values of ecosystem services and integrating this information into spatial plans remains challenging due to the complex nature of ecosystems and the services that they provide to people, as well as the paucity of data sets. In this study of the remote North Ari atoll in the Maldives, we collected ecological and social data and analyzed them to determine the total economic value of ecosystem services such as tourism and reef fisheries. A net present value analysis was undertaken in order to make the economic case for coral reef management. It was found that depending on the scenario, investments in developing and running managed areas yielded benefits of 15.8 – 75.7 million US$ annually for the atoll economy, depending on the discount rate used and the level of investment made in coral reef management. Ecosystem services were also mapped, and areas of high intensity of ecosystem services were identified. Recommendations were made for coral reef management in order to gain maximum benefits from ecosystem services and to promote socio-ecological resilience in North Ari Atoll.

USING CORAL REEF SCIENCE IN MSP TO ACHIEVE PERFORMANCE-BASED ZONING (Abstract ID: 29434)

Marine spatial planning is being undertaken in many coral reef areas of the world, usually with the intent to maximize blue growth and promote integrated marine management. One way to ensure conservation of coral reefs are front and center in marine spatial plans and management is to use coral reef ecology and resilience science to design zoning plans that protect what is ecologically most important, while allowing sustainable use. Performance-based zoning allows the setting of very specific conservation and management objectives, and the implementation of management regimes within each zone to move toward achieving those objectives. Management must be designed so that scientific monitoring allows the assessment of performance, considering both ecological/environmental outcomes and social outcomes. Performance based zoning is not cast in stone but can be dynamic and should be regularly amended and updated in true adaptive management fashion. Geographically large scale MSP and zoning, especially that which integrates planning across the watershed and coastal landscape, can help to achieve true ecosystem-based management and will ensure that conservation does not take a back seat to economic development.

ECOLOGY AND PHYSIOLOGY OF HIGH LATITUDE CORAL COMMUNITIES IN JAPAN UNDER PRESENT AND FUTURE CONDITIONS (Abstract ID: 29344)

Tropical corals are so threatened by climate change that high latitude marginal coral communities may be their last refuge. However, the future of these communities is still uncertain. We are assessing the future of high latitude coral communities and their ecosystems through a program that integrates monitoring, field and laboratory experiments and the use of volcanic CO2 seeps as a natural analogue for ocean acidification. We have studied 20 coral species off Izu, Japan (35°N). The lowest annual temperature (~12°C) often causes bleaching and favors overgrowth by macroalgae. Field incubations of two dominant species, *Porites heronensis* and *Alveopora japonica*, have shown the adverse effects of low temperatures on their physiology. We have found that the two corals have different recovery strategies: high mitotic index of the zooxanthellae in *P. heronensis* during summer and a likely shift to heterotrophy during winter for *A. japonica*. In the laboratory, the thermal performance of *P. heronensis* suggests that up to a 3°C increase in temperature would favor its growth. We are now comparing the performance

of corals and macroalgae at Shimoda (35°N, 12-26°C, low CO2), Shikine (35°N, 14-28°C, low CO2) and a CO2 seep off Shikine (14-28°C, high CO2) to determine the combined effects of global warming and ocean acidification at the boundary between kelp forests and tropical coral communities.

ELEVATED $pCO_2$ SUPPRESSES THE INNATE IMMUNE RESPONSE OF THE CORAL *ACROPORA MILLEPORA* TO LPS CHALLENGE (Abstract ID: 28103)

Continued decline of corals reefs globally have been associated with increased anthropogenic stress. However the effect of these direct environmental stressors on the coral immune response is poorly understood though may promote disease due to an already compromised system. Evidence from mammals and *Drosophila* show that environmental stressful conditions impairs the immune response of the animal and that subsequent pathogen challenge causes increased mortality through disease processes. For corals little is understood on the influence of elevated $pCO_2$ on the animal's immune system and how subsequent additional challenges may impact coral health. Here we investigate the transcriptomic response of the coral *Acropora millepora* to the defined immunogen LPS, and the effects that pre-exposing corals to high $pCO_2$ conditions had on this response. Results from this study revealed that the coral implements key components of the vertebrate innate immune system as a response to an immune challenge. Interestingly, the LPS-induced response was impaired in corals exposed to high $pCO_2$ conditions, with suppression of crucial elements of the innate immunity including Toll-like receptors (TLR), tumor necrosis factor receptor (TNFR) and associate members observed. These results support the hypothesis that the innate immune response in corals might be compromise under future ocean acidification conditions.

CORAL REEFS OF THE WESTERN INDIAN OCEAN – STATUS AND BLEACHING IN 2016 (Abstract ID: 29179 | Poster ID: 607)

The Western Indian Ocean contains under 5% of the world's coral reefs, but is hypothesized to contain the second hotspot of coral reef biodiversity globally. These coral reef ecosystems underpin the economies of the countries in the region, particularly fisheries and tourism sectors, and provide livelihood opportunities and income for local communities. However local threats, e.g. from overfishing, and global threats, e.g. from coral bleaching, are all increasing exponentially with regional human population growth and development. Concurrent with the GCRMN reporting on reef status for the region being finalized in 2016, the region is going through what has been dubbed the "3rd global coral bleaching event". Having been the region that suffered the most from the 1st global event in 1997-98, where mortality of 30-50% of corals was widespread, there is grave concern that 2016 may be as severe or worse. The reporting of reef status will compile summary data from participating monitoring programmes across the 10 countries of the region, following the model of the Caribbean GCRMN report published in 2014, and implementing a DPSIR approach. In terms of monitoring effort, the report emphasizes decreasing resources dedicated to monitoring, with most countries of the region posting declining monitoring from 2009 to 2015. The results of improved regional coordination and commitment of national teams through a coral bleaching response plan will be highlighted in the presentation, along with the levels of bleaching and their impact on overall reef status in 2016.

SHORT-TERM ECOLOGICAL IMPACTS IN THE BIRD'S HEAD SEASCAPE MPA NETWORK (Abstract ID: 28462)

Marine conservation strategies often allocate considerable resources towards the establishment and management of Marine Protected Areas (MPAs) with the expectation they will provide fisheries as well as biodiversity benefits. The "reserve effect" has been demonstrated repeatedly, though this is not universal. Here, we move beyond performance indicators to focus on impact evaluation methods that allow us to document and explain variation in the ecological impacts of MPAs. The recent establishment of an MPA network in the highly bio-diverse Bird's Head Seascape (BHS) in West Papua, Indonesia, represents an opportunity to robustly document the ecological impacts of MPAs, using state-of-the-art impact evaluation techniques. Building on an existing monitoring program in the BHS, we adopt a quasi-experimental design that enables causal inference through the explicit consideration of the counterfactual outcome, thus controlling for observable bias. This approach is critical to help disentangle MPA impacts from broader changes affecting the condition of BHS coral reefs. Ecological baseline and repeat data (every 3-4 years) was collected at seven MPAs at over 200 sites within different management zones and in over 50 sites outside of MPAs. Results indicate MPA ecological impacts vary in both magnitude and direction across indicators and MPAs. Using this novel approach to isolate MPA impacts provides further insights into the characteristics of the MPAs that influence ecological outcomes and subsequently facilitates MPA design to optimize conservation targets.

THE TEMPERATE CORAL OCULINA ARBUSCULA EXHIBITS A HETEROTROPHIC RESCUE EFFECT TO TEMPERATURE STRESS (Abstract ID: 28217)

Anthropogenic increases in atmospheric carbon dioxide concentration have caused global average sea surface temperature to increase by approximately 0.11°C per decade between 1971 and 2010—a trend projected to continue through the 21st century. Research has demonstrated that increased SSTs compromise the coral holobiont (cnidarian host and symbiotic algae) by reducing host calcification and symbiont density. However, we are only beginning to understand the role of heterotrophy in the response of the coral holobiont to elevated temperature, particularly for temperate corals. Here, we conducted two independent experiments to investigate the influence of heterotrophy on the response of the temperate scleractinian coral *Oculina arbuscula* to thermal stress. Colonies of *O. arbuscula* from Radio Island, North Carolina were exposed to four feeding treatments (zero, low, moderate, and high concentrations of *Artemia sp.* nauplii) at two temperatures (average annual SST (20°C) and average summer temperature (28°C) for the period 2005-2012) to quantify the effects of heterotrophy on skeletal growth and symbiont density. Results suggest that heterotrophy produced a rescue effect for colonies exposed to higher temperatures, mediating reduced skeletal growth and symbiont density observed for unfed corals reared at the same high temperatures. Our study highlights the importance of heterotrophy in maintaining coral holobiont fitness under thermal stress and has potential implications for the interpretation of coral thermal stress response to climate change.

FROM THE MICROBIAL SOUP AND THE SLIPPERY SLOPE TO SLIME, TO A NEW NORMAL FOR REEF CORALS (Abstract ID: 28330)

Climate change has contributed to worldwide increases in the frequency and severity of mass coral bleaching events and coral disease outbreaks. In recent years research into the coral microbiome has been directed at understanding the microbial contribution to coral death, disease and reef-wide decline. However it is the corals on reefs of today, and those that survive bleaching events, that will be integral to reefs of the future, under altered environmental regimes. The capacity to sustain a normal or 'healthy' microbial state during bleaching is likely to be a vital factor in coral recovery, survival, disease prevention and adaptation. Here we show that near future climate conditions result in an altered microbial state for corals that survive the breakdown of their algal symbiosis. But where previous research has linked a pathogenic or diseased microbial state to coral mortality from bleaching, here we show that non-pathogenic alterations to micro biome occur in corals that survive bleaching events (synonymous to an altered or 'dysbiotic', rather than symbiotic, state). The microbial state of corals surviving near future climate stressors is likely to have long-term implications to coral reef ecosystems.

THE GREAT BARRIER REEF IS AT RISK OF LOSING THERMAL TOLERANCE (Abstract ID: 29279)

Coral bleaching events threaten the sustainability of the Great Barrier Reef (GBR). Here we show that bleaching events of the past three decades have been mitigated by induced thermal tolerance of reef-building corals and this protective mechanism is likely to be lost under near-future climate change scenarios. We show that 75% of past thermal stress events have been characterized a temperature trajectory that subjects corals to a protective, sub-bleaching stress, prior to reaching temperatures that cause bleaching. Such conditions confer thermal tolerance, decreasing coral cell mortality and symbiont loss during bleaching by over 50%. Importantly, we find that near-future temperature increases of as little as 0.5 °C result in this protective mechanism being lost, which may increase the rate of degradation of the GBR.

RAPID AND HIGH PRECISION MEASUREMENT OF UREA USING HIGH TEMPERATURE: SIGNIFICANCE IN COASTAL ECOSYSTEMS (Abstract ID: 29109)

Urea is an unstable organic nitrogenous compound present in coastal environment derived from the excretion of some aquatic organisms, including human being. Recently it was recognized the importance of urea in nitrogen cycle since the discovery of implication of diatoms in the urea cycling. Therefore, accurate measurement of dissolved urea is required in coastal ecosystems. Production, consumption and degradation of urea are not well understood because of a lack of the appropriate measurement techniques. Therefore, we modified the conventional method from a room temperature to a high temperature system for measuring dissolved urea. Conventional method is based on the formation of colored product when urea reacts with diacetylmonoxime in sulfuric acid solution. High temperature (69°C) with single mix color developing reagent (COLDER) is our main modification. This method can determine about 10-12% more dissolved urea in different coastal environments (0.65-0.72 μM urea-N in coral reef, 0.49-0.58 μM urea-N in seagrass and 1.09-2.28 μM urea-N in mangrove) with 70 times faster measurement speed compared to room temperature procedures. Our results suggest that, high temperature procedure is more suitable, rapid and time saving than room temperature procedure with high precision (SD=0.001,CV=1.2%), high recovery (94-99%) and low detection limit (0.03 μM urea-N). Our method may provide an appropriate indication of the status of urea in nitrogen cycle in coastal communities.

DISAPPEARING CORAL CAYS IN SOLOMON ISLANDS (Abstract ID: 27884)

Coral reefs and the ecosystem services they provide are of vital importance to societies yet are one of the most vulnerable ecosystems to the novel pressures arising from the 'super wicked problem' of contemporary global change. Sea-level rise has been predicted to cause widespread erosion and inundation on some of the low-lying coral cays sitting on top of reefs. However, there is limited understanding on exactly what type of islands are the most vulnerable and the timing and rate of changes. Here, we present the first analysis of coral sand cay dynamics from a sea-level rise hotspot in Solomon Islands. Using time series aerial and satellite imagery from 1947 to 2014 of 33 islands, along with historical insight from local knowledge, we have identified five vegetated reef islands that have vanished over this time period and a further six islands experiencing severe shoreline recession. Shoreline recession at two sites has destroyed villages that have existed since at least 1935, leading to community relocations. The large range of erosion severity on the islands in this study highlights the critical need to understand the complex interplay between the projected accelerating sea-level rise, spatial and temporal changes in climate drivers such as wave-driven processes and local tectonics, to guide future adaptation planning and minimise social impacts.

REVERSAL OF OCEAN ACIDIFICATION ENHANCES NET CORAL REEF CALCIFICATION (Abstract ID: 28392)

Ocean acidification (OA) is projected to shift reefs from a state of net accretion to one of net dissolution this century. While retrospective studies show large-scale declines in coral calcification over the last decades, determining the relative contribution of OA to these changes is difficult due to confounding factors (e.g. warming). Here, we quantified the calcification response of a coral reef flat to alkalinity addition to test whether net calcification increases when ocean chemistry is restored closer to pre-industrial conditions. We used sodium hydroxide to increase the total alkalinity of seawater flowing over a reef flat, with the aim of increasing carbonate ion concentrations and aragonite saturation to values expected under pre-industrial atmospheric $pCO_2$ levels. We developed a dual tracer regression method to estimate alkalinity uptake (calcification) in response to alkalinity enrichment. This approach uses the change in ratios between a non-conservative tracer (alkalinity) and a conservative tracer (a non-reactive dye) to quantify the fraction of added alkalinity taken up by the reef. We estimate that the reef community took up 17.3% ± 2.3% of the added alkalinity, inferring a 6.9 ± 0.9% increase in net calcification. In providing results from the first seawater chemistry manipulation experiment of a natural coral reef community, we provide evidence that net community calcification is depressed compared to values expected for pre-industrial conditions, indicating that OA may already be impairing coral reef growth.

UNDERSTANDING TRAJECTORIES OF RECOVERY AND DECLINE OF LAKSHADWEEP REEFS IN THE WAKE OF REPEATED CLIMATE DISTURBANCES AND THE CONSEQUENCES FOR FISH COMMUNITIES (Abstract ID: 28686)

As climate disturbances increasingly come to define the ecology of tropical reefs, understanding the trajectories that systems take in the wake of these events becomes critical to managing and enhancing their buffer capacity. We tracked changes in benthic cover and fish composition on reefs across the Lakshadweep Archipelago, characterised by low fishing and oligotrophic waters. In the wake of the 1998 bleaching, these reefs showed qualitatively different responses, driven mostly by storm exposure and depth. Stable reefs (typically deeper, protected sites) were largely resistant to bleaching and did not show major changes in coral cover. In contrast, Dynamic reefs (typically shallow, storm exposed sites) had coral compositions dominated by bleaching susceptible species but with very rapid rates of recovery linked to high recruitment of fast-growing competitive coral. Finally Degrading reefs (typically shallow, storm-protected sites) were characterised by bleaching susceptible species but with low post-disturbance recruitment and survival of coral. These trajectories in benthic cover had major consequences for several functionally important species of benthic, long-lived fish including groupers and corallivore butterflyfish that could only survive in stable reefs. Our results highlight that even in locations with relatively low fishing pressure, the imprint of climate change is changing basic ecosystem dynamics in large and unexpected ways.

CATALYSING MANAGEMENT OF MARINE RESOURCES THROUGH A FISHER'S ELECTRONIC REGISTRY AND LICENSING SYSTEM (Abstract ID: 28018 | Poster ID: 566)

Governance on artisanal fishing effort is often a challenging task partly due to the inherent sparsity of these small-scale fishers, which frequently poses significant logistical constrains for the authorities. The fisher's electronic registry and licensing system built for the Department of Fisheries in Honduras is a web-based, low cost data handling system that is easy to use with a portable laptop and printer, efficiently emitting physical licenses that deliver a sense of direct participation to fishers. Through the progressive development of this practical, affordable and intuitive tool the authorities of coastal-marine resources are now generating opportune and accurate information on the degree and the distribution of the once underestimated artisanal fishing effort. The central database is also providing the basis for complementary fisheries management tools such as a catch data monitoring system and a participatory environmental crime watch web service.

LONG-TERM CORAL COMMUNITY STABILITY IN A DISTURBED MARGINAL REEF IN KUWAIT (Abstract ID: 27921)

Coral reefs in Kuwait occur at high latitude (29 N) and in extreme environmental condi-

tions (SST range: 13 to 32 C, annually), and have been subject to chronic anthropogenic pressure in recent decades (recurrent bleaching, oil spills, chronic recreational anchoring and diving impacts). We intensively surveyed coral communities at six sites around Kubbar Island in 2015 and compared these to quantitative survey results collected at the same sites 31 years earlier (1984) as well as results from several sites resurveyed a decade ago (2003) in order to characterize changes in coral community structure in this marginal reef environment. Mean coral cover was 25% in 2015 compared with 34% in 1984, but declines in coral cover were significant at only one site. The decline in coral cover at this single site was mainly due to a >80% loss of formerly dominant Acropora, and a concomitant shift towards a lower cover community dominated by massives. A total of 13 coral genera were observed across sites, comparable to the 12 observed in 1984 and the 13 observed in 2003. Urchins have historically been considered an important bioeroder on Kuwait reefs, reaching densities of up to 100 m-2. Echinometra mathaei density averaged 9.7 urchins m-2 in 2015, far lower than the 62 urchins m-2 observed in the 1980s, suggesting that earlier observations represented a bloom following bleaching that occurred in the early 1980s. Overall, the results of this study show a high degree of long term stability in coral community structure in the marginal and heavily disturbed environment of northern Kuwait.

DO DISEASES THREATEN THE CORAL REEFS OF KISH ISLAND, PERSIAN GULF? (Abstract ID: 29300 | Poster ID: 162)

Corals in the Persian Gulf exist in a harsh environment with extreme temperature and salinity fluctuations. Understanding the health of these hardy Gulf corals may prove useful for predicting the survival of other corals facing the impacts of global climate change. In this study, the health state of corals were surveyed along belt transects at four sites on the east side of Kish Island, Iran. Kish Island is located in the northern part of the Persian Gulf and is a favorite tourist spot. Within the four sites surveyed, a total of 474 colonies were found belonging to 13 coral genera. The dominant corals were Acropora (38% of the coral colonies), Porites (24.1%), and Favia/Favites (23%). Signs of excessive sedimentation occurred on all corals except acroporids and physical damage was found on 17% of the corals. Three tissue loss diseases (avg. prevalence±SE) were found in Porites including Porites multifocal tissue loss (8±2.3%), Porites chronic tissue loss (1±1%) and a Porites tissue loss disease, which had distinct peeling tissue at the lesion edge with a green exposed coral skeleton (7.25±3.7%). Another tissue loss disease, Favia subacute tissue loss, was also recorded (1±1%) but no signs of disease were observed on any of the other coral. Other coral lesions included pink discoloration in Porites associated with algae invasion or boring organisms, sponge overgrowth on Porites and mucus sheathing on Favia/Favites. The Gulf region is understudied and this represents one of the first surveys of coral health and disease on these reefs.

ACCELERATING SCALING UP INITIATIVES TOWARDS SUSTAINING CORAL REEFS IN THE PHILIPPINES (Abstract ID: 29939 | Poster ID: 570)

The movement towards more effective coral reef conservation in the Philippines has shown considerable progress. Albeit, concerns persist as to whether the progress so far are enough to be able to catch up with the prevailing threats to coral reefs. Accelerated efforts are needed to improve the effectiveness of Marine Protected Areas (MPA) and scaling up efforts such as through MPA networks and local government alliances. We show that scaling up efforts can help achieve its target within our lifetime through multilevel governance. Efforts like the Marine Protected Areas (MPA) Support Network and other coordinated partnerships in Marine Key Biodiversity Areas (MKBA) are crucial. Using ecological connectedness, critical habitats and trigger species, envelope the priority areas of local and subnational governance initiatives. Protecting 10% of coral reefs has been projected to take a while, despite the significant increase in the size and rate of effective management. Areas needing urgent gap filling to meet future challenges are in the West Philippine Sea and the North Philippine Sea. Initial decades of accelerated marine conservation suggest improved effectiveness with national programs linked to local efforts and also to broader geographic arenas. National government agencies in collaboration with non-government organizations have made headway in finding synergies in marine biodiversity conservation. An overarching archipelagic framework needs to be implemented to pave the way to a Sustainable Philippine Archipelagic Development Agenda.

DIFFERENTIAL EFFECTS OF CO2 AND WARMING ON PREDATOR-PREY INTERACTIONS IN CORAL REEF FISH (Abstract ID: 27925)

Ocean acidification and warming, driven by anthropogenic CO2 emissions, are considered to be among the greatest threats facing marine organisms affecting physiology and behaviour in fishes. We tested the independent and interactive effects of short-term elevated CO2 and temperature exposure on the predator-prey interactions of common pairs of coral reef fishes (Pseudochromis and Pomacentridae) as well as the effect of elevated CO2 exposure on the escape responses of juvenile fish and whether such effects are altered by transgenerational acclimation. We found predator success increased following predator and prey exposure to elevated CO2 and temperature. Overall, high temperature had an overwhelming negative effect on the escape behaviour of the prey compared to the independent effect of CO2 or the combined exposure to elevated CO2 and temperature. We observed little influence of CO2 on the behaviour of the predator, suggesting that attack behaviour was robust to this environmental change. Finally we found that elevated CO2 negatively affected the reactivity and locomotor performance of juvenile fish, but transgenerational acclimation reduced these effects. These are the first studies to address how the kinematics at the basis of predator-prey interactions may change in response to independent and concurrent exposure to elevated CO2 and temperature, and whether there is any potential for acclimation to occur.

FISHING DOWN NUTRIENTS: SELECTIVE HARVEST REDUCES NUTRIENT CAPACITY IN CORAL REEF ECOSYSTEMS (Abstract ID: 29597)

Overfishing is a major driver of global coral reef declines and is associated with reduce biodiversity within these ecosystems. Overwhelming evidence demonstrates that biological diversity is a primary driver of ecosystem function, providing important motivation for conservation efforts. Yet while it is clear that biodiversity loss can reduce ecosystem functioning, there are many other underlying drivers by which humans exact changes to ecological communities. Here we show that although species richness is a good predictor of ecosystem function in highly diverse coral reef ecosystems, it is not a primary driver of ecosystem function loss in the context of one of the greatest threats to marine biodiversity (over-fishing). We modeled five nutrient processes of storage and supply, herein "nutrient capacity", and multifunctionality onto 143 species of coral reef fishes across 110 coral reef fish communities, ranging from heavily fished to protected. We found that despite no substantial changes in the number of species within a community, fishing reduced ecosystem functioning by nearly half. Instead the primary driver of reduced ecosystem function was changes in trophic structure of the communities due to targeted fishing of select species. There is a clear need to protect against species loss, but if a primary goal is to maintain high levels of ecosystem function, focusing conservation efforts on maintaining trophic structure and community size structure is critical. http://faculty.washington.edu/jeallg/Home.html

UP-REGULATION OF CALCIFICATION FLUID PH IN MASSIVE PORITES SPP. CORALS: A RESPONSE TO COMPENSATE FOR OCEAN ACIDIFICATION EFFECTS (Abstract ID: 29293)

We acclimated multiple sub-colonies of four genotypes of massive Porites spp. corals at 25°C and 2 seawater pCO2 concentrations representing the present day (400 ppm) and future atmospheric conditions (750 ppm) for > 5 months. At the end of the acclimation, calcification rates were significantly reduced (typically by 30-60%) in three of the genotypes in the high seawater pCO2 but were unaffected in one genotype. We analysed the boron isotopic composition of the skeleton deposited after the acclimation period to estimate the pH of the extracellular fluid used for calcification. Corals actively increase the pH of the calcification fluid above that of ambient seawater, increasing the proportion of dissolved inorganic carbon present as CO32- at the calcification site and yielding high aragonite saturation states, favourable for the precipitation of the skeleton. All corals at high seawater pCO2 upregulated calcification fluid pH more than their lower pCO2 counterparts thereby partially offsetting the reduction in seawater pH associated with high seawater pCO2. At 750 ppm CO2, two of the genotypes attained the same calcification fluid pH observed at 400 ppm. We observed a strong correlation between calcification fluid pH and coral calcification rate. Our data show that some massive

Porites corals are able to adapt to high seawater pCO2 by upregulating calcification fluid pH to maintain the high calcifying fluid pH required for rapid calcification. We do not know the energetic cost of this adaptation but it persists beyond several months.

LARVAL FISH DISPERSAL IN A CORAL REEF SEASCAPE (Abstract ID: 28238)

Larval dispersal is a critical yet enigmatic process in the persistence and productivity of marine fish metapopulations. We quantified larval dispersal among 8 subpopulations of clownfish (Amphiprion percula) and butterflyfish (Chaetodon vagabundus) in a network of marine reserves spaced between 10 and 120km apart across a ~10,000km2 seascape in Papua New Guinea. Observed dispersal distances matched well with a modeled exponential declining function for A. percula, providing a mean dispersal of 15-20km and 95% of recruitment occurring within 30-45km of the source. The observed mean dispersal distance was longer (50-60km) for C. vagabundus with the modeled dispersal kernel declining only gradually from spawning locations. Our study showed that dispersal can be empirically measured on a spatial scale sufficient to parameterize spatially-explicit models and evaluate the design and performance of networks of marine reserves.

FROM LEAF NETS TO ARBALETES - BLENDING TRADITIONAL AND MODERN METHODS TO COLLECT SAMPLES FOR LARVAL DISPERSAL RESEARCH AT KA'UPULEHU, HAWAI'I (Abstract ID: 30052)

Fishing community engagement in scientific research accomplishes multiple objectives including increased efficiency obtaining samples from target species, increased understanding of research results, and improved advocacy for management initiatives. We worked with Hawaiian elders and fishermen to use traditional methods of group fishing as well as innovative spearguns to collect samples for a genetic study of the resource fish species *Acanthurus triostegus*, or Manini. Utilizing both ancient and modern technology, we were able to collect sufficient samples of this important resource fish species to derive information on larval dispersal in west Hawai'i Island. In this presentation, we consider the efficacy of different methods used to obtain fish and propose that abandonment of traditional fishing methods may be a function of declines in fish abundance as much as other barriers to traditional practice and offer an example of political advocacy from an unlikely source following direct engagement in scientific data collection.

MARINE PROTECTED AREAS BUFFER DIRECT AND INDIRECT EFFECTS OF MONSOON SEASONALITY ON TROPICAL SEAGRASS FISH COMMUNITIES (Abstract ID: 28162)

Climate change is expected alter not only the general climate patterns but also seasonal variability, with direct and indirect effects on species and ecosystems. Marine protected areas (MPAs) are known to rebuild fish stocks, increase local biodiversity and strengthen ecosystem functions. However, the extent to which they can sustain the full diversity of ecosystem services in a changing climate is still unclear. Here, we investigate the interactive effects of MPAs and monsoon seasonality on seagrass associated fish communities. We carried out a field survey in two marine protected areas (MPAs, no-take zones) and two non-protected (fished) sites around Zanzibar (Tanzania) during three monsoon seasons in 2014-2015. Fish and seagrass community surveys were conducted in replicated transects. Since seagrass cover may vary between seasons, which in turn could affect the associated fish community, we used path analysis to discern whether seasonality affects fish communities directly, or indirectly through effects on the seagrass beds. Within MPAs, we found no direct or indirect effects of seasonality on seagrass fish. In fished areas, there was both a direct effect on juvenile, sub-adult, and adult fish densities; and an indirect effect (mediated by seagrass cover) on total and sub-adult fish densities. Despite the low level of replication (two MPAs), our findings suggest that well enforced MPAs could play an important role in buffering some of the direct and indirect effects of future climate variations on fish communities, and thus in the maintenance of ecosystem services.

HIGHER MORTALITY BUT INCREASED GROWTH RATES OF CORAL ON IMPACTED REEFS AT JEDDAH, SAUDI RED SEA (Abstract ID: 29082 | Poster ID: 103)

ABSTRACT The coast of Saudi Arabia contains many of the best developed fringing reefs in the Red Sea. However, coral communities on reefs closest to central Jeddah has been badly affected by a wide range of impacts including extensive coastal infilling, discharge of untreated as well as treated sewage, unregulated fishing, coral bleaching and disease, and outbreaks of Crown-of-thorns starfish. Coral growth has been widely used as a proxy for reef health and, to inform measures intended to improve environmental conditions, we used an experimental approach to assess which of these impacts had been most critical. Coral fragments of two species (Acropora hemprichi and Pocillopora verrucosa) were cultured in mid-water suspension (so as to minimise the impact of benthic predators and sediment deposition) at 6 different sites located north and south of Jeddah. Survivorship and growth rates were monitored as well as chemical and physical parameters and the associated bacterial biota. Results revealed that the mean rate of coral growth was actually higher at some of the impacted sites, especially those closest to sources of domestic and municipal sewage at which nutrient levels were found to be elevated. However, coral mortality was also higher at these same sites and coral cover on adjacent reefs lower. The differences in survivorship between sites may reflect reduced health of coral fragments, higher rates of growth of competitive turf algae, reduced rates of grazing by herbivorous fishes and changes in associated bacterial fauna at the sites most subject to impact.

TROPICAL DEAD ZONES AND THE COLLAPSE OF CORAL REEFS (Abstract ID: 29618)

Hypoxic dead zones are an increasingly common form of coastal habitat degradation that can have catastrophic consequences for biodiversity, ecosystem function, and human wellbeing. Dead zones are known primarily from temperate regions, but little is know about the potential threat of hypoxia in the tropics, despite the fact that risk factors, including eutrophication and elevated temperatures, are commonplace. Here we document an unprecedented hypoxic event on the Caribbean coast of Panama and assess the global risk of dead zones to coral reefs worldwide. The event caused massive mortality to corals and other reef-associated organisms, but observed shifts in community structure combined with laboratory experiments revealed that not all coral species are equally sensitive to hypoxia. Analyses of global databases suggest that tropical dead zones have been severely under-reported, perhaps by an order of magnitude, due to lack of local scientific capacity for their detection. Our findings suggest that dead zones have already impacted the structure and function of coral reefs, and that a comprehensive understanding of dead zone dynamics requires consideration of tropical ecosystems. The growing threat of coastal hypoxia should be incorporated into monitoring and management plans for coral reef resilience.

A CRITICAL EXAMINATION OF THE LINKAGES AND OUTCOMES OF BIODI-

VERSITY VS. FISHERIES CONSERVATION INTERVENTIONS FOR CORAL REEF SYSTEMS (Abstract ID: 29493)

Two of the premier goals of marine conservation are to achieve sustainable fisheries, and maintain biodiversity. It is often assumed that these goals are compatible because of strong and positive functional links between them. For example, in contrast to complete dependence upon a single prey taxon, a diverse assemblage of forage species can better support populations of commercially targeted fish predators. Also, sustainable fishing practices can enhance biodiversity by reducing bycatch of non-target species. However, there is also a great potential for negative tradeoffs from interventions that support immediate human needs (eg fishing) versus those that support long-term human wellbeing (eg resilience through biodiversity pathways). These are particularly severe in coral reef environments, a model for ecosystem service flows in hyperdiverse tropical systems. While many conservation strategies here take for granted the existence of a strong and positive link between sustainable fishing and biodiversity, the question has not been subject to critical evaluation To bridge this knowledge gap we have sought to: 1) identify interventions routinely deployed to achieve sustainable fisheries or biodiversity maintenance on coral reefs, 2) consider the set of theoretically possible and likely outcomes that result, and 3) illuminate these based upon a literature review and expert workshop, to understand the outcomes of these interventions in real world environments. We discuss our results in the context of operationalizing marine ecosystem-based management in coral reef environments.

SHIFTS IN CORAL-ASSEMBLAGE COMPOSITION DO NOT SECURE REEF FUNCTIONING (Abstract ID: 29735)

Coral communities are changing rapidly worldwide through loss of coral cover and shifts in species composition. Although many reef-building corals are likely to decline, some weedy opportunistic species might increase in abundance. Here we explore whether the reshuffling of species can maintain ecosystem integrity and functioning. Using four common Caribbean reef-building coral genera we modeled rates of reef construction and complexity. We show that shifting coral assemblages result in rapid losses in coral-community calcification and reef rugosity that are independent of changes in the total abundance of reef corals. These losses are considerably higher than those recently attributed to climate change. Dominance patterns of coral assemblages seem to be the most important driver of the functioning of coral reefs and thus, the future of these ecosystems might depend not only on reductions of local and global stressors, but also on the maintenance of keystone coral species.

THE MAINTENANCE OF CORAL BIODIVERSITY VIA RELATIVE NONLINEARITY OF COMPETITION (Abstract ID: 28929)

The high levels of biodiversity in reef coral assemblages have proven difficult to explain solely by niche partitioning. Other coexistence-promoting mechanisms, such as the storage effect, must therefore be operating. Relative nonlinearity of competition is a coexistence-promoting mechanism that allows each species to be favoured under different resource levels due to differences in the functional response of the per-capita population growth rate to resource availability. To date, it has only been shown in highly idealized model communities. In reef-coral assemblages, where space is a limiting resource, this mechanism could arise from differences in size-dependent susceptibility to mechanical disturbance between growth forms. We tested for relative nonlinearity of competition in reef-coral communities using competition models that we calibrated with empirical estimates of demographic rates for two different pairs of competitors (tabular vs. digitate corals and tabular vs. massive corals). Results revealed that the tabular species is favored under low resource availability (i.e. when coral cover is high), while digitate and massive corals are favored under high resource availability. This occurs because the tabular corals are superior competitors in calm conditions, where large and fecund colonies are present in the population. After a disturbance, the large tabular corals are dislodged, reducing the population fecundity of tables, relative to their competitors. Our results confirm the plausibility for coral reefs of this previously hypothetical mechanism of coexistence.

SCIENCE-INFORMED CONSULTATION, PUBLIC INVOLVEMENT, AND MANAGEMENT DECISIONS:PLANNING A MARINE RESERVE IN BISCAYNE NATIONAL PARK, USA (Abstract ID: 28418 | Poster ID: 632)

The National Park Service (NPS) approved a 2015 management plan for Biscayne National Park that included a 10,512 acre marine reserve protecting a third of the park's reefs. The plan was a culmination of fifteen years of planning that included 22 public meetings with 1000 attendees, 43,000 public comments, and three plan versions. The marine reserve was controversial, with opposition to fishing restrictions and arguments for greater reef protection. Following a 2012 Congressional hearing on the draft plan, the NPS consulted with the State of Florida to offer two new restricted-fishing alternatives in lieu of a marine reserve: one alternative with a zone with required special fishing permits and another with a seasonal fishing zone. Following new information on the state of the park's reefs after the 2014 and 2015 coral bleaching events, new studies on marine reserves and impacts of seasonal closures and restricted fishing on targeted fish species and recreational fishers, and extensive public comments, the NPS chose a marine reserve. After a 2015 Congressional hearing on the final plan, the NPS made a commitment to monitoring and research, in consultation with appropriate federal and state agencies, for up to 20 years to determine the extent to which the reserve achieves its stated goals as compared to baseline conditions. Another key commitment is that the NPS will consider recommendations during this timeframe on monitoring protocols as well as whether to continue or modify the marine reserve, including its size, geographical extent, and specific rules and restrictions.

SISTER SPECIES OF THE ORDER ZOANTHARIA (CNIDARIA: HEXACORALLIA) BETWEEN ATLANTIC AND PACIFIC/INDIAN OCEANS (Abstract ID: 28483)

Understanding speciation processes is one of the main questions in evolutionary biology. Among benthic taxa, zoantharians (Cnidaria: Hexacorallia) comprise an abundant group in shallow waters, and colonies are used as shelter or food source. Furthermore, they are an interesting model to investigate closely related species, as there are reports of sister species with highly similar molecular sequences from different ocean basins (Atlantic and Indian/Pacific). However, no study has analyzed such pattern in zoantharians and which are these pairs remains unknown. Herein we investigated closely related representatives of the order Zoantharia performing phylogenetic analyses of genera that have species in both oceans basins. In addition, we analyzed species morphological data. Our aim is clarify which are these pairs and discuss how this pattern was likely generated. There are nine zoantharians pairs where one species is reported from the Atlantic Ocean and another from the Pacific/Indian oceans in four out of ten genera analyzed. These sister species present identical mitochondrial and closely related nuclear sequences in addition to highly similar morphological characters. The frequency of sister zoantharians reveals an unusual pattern compared to what is known for shallow-water reef animals, like corals and most fishes, which have deep genetic distances between species from different ocean basins. Due to this high occurrence of pairs and to the species widely distribution within an ocean, it is likely that a vicariant event(s) has led to sister species in Zoantharia.

ALGAL BIOASSAYS SHOW LAND-BASED, ANTHROPOGENIC NITROGEN IS DELIVERED TO REEF BIOTA BY GROUNDWATER IN HAWAII AND AMERICAN SAMOA (Abstract ID: 29691)

Submarine groundwater discharge (SGD) is a source of land-based contaminants to coastal ecosystems, yet the impact of this process on marine biota remains understudied. To determine if plants assimilated SGD-derived nitrogen (N) on otherwise oligotrophic reefs, we compared the N parameters ($\delta^{15}N$ values and N concentration) of naturally occurring macroalgae with those of surface water, coastal groundwater, and terrestrial groundwater in Hawaii and American Samoa. In addition, tissues of *Ulva*spp. were deployed for 5-6 days to determine the extent of nutrient pollution at 8 coastal sites in Hawaii. Reduced salinity, elevated $^{222}Rn$, and high nutrient levels in beach porewater and surface water relative to ambient marine water provided evidence that SGD was a sub-

stantial vector for nutrient delivery to all study sites. The highest $\delta^{15}N$ values in algal and water samples were found adjacent to wastewater treatment facilities that dispose treated effluent into groundwater via injection wells in Hawaii. The lowest $\delta^{15}N$ values and highest N concentrations in water and algal tissues were found at locations adjacent to sugarcane fields. On Tutuila, high $\delta^{15}N$ values in nearshore algal and water samples, relative to a control site, suggest that wastewater was a source of N to reefs adjacent to three villages. In general, regions with little human impact had relatively low N concentrations and $\delta^{15}N$ values. Within developed regions of Hawaii and American Samoa, SGD delivered N derived from wastewater and fertilizer to marine macroalgae across large spatial scales.

THE PERFECT STORM: MATCH-MISMATCH OF BIOPHYSICAL EVENTS DRIVES LARVAL FISH CONNECTIVITY BETWEEN PULLEY RIDGE MESOPHOTIC REEFS AND THE FLORIDA KEYS (Abstract ID: 29346)

Mesophotic coral reef ecosystems are remote from coastal stressors and may be the key to resilience. While they remain for the most part exposed to fisheries overexploitation, nothing is known so far about larval fish connectivity between mesophotic and shallow ecosystems. We use a biophysical model to test the hypothesis that Pulley Ridge, a mesophotic reef in the Gulf of Mexico that hosts a variety of shallow-water tropical fishes, may replenish shallow fish populations in the Florida Keys. To identify spatio-temporal patterns of vertical connections we developed a 3-D coral reef habitat module for the open-source Connectivity Modeling System and simulated larval transport of a demersal spawner, the bicolor damselfish Stegastes partitus. Virtual larvae were released daily between 60-80m from Pulley Ridge over 60 lunar spawning cycles, and tracked until settlement within a high resolution (900 m) regional hydrodynamic model. These probabilistic simulations reveal mesophotic to shallow connections with large, yet sporadic pulses of larvae settling in the Florida Keys. Modal and spectral analyses on the spawning time of settled larvae, and on the position of the Florida Current front along Pulley Ridge, demonstrate that specific physical-biological interactions modulate these "perfect storm" events. This study demonstrates that mesophotic coral reef ecosystems can also serve as refugia for coral reef fish and suggests that they have a critical role in the resilience of shallow reef communities.

A FIVE YEAR ASSESSMENT OF CORAL IN FAGA'ALU BAY, AMERICAN SAMOA - HAS FIVE YEARS OF MANAGEMENT MADE AN IMPACT? (Abstract ID: 27799)

Faga'alu Bay on Tutuila island in American Samoa is an US NOAA National Priority Watershed, and has shallow nearshore reefs along the bay edges. In 2012, four long-term transects were laid by installing six steel pins for each transect, with two transects on each bay side to allow for comparative monitoring. One side of the bay is heavily influenced by stream effluent, which carries high loads of sediment from a quarry, while the other side of the bay is rarely reached by the stream plume. Photoquads were taken along transects on a quarterly basis each year and will be analyzed for percent live at the functional level with the following categories: hard coral cover, rubble, crustose coralline algae, and macroalgae cover. Based on field observations, we expect data to show the bay side with minimal stream influence to be more resilient to current bleaching and Crown of Thorn Starfish impacts, leading to higher overall live coral cover. Conversely, we expect data to show the bay side influenced by sediment to have lower live coral cover, based on observations of a lack of new growth. The rock quarry implemented extensive new sediment management techniques in 2012-2014, thus we hope results of the analysis will show reduced macroalgae and new coral growth on the less impacted side of the bay.

SYNERGISTIC EFFECTS OF OCEAN WARMING AND ACIDIFICATION ON GROWTH AND SURVIVORSHIP OF COMMON REEF-BUILDING CORALS (Abstract ID: 28537)

Ongoing climate change is considered to be one of the greatest threats to the persistence of reef building corals. More specifically, increasing temperatures are expected to be compounded by ocean acidification, leading to declines in abundance and survivorship of corals. To determine how corals will respond to the combined effects of warming and ocean acidification, two common and fast growing *Acropora* corals (*Acropra muricata* and *Acropora hyacinthus*) were used in a fully factorial experimental study using three temperature treatments (26 °C, 28.5 ° C and 31 ° C) crossed with three levels of $pCO_2$ (400 ppm, 675 ppm and 950 ppm). Future temperature stress caused a 10 % decline in survivorship, and 10-50 % decline in calcification across both coral species. End of century $pCO_2$ reduced survivorship and over long-term lead to 50 % reduction in calcification. Therefore, temperature had a bigger negative effect than $pCO_2$. Without adaptation or acclimation, branching corals species most sensitive to temperature stress and ocean acidification are likely to suffer from declines in health and survivorship that would drastically reduce reef complexity, and cause shifts in ecosystem function.

A FUNDAMENTAL PARADIGM FOR CORAL REEF CARBONATE SEDIMENT DISSOLUTION (Abstract ID: 29975)

The success of coral reefs depends on a positive balance of calcium carbonate production exceeding dissolution, erosion, and material export. As a result of ocean acidification, coral reefs could transition from net accretion to net erosion owing to decreasing rates of calcification and increasing rates of CaCO3 dissolution and bioerosion. Here, we present a fundamental paradigm that aims to explain the main driver of carbonate sediment dissolution on coral reefs based on theory and empirical datasets of pore water carbonate chemistry from diverse reef locations in the Atlantic and Pacific. We suggest that carbonate sediment dissolution is most strongly controlled by the extent of organic matter decomposition in the sediments, but that the magnitude of dissolution is influenced by how much decomposition is required to reach pore water undersaturation with respect to the most soluble bulk carbonate mineral phase present in the sediments, a condition defined as the Carbonate Critical Threshold (CCT). Decomposition of organic matter beyond the CCT under aerobic conditions results in stoichiometric proportional dissolution of carbonate sediments. As ocean acidification proceeds over the next several decades, the extent of organic matter decomposition required to reach the CCT will decrease, carbonate dissolution will increase, and subsequently the accumulation of carbonate sediments will decrease.

ANALYSIS OF THE COMPETITION BETWEEN LOBOPHYTUM PAUCIFLORUM WITH TWO HARD CORALS (Abstract ID: 29069)

Competition between colonies has shaped coral reef communities throughout their evolutionary history. The product of individual interactions is the overall health of a colony, and if the colony's immune system is compromised, it is less likely to win a competitive interaction. Observational studies imply that contact with, or proximity to competitors triggers immune responses and defense mechanisms on hard corals. The limited research that has been done on coral immunity has focused on hard corals, and little is known about the molecular responses of soft corals to immune challenge or contact with other corals. To understand the molecular responses of corals in non-contact competition we used an experimental approach. Fragments of the soft coral L. pauciflorum were placed in individual tanks together (not in contact) with nubbins of one of two hard coral species: A. millepora/P. cylindrica. The species, selected because of the extensive molecular datasets existent, will enable comprehensive gene expression analyses. The behavior of both hard and soft coral in these experiments was monitored over the following two months, and samples taken for gene expression analysis. Aggressive behavior was observed by the hard corals towards the soft coral, and preliminary results imply that the presence of the soft coral affected the polyp activity of the hard corals. These results suggest that hard corals were reacting in proximity to a potential competitor. Gene expression analyses are under way to enable a deeper understanding of the molecular bases of this competitive interaction.

USE OF MESOPHOTIC CORAL ECOSYSTEMS BY INVASIVE WESTERN ATLANTIC LIONFISH (Abstract ID: 28308)

The severe negative effects of invasive lionfish (*Pterois volitans* and *Pterios miles*) on western Atlantic shallow reefs are well documented, yet despite lionfish recorded on deeper reefs, the use of mesophotic coral ecosystems (MCEs) in invasive lionfish ecology and life history remains a significant gap in our knowledge. We combine studies of lionfish abundance and body length on shallow (0-30m) and mesophotic (30-150m) reefs from 63 sites in seven western Atlantic countries. Lionfish were found at similar abundances on adjacent shallow and mesophotic invaded reefs and in some locations MCE lionfish were larger than shallow individuals. This suggests MCEs may form part of a natural ontogenetic migration, with older lionfish found at greater depths. To further understand these patterns we conducted detailed lionfish surveys around Utila, Hondruas from 5-85m depth during June-September 2015. Our results indicate a depth refuge around Utila, with greater densities of larger lionfish recorded on MCEs than shallow reefs. We took detailed measurements and dissection data of circa. 500 lionfish across this depth range. Male lionfish were found to be more reproductively mature on MCEs than shallow reefs, though interestingly reproductive maturity and mean gonad weight was not found to be different with depth for female lionfish. This study highlights the need for lionfish adaptive management to consider lionfish populations below the depth limit of recreational SCUBA diving, as the focus of most previous control (culling) measures has been shallow water.

QUANTITY, NOT QUALITY – FIRST LARGE-SCALE CENSUS OF INDO-PACIFIC SCLERACTINIAN CORALS (Abstract ID: 30102 | Poster ID: 702)

Over the past centuries, the global abundances of humans and most wild species have followed markedly opposite trajectories. While the human population has grown exponentially, an increasing number of species is considered threatened by extinction, including one-third of scleractinian corals. In contrast to human population size estimates, our quantitative understanding of status and trends in abundance is highly limited for most taxa. This is particularly true for corals. Their vast geographic range and population sizes entail inevitable trade-offs between taxonomic and spatial resolution. Data on species-level abundances is therefore scarce, geographically biased towards well-studied reefs and species and not readily collatable for meta-analyses due to inconsistencies in sampling design. This study provides for the first time, census population size estimates for more than 300 scleractinian corals at a longitudinal scale of 10,000km (Indonesia to French Polynesia). Estimates are calculated using species-level abundance data from a single, hierarchically structured (fringing reefs in 5 regions, 3 islands, 4 sites, 3 habitats: reef flat, slope and crest) and methodologically consistent dataset and corresponding regional estimates of reef area. This first large-scale quantitative account of scleractinian abundances will significantly advance our understanding of their conservation status and coral population biology in general. Recent estimates of global tree density illustrate the informative value of providing quantitative reference frames for global biodiversity.

NUCLEAR BOMBS AND CORAL: GUAM CORAL CORE REVEALS OPERATION-SPECIFIC RADIOCARBON SIGNALS FROM THE PACIFIC PROVING GROUNDS (Abstract ID: 27966 | Poster ID: 9)

Radiocarbon (14C) analyses on a coral core extracted from the western Central Pacific (Guam) has revealed a series of early peaks in the marine bomb 14C record. The typical marine bomb 14C signal, one that is phase lagged and attenuated relative to atmospheric bomb 14C, is present in the coral core and is consistent with other North Pacific records. However, 14C levels that are well above what can be explained by air-sea diffusion alone punctuate this pattern. This anomaly has been demonstrated to a limited extent in other coral cores of the Indo-Pacific region, but is unmatched relative to the magnitude and temporal resolution recorded in the Guam coral core. Other records have shown an early Δ14C rise on the order of 40-50‰ above pre-bomb levels, with a subsequent decline before continuing the gradual Δ14C rise that is indicative of air-sea diffusion of 14CO2. The Guam coral Δ14C record provided three strong pulses in 1954-55, 1956-57, and 1958-59 that are superimposed on the pre-bomb to initial Δ14C rise from atmospheric bomb 14C. Each of these peaks can be directly linked to testing of thermonuclear devices in the Pacific Proving Grounds at Eniwetok and Bikini Atoll of the Marshall Islands. The measurable lag in reaching Guam can be tied to ocean surface currents and can be traced to other regional Δ14C records from corals, providing a transport timeline to places as distant as the Indonesian throughflow, Okinawa and Palmyra. These observations were validated with surface current modeling.

NEW CHALLENGES FACED BY DOMINANT CORALS IN HONG KONG MARGINAL CORAL COMMUNITIES (Abstract ID: 29360)

The marginal coral communities in Hong Kong are dominated by a few species. Notable of these is *Platygyra acuta* which dominates many of the communities in NE Hong Kong. Studies conducted over the years have focused on the question "what makes it dominant". Experimental results have shown it to possess some dominant characteristics, including competitive aggressiveness and high tolerance to several environmental stresses, like elevated sea water temperature, lowered salinity ad high nutrients. On the other hand, it being very slow growing with very low recruitment rate appears to compromise these advantages. Recently, it is also shown to be very prone to sea urchin attack and sensitive to diseases, with the latter being associated with eutrophication and harmful algal bloom. Environmental changes brought about either by global climate change or anthropogenic activities are likely to erode the competitive advantages of *P. acuta*. With dominant species becoming less dominant, there could be significant implications on structural changes in Hong Kong coral communities. This project is supported by RGC GRF 14122215.

IS THE STATUS OF CURRENT BENTHIC CORAL REEF COMMUNITIES OF SAUDI ARABIA LINKED TO ENVIRONMENTAL PARAMETERS? (Abstract ID: 30128 | Poster ID: 56)

Chemical and physical characteristics of marine environments are important factors shaping coral reef communities. The Red Sea, which extends from around 27° N to 13° N, shows significant gradients in the chemical and physical conditions, establishing boundaries for species populations and transitions in benthic communities. Accordingly, early surveys of the 1990s found differences in Scleractinia-dominated benthic communities along a north-south gradient, separating three faunistic zones. However, the latitudinal transitions of benthic coral reef communities have recently been questioned for Saudi Arabian Red Sea Coral reefs as temporal shifts and geographic homogenization of the benthic communities were observed. Benthic ecosystem alteration over time caused by environmental change and ongoing regional degradation by coastal development were suggested. Here, we present results of coral reef assemblages from the northern (Duba), central (Thuwal, Jeddah) and southern (Al Lith, Farasan Islands) Saudi Arabian Red Sea. Coral reef surveys were conducted between 2014 and 2016 using photo quadrate-transects at 2-5m and 10m depths. We investigate whether a homogenization of Scleractinia communities prevails over the apparent gradients of salinity, temperature, nutrients and primary production. The status and differences in coral reef communities were assessed and compared with local water parameters (phosphate, nitrate, chlorophyll a, and temperature). The results are being discussed in the context of potential factors driving the spatial coral reef community patterns.

ABUNDANCE PATTERNS OF CORAL-DEPENDENT REEF FISHES IN SELECT SITES IN THE PHILIPPINES (Abstract ID: 29099)

Abundance and species diversity of coral-dependent fishes are affected by coral cover and so are often used as indicators of coral reef health. The community structure of coral-dependent reef fishes in relation to the benthic composition was analyzed for

at least 17 municipalities in the Philippines. Fish abundances were obtained through underwater fish visual census (n≥6 50-meter transects per municipality). Benthic cover was obtained using photo transect method along the same transects. At least 80 species from seven families (Chaeototidae, Pomacanthidae, Pomacentridae, Labridae, Apogonidae, Zanclidae, Serranidae subfamily Anthiinae) were observed in the sites. Abundances of coral-dependent fish were generally low, except for small pomacentrids Chromis ternatensis and Dascyllus reticulatus that shelter in branching Acropora and Pocillopora. Some sites had very similar benthic cover but had the most dissimilar adult fish community (e.g. Lian and Sablayan), which could be attributed to extensive fishing for the aquarium trade. Most aquarium fishes are coral-dependent and there are 10-15 reported aquarium fishers in Lian. Juvenile recruitment appeared to be similar across the municipalities. This study shows that other factors, such as threats from fishing, should be used in combination with the abundance and species diversity of coral-dependent fish in assessing coral reef health, and that the aquarium fish trade may have a large impact on fish community structure.

SUPPORTING SMART CHOICES FOR CORAL REEF MANAGEMENT AND POLICY IN A CHANGING WORLD (Abstract ID: 28870)

Climate change, global and regional economic flux, human populations, and coastal and urban developments are among the many forces influencing the status and trend of coral reefs. Decision problems on coral reefs are multi-faceted issues influenced by local and global cumulative impacts within linked social-ecological systems. For coral reef managers and policy makers to make informed decisions in this complex setting, tools are required that improve clarity of issues, options, risks and the consequences of actions. The purpose of this talk is to paint a picture of how decision science, specifically a structured decision-making approach, can provide such clarity. We use (1) coastal development projects, (2) land-use management, and (3) control of Crown of Thorns Starfish (COTS) as examples to illustrate the key elements of a structured decision process. We demonstrate the role of models in informing and predicting consequences and their uncertainty. We provide a case study for the Great Barrier Reef to illustrate how multiple objectives (environmental, social and economic), pressures (e.g. climate change, water quality, COTS) and scales (local, regional, global) can be broken down into clear and tangible decision problems. Although global drivers are not under the direct control of reef managers, understanding their influence on the system can guide efforts to alleviate interacting local-scale effects and in setting realistic goals for regional-scale management strategies. http://www.aims.gov.au

CARBON ABSORPTION AT TRANSPLATATION OF CORAL REEFS IN NIRWANA BEACH, PADANG, WEST SUMATRA, INDONESIA (Abstract ID: 28814)

ABSTRACT Coral reefs is one of the most important ecosystems in the sea. Coral reefs not only provide place for feeding but also capable of carbon absorption in skeleton. This research was conducted on June 2014 in the area of transplantation of coral reefs in coastal waters, Nirwana Beach Padang, West Sumatra, Indonesia. This study aimed to see the amount of carbon stored in three species of coral reefs. The Three species of coral are Acropora formosa, Acropora millepora, Acropora humilis that transplanted during the six months sampled and measured the amount of carbon stored in coral skeletons using techniques Spectrofotometry. The results from this study show the carbon sequestered in the coral skeleton Each of these coral species in this study have different absorption, the absorption of the highest in this study is Acropora humilis. Keyword: Coral Reefs, Carbon, Coral Transplantation

SEASONAL VARIABILITY OF MESOPHOTIC BENTHIC COMMUNITIES AT TWO SITES AND DEPTHS OFF LA PARGUERA, PUERTO RICO (Abstract ID: 29778)

Coral reefs are dynamic environments, and rapid changes in benthic cover can occur in response to environmental conditions or biological interactions. Mesophotic coral ecosystems are thought to be more stable than shallow coral reefs because it is assumed that variations in environmental parameters (e.g., temperature) are reduced at depth, and MCEs are buffered by depth or distance from shore from surface-based disturbances. We investigated changes in percent benthic cover at quarterly intervals over one year at two mesophotic sites along the insular slope: El Hoyo (low rugosity, low slope) and Hole-in-the-Wall (high rugosity, high slope). Data were obtained from two replicate high-resolution phototransects conducted at each of two depths (50, 70 m) at each site. Nonmetric multidimensional scaling showed that site and depth combinations tended to cluster separately, with individual transects within site/depth typically having less than 80% but greater than 60% similarity over space and time. Temporal trends were similar across sites and depths. Dominant changes occurred among the algae, particularly *Dictyota* and *Schizothrix*, with the former oscillating from near 0 to over 30% cover, peaking in March and September. The latter species showed a general increase over time. The magnitude of change was higher at 50 m. The degree and magnitude of variability at mesophotic depths was less than previously documented at 30m depth. While temporal variability declines with depth, relative impacts must account for potential reductions in productivity as well.

UNRAVELING THE COMPLEXITY OF THE CORAL MICROBIOME: DESCRIPTIONS OF PUTATIVE AND CONFIRMED ENDOSYMBIONTS (Abstract ID: 28195)

Corals engage in relationships with prokaryotic microorganisms which are thought to play important roles in coral health. However, the significance or role of most prokaryotic endosymbionts in corals has remained elusive, and this is partially attributed to the complexity of the prokaryotic communities within the biogeochemically diverse mucus, tissue and skeletal microenvironments of corals. Here we present small subunit ribosomal DNA gene-based sequencing data of bacteria and archaea from decalcified coral tissues of common Caribbean and Pacific corals which demonstrates that corals do harbor specific tissue-associated, putative endosymbiotic bacteria and archaea. In some cases, we utilized specific probes with fluorescent in situ hybridization and microscopy to visualize and localize these cells within the tissues of the coral, thereby confirming their endosymbiotic nature. We will describe the location of these endosymbionts in corals, the potential significance of these relationships, and our ongoing efforts to elucidate the functional interactions between prokaryotic cells and the coral holobiont.

GENOME ANALYSIS OF CORAL DINOFLAGELLATE SYMBIONTS HIGHLIGHTS EVOLUTIONARY ADAPTATIONS TO A SYMBIOTIC LIFESTYLE (Abstract ID: 28676)

Members of the genus Symbiodinium, best known for their ability to form symbiotic

relationships with scleractinian corals, harbor among the smallest dinoflagellate genomes providing an opportunity to interrogate genomic evolution and endosymbiosis in this enigmatic group of protists. We sequenced the genome of Symbiodinium microadriaticum (clade A1) and compared it to the available genome of Symbiodinium minutum (clade B1) and transcriptomes from other dinoflagellates. Despite a conserved preference for non-canonical splice-sites, unidirectional gene arrangement, and a paucity of regulatory upstream motifs, both genomes showed an unexpected degree of genomic divergence. Comparative analyses of the encoded protein sets revealed a strong enrichment of transmembrane transporters involved in the exchange of nutrients in dinoflagellates. Importantly, we find that Symbiodinium, in contrast to other dinoflagellates, have evolved an extensive repertoire of bicarbonate transporters and carbonic anhydrases to ensure provision of CO2 for photosynthesis, as well as ammonium transporters to counter nitrogen limitation, possibly to evade growth control by the host. Phylogenetic analyses of these transporters suggest lineage-specific expansions that imply stark physiological differences between species that may define differences in host compatibility. Our results unravel several genomic aspects underlying the ecological success of dinoflagellates, and highlight the importance of gene duplications as an evolutionary mechanism for adaptation in dinoflagellates and Symbiodinium.

UNDERSTANDING PHILIPPINE REEF FISH DIVERSITY AMIDST RISING THREATS AND MANAGEMENT EFFORTS (Abstract ID: 29458)

The Philippines is part of the global epicenter of marine biodiversity but our knowledge on the state of its own marine biodiversity remains incomplete. Biodiversity assessments have been few, especially since they require large resources for sample collections. This gap is critical because of the urgency to improve conservation amidst rising threats. Here, we used information from underwater visual census to study reef fish diversity trends (i.e. species richness and species diversity). Data collected from 1991 to 2015 in over 2,200 transects and 167 cities/municipalities were used to assess spatio-temporal trends in diversity and to identify potential hotspots for reef fishes in the country. Information on the current protection status of the different sites was also used to determine priority conservation areas. Initial analyses show that most sites have low to moderate levels of species richness and diversity despite the presence of marine protected areas (MPAs) although species richness has remained high in other areas even without clear management initiatives. The study explores the role of both natural ecological processes and exposure to threats on the observed patterns of diversity in Philippine reef fishes. The need to complement protection efforts with other fisheries management strategies to address overexploitation and destructive fishing practices is also highlighted. Facilitating conservation issues are put into context with their strategic relevance and implementation.

LEVELS AND DRIVERS OF COMPLIANCE WITH MARINE PROTECTED AREAS (Abstract ID: 29921)

Marine protected areas (MPAs) are widely used tools for marine conservation and fisheries management. Compliance alone is a strong predictor of fish biomass within MPAs. Hence, fishers' compliance is critical for MPA effectiveness. However, there are few studies looking into compliance with MPAs. Without such information, practitioners have limited opportunities to provide effective interventions. The effectiveness of MPAs relies largely on users' compliance, particularly from fishers, because fishing can profoundly degrade global marine biodiversity and ecosystems. The mere presence of an MPA does not guarantee fishers' compliance, and its effectiveness can be eroded by illegal fishing. Indeed, the ecological performance of MPAs has been linked to fishers' compliance. In this talk I explore the levels and drivers of fishers' compliance with MPAs. By studying 12 coastal MPAs in Costa Rica, I investigate the roles of different variables in influencing fishers' compliance. Compliance levels were higher in MPAs: (1) with multiple livelihoods, (2) where government efforts against illegal fishing were perceived to be effective, (3) where fishing was allowed but regulated, (4) where people were more involved in decisions, and (5) that were smaller. I also provide a novel and practical measure of compliance: a variable formed by the number of illegal fishers and the frequency of illegal fishing. I underline the centrality of people's behavior in nature conservation, and the importance of grounding decision-making on the social and institutional realities of each location.

CONTROLS ON REEF DEGRADATION AND RECOVERY (Abstract ID: 28058)

Reef frameworks in the western Atlantic and eastern Pacific record the millennial-scale persistence of dominant coral species. These coral populations were at times disrupted by the direct and indirect impacts of climate change, and by other large-scale perturbations. If macroalgae dominated these reefs in the past, that dominance would have been a consequence rather than a cause of coral mortality. At annual to decadal scales, contemporary coral and macroalgal dynamics appear to be decoupled in the absence of external drivers, whether the cover of living coral is low or high. Macroalgal cover tends to fluctuate in a complementary fashion with CTB (crustose coralline algae, fine algal turfs, and bare space), independent of coral cover. When modern coral populations are killed, the space opened may or may not be colonized by macroalgae; macroalgal dominance, when it occurs, is again a consequence rather than a cause of coral mortality. Macroalgal cover may be either dependent on or independent of levels of herbivory by sea urchins and, in some cases, herbivorous fish. The future trajectories of many coral populations will likely be driven primarily by climate change, in which case enhancing herbivory might provide partial help as a management strategy. However, overemphasizing local issues such as the abundance of parrotfish will not save coral reefs.

GENETIC STRUCTURE OF BICOLOR DAMSELFISH IN CAMPECHE BANK CORAL REEFS (MEXICO) (Abstract ID: 29863 | Poster ID: 193)

Long term ecosystem resilience is related to the degree of connectivity present within and between populations. We studied genetic connectivity (gene flow) indirectly through allele frequency analysis. We sampled bicolor damselfish (Stegastes partitus)-a small territorial demersal fish- to study dispersal. Dispersal occurs exclusively during the pelagic larval phase (PLD = 28 days). In order to study genetic connectivity in ecological time scales, we sampled recruits and used microsatellites as molecular markers. Three reefs were sampled: Cay Arenas, Cay Arcas, and the Alacranes atoll, wich are separated by 200 - 350 kilometers. The project consisted of PCR, genotyping in an automated sequencer, and computer analysis of the allele frequencies observed. Several methodologies were used to analyze the data. We quantified genetic diversity, and evaluated genetic structure using: private alleles, traditional hierarchical coefficients (Gst, Rst, global and pairwise), AMOVA, genetic distance measures, J'ost D, PCoa, cluster assignment tests, and network analysis. Results showed weak genetic structure thereby low levels of gene flow between sites. The genetic composition of recruits showed some similarities between sampling sites, suggesting that even though there's genetic heterogeneity in the system, recruits have the capacity to disperse between the three reefs sampled. The degree and manner in wich the genetic diversity is distributed among coral reefs is important in the elucidation of the scale of connectivity in reefs, both for basic science and conservation planning.

PHYLOGENY AND EVOLUTION OF THE CORAL FAMILY LOBOPHYLLIIDAE (Abstract ID: 28618)

The family Lobophylliidae is a widespread and ecologically important group of scleractinian corals. It is undergoing a major taxonomic revision thanks to the combination of molecular phylogeny reconstructions and novel morphological data. In this study we examine specimens of many different lobophylliid genera and species collected from numerous localities throughout the Indo-Pacific and the Red Sea. Sequencing of several molecular loci (both nuclear and mitochondrial DNA) is combined with detailed exami-

nation of skeletons at macromorphologcial, micromorphological, and microstructural scales. Phylogenetic relationships among taxa within the Lobophylliidae are proposed and discussed in an evolutionary framework. Molecular and morphological datasets are mostly in agreement and allow the discovery of new species in the genera*Acanthastrea*, *Echinophyllia*, and *Lobophyllia*, whereas some taxa, erroneously synonymized with other ones, are resurrected. In one case, a deep genetic divergence does not reflect a morphological distinction, allowing the discovery of a new cryptic genus from the Indian Ocean and the Red Sea. The obtained data represent a considerable improvement in the understanding of the evolution of this coral family and reveal hidden biodiversity and unexpected biogeographical patterns.

RESOURCE USE, INCIDENTAL RESILIENCE AND THE DANGERS OF ACCIDENTAL CONSERVATION IN THE LAKSHADWEEP REEFS (Abstract ID: 28562)

While identifying the last pristine reef refugia in a rapidly changing climate is critical, finding models to manage more typical reefs (with high resource-dependent human communities) is a more urgent imperative. The Lakshadweep Islands are a possible model reconciling livelihoods and reef resilience. We tracked reef responses to repeated bleaching events since 1998, documenting considerable resilience, due to high herbivory, high predator density, and adequate settlement areas. This resilience is an unplanned consequence of a fisheries programme in the 1980s to promote a pelagic tuna fishery. Tuna quickly replaced reef fish as the dominant fishery with epiphenomenal reef resilience benefits. However, responding to new markets, fishers have, since 2010, begun to exploit reef fish once again. This return to reef fishing is characterised by a qualitative shift in the relationship fishers have with the reef. While past reef fishing was for domestic consumption, the majority of the catch today supplies international markets, exploited merely as an economic commodity. Our studies further show that with two generations of disuse, traditional institutions of resource control no longer exist across the archipelago. Without these restrictions, after 4 years of fishing, we documented major declines in the many target groups. This threatens to unravel the resilience the reefs currently possess. While the Lakshadweep case study is a possible model of a workable win-win solution, it is a cautionary tale of the potential dangers accidental conservation interventions can hold.

LOW SCLERACTINIAN CORAL DENSITY IS ASSOCIATED WITH INCREASED DENSITY OF A COMMON REEF FISH PARASITE (Abstract ID: 29823)

Live scleractinian coral cover is declining worldwide. While loss of stony coral cover is positively associated with decreasing fish diversity and abundance, the effects on smaller reef organisms are less-well studied. Gnathiid isopods are small external parasites that feed on the blood of a wide range of host fish species. Unlike many external parasites, they associate with hosts temporarily, spending most of their lives in benthic substrate. In spite of their impact on hosts and ecological importance, little is known about the factors that influence their distribution and abundance on coral reefs. We quantified the density of the Caribbean gnathiid, Gnathia marleyi using light traps deployed on shallow reefs in the US Virgin Islands, and characterized the benthic habitat and fish communities associated with each sample. Among the twelve variables examined, live coral cover was the best predictor of gnathiid density, with gnathiid density increasing with decreasing coral cover. Gnathiid density was negatively correlated with daytime fish abundance, but positively correlated with nighttime fish abundance. In a parallel study using fish-baited traps in the central Philippines, live coral was also a significant predictor of overall gnathiid density. These findings corroborate laboratory studies showing that gnathiids avoid and are consumed by live coral and suggest that live stony coral or a close associate may be a limiting factor in gnathiid density. Live coral may thus serve as a refuge from parasitism for reef fishes.

DELINEATING PRIORITY AREAS FOR MARINE BIODIVERSITY CONSERVATION IN THE CORAL TRIANGLE. (Abstract ID: 28278)

A challenge in implementing marine biodiversity conservation is in identifying representative networks for biodiversity protection with standardized and consistent criteria. Here we developed a concise set of ecological and biological criteria of identifying areas significant for biodiversity conservation. Four criteria were based on habitat characteristics and another four based on species' feature. To assess these criteria, We propose five key biodiversity variables: habitat cover, species attributes, species richness, geographic range and population abundance. We used data derived from open-access biodiversity informatics databases and applied our framework to the Coral Triangle region. We used a modelled geographic distribution of 12,783 species to map species richness, and 39,452 points of occurrence of 1,742 species to generate distribution maps of threatened species. The coverage of biogenic habitats (i.e. coral reefs, seagrass and mangrove forests) was used to assess the habitat distribution. Spatial analysis and multi-criteria evaluation were developed to objectively and systematically prioritise areas with high biodiversity conservation values. We found that ecoregions of Papua, Eastern Philippines, Halmahera, Banda Sea and Salomon Sea were the high priority areas for biodiversity conservation. The criteria and key biodiversity variables proposed here are a potential tool to facilitate the identification of additional important areas for marine biodiversity and contribute to minimizing gaps in ecological representativeness within the protected areas networks.

ROVING PREDATORS RELOADED: AN INVESTIGATION OF SHARK AND JACK POPULATIONS IN SHALLOW (0-30M) AND MESOPHOTIC DEPTHS (30-100M) IN THE HAWAIIAN ARCHIPELAGO (Abstract ID: 28880)

Coral reef roving predators (sharks, jacks, snappers) are generally believed to be depleted around human population centers. In Hawaii, most of the data to support this conclusion comes from underwater visual censuses of shallow water reef ecosystems (0-30m). However, information on the density and distribution of mobile predators in mesophotic depths (30-100m+) remains sparse. Survey techniques suitable for mesophotic surveys (e.g. technical dive surveys, submersibles) tend to be expensive, logistically challenging, or may only cover a relatively small number of sites per day. A simple, low-cost alternative approach suitable for a wide range of depths is the use of baited remote underwater stereo-video systems (stereo-BRUVs). Between 2012–2014, we deployed stereo-BRUVs to assess roving predator populations around the main Hawaiian Islands (MHI; Maui, Lanai, Molokai, Oahu) and the Northwestern Hawaiian Islands (NWHI; French Frigate Shoals, Lisianski Island/Neva Shoals, Pearl and Hermes Atoll, Midway Atoll), targeting sites previously surveyed by divers (0-30m), along with mesophotic sites (30-100m). Stereo-BRUVs surveys found several species of roving predators are significantly more abundant in mesophotic habitats than in shallow habitats. Although results corroborate diver surveys that roving predators are much more abundant in the remote NWHI than in the populated MHI, the greater depth coverage and diver independent nature of stereo-BRUVs surveys provides much more information and more accurate estimates of relative abundance than was previously available.

HELIOPORA PHASE SHIFT ON A PHILIPPINE CORAL REEF? (Abstract ID: 29710)

Ecological shifts in the face of climate change have usually been discussed in the context of algal-coral phase shifts particularly as a consequence of ocean acidification and thermal anomalies. Our observation of the reef in Bolinao is different from what has been widely proposed in the literature. Algal cover has remained low when compared to the suggested threshold of an algal-phase shift. In this paper we propose a different ecological shift, which may be considered an intermediate phase towards an algal-coral phase shift. A Heliopora phase shift and the mechanism is different from what has been proposed for algal phase shift. While coral-algal phase shifts are associated with the loss of top-down control mechanisms such as overfishing and others like soft corals and sponges shifts are implicated to bottom-up dynamics, Heliopora phase shift is driven by a different mechanism, the warming of sea water as confirmed by laboratory experiments, which induced an aggressive growth of this coral. H. coerulea has changed the bottom cover and community structure of a Bolinao Reef, Northwestern Philippines. We suspect this to be caused by the long-term increase of sea surface temperature in the West Philippine Sea region by approximately 2oC during the past two decades.

PROTECTING THE LONG TERM HEALTH OF THE GREAT BARRIER REEF

THROUGH RESTORATION AND ENHANCEMENT OF ADJACENT COASTAL ECOSYSTEMS (Abstract ID: 28624)

The health and resilience of the Great Barrier Reef are critically dependent on the catchment's coastal ecosystems and the quality of water discharged from the catchment. In the past, little regard has been given to the role coastal ecosystems in the catchment have on the health of the Great Barrier Reef. It is estimated that approximately 40% of remnant vegetation in the Great Barrier Reef catchment had been cleared by 2009, and 74% of the catchment was used for grazing. Of the 424,000km2 that makes up the Great Barrier Reef catchment less than 10% is protected as National Park. Much of the ecological services of the Great Barrier Reef catchment have been lost or heavily modified and this is reflected in the declining health of the Great Barrier Reef, particularly inshore areas. Today there is an increased public appreciation for the influence the catchment has on the receiving waters of the Great Barrier Reef and its biodiversity. The Great Barrier Reef Marine Park Authority places considerable importance on a coordinated and collaborative approach to the management of the catchment and Reef. The Authority has collaboratively developed a set of principles and decision-making tools to assist natural resource managers, decision makers, landowners and managers, to enable them to restore, maintain or enhance the environmental values and ecological functions of coastal ecosystems to support the long-term health of the Great Barrier Reef.

SKELETON ULTRASTRUCTURE OF CORALLINE RED ALGAE MIRRORS MOLECULAR BIOLOGICAL PHYLOGENY (Abstract ID: 28281)

Coralline red algae are calcifying, globally occurring algae well suited for ecological and climatological studies. Classification mainly focuses on the soft tissue anatomy of their reproductive cavities, secondary connections between filament cells (secondary pit connections or cell fusions) and the existence of genicula. Contrary to morphologically based taxonomy molecular studies suggest that except conceptacle characters none of the common features used are diagnostic for specific families, creating often paraphyletic and polyphyletic morphological clades. SEM analyses of epithallial cells, meristem cells and the vegetative thallus show that the calcite crystallites formed within the polysaccharide matrix of the corallinacean cell walls are taxon specific. This analysis is based on a global sample set including the genera *Phymatolithon, Lithothamnion, Lithophyllum, Titanoderma, Spongites, Porolithon, Hydrolithon, Neogoniolithon, Mastophora* and *Sporolithon*. While it is generally assumed that epithallial cells roofs do not calcify, our results show that they fully calcify in nearly all genera and the calcite crystallites have distinct genus specific shapes. Together with the cell wall crystallites, these epithallial crystals can thus be used as a taxonomic tool on at least a generic level and, thus, offer to be a powerful morphological tool for the classification of calcareous red algae. Furthermore, a comparison of the observed ultrastructure morphology with phylogenetic trees based on molecular data of extant coralline red algae shows a clear match.

EFFECTS OF SCHOOLING AND HABITAT CONFIGURATION ON THE BEHAVIOR OF PARROTFISH TOWARDS PREDATORS (Abstract ID: 28122)

Predation risk has been shown to inhibit locally the foraging activities of roving herbivores, but the effects of predator identity, schooling, and habitat configuration on the behavior and microhabitat selection of herbivores has not been directly tested. We examined the behaviors of solitary and schooling juvenile parrotfish in the presence of either a grouper (ambush predator) or snapper (roving predator) and without predators. Fishes were filmed in 2x2 $m^2$ tanks containing artificial microhabitats (i.e., branching coral, massive coral, and rubble) arranged in six different configurations such that each microhabitat type varied in their degree of contiguity. We determined the microhabitat preference of parrotfish for foraging and refuge. We found that the anti-predator responses of parrotfish were stronger towards snapper than grouper, often resulting in parrotfish hiding under corals at the expense of foraging, especially when rubble patches are contiguous. Schooling mitigated the predation risk effect of snapper although the foraging rate of focal parrotfish was still lower than when predators were absent. Parrotfish did not show significant microhabitat selection in the absence of predators but preferred to forage on rubble in the presence of either predator. Results show that predation risk effects are dependent on predator identity, presence of conspecifics, and habitat configuration. Microhabitat use was context-dependent and such fine-scale decisions may be important in determining the grazing patterns of parrotfish.

CORAL REEF OF SARAWAK, BORNEO (Abstract ID: 27877 | Poster ID: 79)

Sarawak is one of the biggest state in Malaysia, located between the latitude 0° 50'and 5'N and longitude 109° 36' and 115 ° 40'E. Sarawak has the second longest coastline 1051km in Malaysia, thus the EEZ of Sarawak occupies the southern part of the South China Sea with an area of 160,000 km² (area 124,449.5 sq km). The coral reef biodiversity was studied from 2004 to 2015. The aim was to collect baseline data on the corals and coral associated living resources. Study area were divided into four areas, Kuching, Bintulu to Miri, Luconia and Lawas. Most of the coral reefs in Sarawak are found offshore, with the depth more than 18m and geographically patchy.

LEADERSHIP IN HAWAI'I CORAL REEF FISHERIES (Abstract ID: 29901)

Leadership is often touted as a solution to fisheries and coral reefs management problems. However, most leadership research exhibits an embedded normative bias and skews analysis towards the individual. Further, few studies observe leadership as a construct or empirically examine its component parts. Here, leadership is observed in the context of coral reef fisheries co-management in the main Hawaiian Islands. In Hawai'i, an institutional pathway allows communities to partner with the State of Hawai'i to co-manage coral reef fisheries. However, few successful partnerships have emerged in the past 25 years despite enabling legislation, a set of highly motivated communities, significant NGO and foundation support, and seemingly a multitude of local leaders. To investigate local leadership in Hawai'i coral reef fisheries, 45 interviews were conducted over three years with individuals from NGOs, academia, government, and fishing communities across Hawai'i. Respondents were asked about the importance of leadership in the context of co-management, and other leadership components derived from the academic literature. Although respondents offered some diverse viewpoints, there was general agreement that leadership functioned well when local leaders acted as facilitators or organizers and possessed a wide network of relationships. These findings support the conceptualization of leadership as a process in coral reef fisheries. Findings from this paper should contribute to better understanding of effective local level leadership in coral reef fisheries co-management.

ASSESSING REEF FISH RESILIENCY AND PRODUCTIVITY IN THE PHILIPPINES (Abstract ID: 29123 | Poster ID: 576)

The Coral Reef Visualization and Assessment (CoRVA) Program – Reef Fish Resiliency and Productivity (Project 3) is a nationwide effort initiated by the Biodiversity Management Bureau of the Department of Environment and Natural Resources (BMB-DENR), to assess the existing reef fish community status in the Philippines. The project aims to evaluate the resilience and productivity of reef fish communities in selected National Integrated Protected Areas System (NIPAS) sites and within Verde Island Passage (VIP) which is designated as an important biodiversity corridor. The undertaking employed intensive collection of reef fish community and biological data deemed important in providing insights on the relative resilience of reef fishes. Information generated from the project is expected to contribute in the preparation of important management strategies necessary to ensure reproductive success, habitat health, and sustainability of reef fisheries in the country. The project integrates current information on adult community and trophic structure; reef fish recruitment and habitat association; and age at first sexual maturity of selected iconic reef fishes to obtain a better perspective on the present state of reef fish communities in specially managed sites across the country. In the first year of its implementation, both trainings and assessments have been conducted in four NIPAS sites and in VIP. The results showed that the relative resilience of reef fish species varied across sites; and within these sites, differences were also observed between managed and open access reefs.

EFFECT OF BOOSTER BIOCIDES, IRGAROL ON CORALS FROM MALAYSIAN REEF, SOUTH CHINA SEA, AS INDICATE BY FATTY ACID MARKERS (Abstract ID: 27971)

Changes of fatty acid composition in the reef building coral Galaxea fascicularis that was exposed to the boster biocide, Irgarol 1051 was determined. Laboratory exposure experiments evidenced that Irgarol 1051 have significant impact on fatty acid composition of the coral even if exposed at the low levels of this biocide. Healthy G. fascicularis from Bidong Island, Malaysia had higher fatty acids profile compared to its non-healthy. The results showed that, fresh and control samples of G. fascicularis were dominated by polyunsaturated fatty acids, and the mean concentration of these fatty acid significantly decreased after the coral was exposed to the biocide ($p< 0.05$). It is proven that corals that exposed by Irgarol 1051 have significantly higher concentration of monounsaturated fatty acids ($p< 0.05$), might due to the colonization of bacteria on the dead parts of the coral. The present findings demonstrate that Irgarol 1051 threatens the health of corals due to changes of fatty acids composition of G. fascicularis and may have implications on metabolisms of the corals.

CORAL BLEACHING EVENTS IN KANEOHE BAY, OAHU HI: WHAT HAVE WE LEARNED? (Abstract ID: 28807)

The occurrence and severity of mass coral bleaching has increased dramatically over the last two decades with almost every reef region in the world suffering extensive bleaching and mortality. The first coral bleaching event in Kaneohe Bay occurred during 1996 and was followed by more severe events in 2014 and 2015. Generalizations based on the 1996 event did not hold during the 2014 event. Likewise, the patterns observed in 2014 diverged from what we thought was learned from the previous two events. The unexpected patterns of bleaching and mortality were due to a number of factors including: 1. Localized patterns of water circulation, 2. Variation in irradiance due to different patterns of cloud cover and temporal variation in turbidity, 3. Differences due to seasonal timing and duration of the warm water event, 4. Influence of localized fresh water flood events interacting with temperature bleaching, 5. A shift in species sensitivity in the abundant coral *Montipora capitata* as well as minor changes in species composition (e.g. reduction in *Pocillopora damicornis* and elimination of *Montipora dilitata* ) due to high temperature. The reefs of Kaneohe Bay have shown remarkable resilience to a wide variety of natural and anthropogenic insults over the centuries, but the pressing new question centers on whether coral reefs can survive under continuously increasing temperature and ocean acidification along with changes in sea level, precipitation and more severe storm activity predicted under climate change models.

PATTERNS OF CORAL BLEACHING IN AMERICAN SAMOA (Abstract ID: 28835 | Poster ID: 353)

The ongoing global coral bleaching event began in the North Pacific in the summer of 2014 and expanded to the South Pacific and Indian Oceans in 2015. The NOAA Coral Reef Watch outlook indicates it is likely to continue well into 2016. An ecosystem-scale assessment of coral populations in American Sāmoa from February to March 2015 provides crucial information about the distribution and abundance of corals and the prevalence of bleaching at multiple spatial scales to affected genera and species. A two-stage stratified random sampling design was employed to survey 188 sites across 5 islands/atolls: Ofu-Olosega, Rose, Swains, Ta'ū, and Tutuila. The stratification scheme incorporated island sectors, three reef zones (fore reef, back reef, and lagoon), and three depth categories (0–6 m, >6–18 m, and >18–30 m), where present. Coral abundance, size, partial mortality, condition (e.g. bleaching) were surveyed within two 10-m2 belt transects per site. Population prevalence of bleaching for all scleractinian corals combined was 5.47% (SE 0.61%), ranging from 66.04% to 0% among genera, and from 66.67% to 0% among selected species. The most affected genera include Isopora, Montastraea, Leptoseris, Fungia, Pavona, Pocillopora, and Porites. Bleaching prevalence varied across islands/atolls, strata, genera, and species. These results provide a quantitative assessment of bleaching patterns across habitat space, genera, and species during the survey period. In addition, the spatial pattern of bleaching identifies potentially vulnerable and resilient reefs in American Sāmoa.

SPECIES BOUNDARIES IN TABULAR ACROPORA SPECIES IN OKINAWA (Abstract ID: 29103)

The molecular revolution has greatly increased our understanding of evolutionary relationships in the Scleractinia, however, in some taxa, such as the genus Acropora, molecular markers for distinguishing species have yet to be developed. Consequently, progress in establishing species boundaries in these genera will require alternative approaches, such as detailed observations of the timing of reproductive events and cross-breeding trials. Here, we used gross morphology, morphometrics, breeding trials and six molecular markers to explore the species boundaries in the tabular Acropora species complex in Okinawa. Gross morphology suggests at least 4 different groups, morphometric analyses suggest two to four groups, breeding trials suggest two or three groups, however, the two molecular markers analysed to date suggest that all 24 colonies belong to one species. The most likely explanation for these patterns is that rare hybridization events homogenise the gene pools of groups that are otherwise biologically and morphologically distinct. We conclude that a number of lines of evidence are required to establish species boundaries in corals and the boundaries chosen will depend on the question of interest.

COMMUNITY PARTICIPATION IN THE MARINE PROTECTED AREA (MPA) ESTABLISHMENT PROCESS IN INDONESIA: ITS OPPORTUNITIES AND CHALLENGES (Abstract ID: 27874 | Poster ID: 665)

MPA legislation in Indonesia includes provision for community involvement in the establishment of MPA.This research examined participation in the MPA legislation and the extent to which the establishment of MPA has become more democratic and decentralized.Research sites were selected based on different levels of MPA;they are:national-level MPA at Savu Sea,district MPA at Derawan,and village no-take areas at Pangkep.It was found that MPA legislation provides opportunities for communities to be informed and consulted in the establishment process.However,this falls short of the active participation that is required in order for MPAs to be successful.Field research results showed that complex web of legislation from different levels of government influenced the participation.Gaps in legislation and mismatches with other national legislation have meant that legislation is only applied for national-level MPAs.However,no provision for community involvement in their managements and thus,no incentive for communities to participate.Degree of participation depend on available budget.MPA establishment teams had to prioritize the use of limited funding that led to work with government agencies,whose support was needed to override mismatches in policies and legislation that might threaten the existence of MPAs.Consequently,community participation was considered a secondary priority.To enhance participation in the MPA,communities still rely heavily on government and NGOs to improve their capacity to participate meaningfully.Commitment from these stakeholders is required to build community capacity to play a leading role in the MPAs.

MANIPULATION, INTRODUCTION, AND FATE OF THERMOTOLERANT ALGAL SYMBIONTS IN REEF-BUILDING CORALS (Abstract ID: 30023)

The ability of some reef corals to undergo changes in their algal symbiont communities in favor of thermotolerant *Symbiodinium* is one mechanism by which corals may survive bleaching events and persist into the future despite continued warming. To investigate the dynamics of these unusual symbionts we used a novel transplantation method to experimentally introduce thermotolerant symbionts into healthy corals. We used controlled bleaching at 32°C to remove the 'native' *Symbiodinium* C3 from replicate cores of the Caribbean coral *Montastraea cavernosa*, and recovered them at 29°C with thermotolerant symbionts (*Symbiodinium* D1a, aka *S. trenchi*). These 'stress hardened' cores no longer bleached when exposed to 32°C. We then reciprocally transplanted tissue plugs from these manipulated cores into control (unbleached) cores containing C3, and vice versa (N=20 pairs from 5 colonies). The fate of these introduced symbionts, measured in mini-transects across cores using quantitative PCR, was dependent on (1) temperature, with D1a displacing C3 within 3-6 months when maintained at 29°C , but C3 displacing D1a at 22°C; (2) the relative abundance of introduced vs. resident symbionts; and (3)

the type of symbiont introduced. As thermotolerant symbionts become more common on disturbed reefs worldwide, these findings help us understand their origin and spread, investigate their relative costs and benefits to reef ecosystems, and consider potential interventions to help reefs survive continued warming.

MULTI-DECADE MONITORING OF REEF-BUILDING CORALS ON THE FLORIDA KEY REEF TRACT (Abstract ID: 28786)

The Florida Keys reef tract is a highly degraded ecosystem with low coral cover on most reefs, which has been attributed to warm-water bleaching, cold-weather events, coral diseases, and anthropogenic sources of nutrient influx. Using a data set that has been sampled seasonally for over 20 years, we look at tissue biomass, chlorophyll a content, maximum photosynthetic capacity of PSII (Fv/Fm), Symbiodinium density, and dominant Symbiodinium genotype of three reef-building coral species (Orbicella spp.) in the Florida Keys. Data has been collected during two of the three worldwide bleaching events and shows anomalies in coral biomass and Symbiodinium measurements. Biomass of deep and shallow reef-building corals had lowest biomass following the 1997-98 worldwide bleaching event but steadily increased and exceeded original biomass between 1998 and 2014. Interestingly, Symbiodinium density and chlorophyll a content have remained consistent despite an increase in tissue biomass. Fv/Fm initially decreased following the 1997-98 bleaching event but leveled out and have remained relatively constant. During 1997-98 and 2014-15 bleaching events Fv/Fm fell to extremely low values indicating that, like temperature, a Fv/Fm threshold may also exist. Long term monitoring of reef-building corals is key to understand how corals respond to environmental stress and their recovery over long periods of time.

REEFS OF FUTURE PRESENT: HONG KONG CORALS FROM THE QING DYNASTY TO THE INFORMATION AGE (Abstract ID: 30014)

My geologist friends tell me that Hong Kong has no 'proper' coral reefs. This is because there is no evidence of carbonate formations upon which living corals are still found. Instead, corals grow on exposed bedrock in a patchy distribution and any exposed carbonates are quickly eroded away. Were there proper coral reefs in the past? Consider that during the Qing Dynasty the industrial production of slaked lime was extensive throughout Hong Kong, yielding 40 tons per year from mining living bivalve and coral communities. Indeed, historical records and archaeological evidence describe a very different environment in the past; where apex predators, megafauna, and diverse reef invertebrates were common. Through archeological digs, we show that the diversity and abundance of corals and other invertebrates declined markedly over the last century, including the extirpation of several coral species. We analyzed subtidal push cores to show that coral abundance has decreased by 50%, and coral fragment identification from sediments to delineate a 40% contraction in the range of important staghorn corals. Today, coral decline is closely linked to coastal development and pollution, which limits the recovery of coral communities. However, thanks to government efforts at improving water quality, we demonstrate that active restoration of coral communities is possible. Through targeted propagation and transplantation we show that staghorn corals have high rates of growth and survivorship in areas where they were previously eliminated giving hope to the future of these marginal reefs.

DETERMINING THE SUSTAINABILITY OF REEF FISHES FOR THE AQUARIUM TRADE IN SELECT SITES IN THE PHILIPPINES (Abstract ID: 29132)

Aquarium trade heavily relies on coral reef resources. In the Philippines, a top exporter of aquarium fish, the sustainability of this trade is a concern due to its capture methods and unreliable trade figures, as well as the lack of clear management policies and regulations. This study determined the status and sustainability of target reef fishes for the aquarium trade by comparing the level of exploitation and standing stock in four sites, namely, Lian, Batangas; Bongao, Tawi-Tawi; Cawayan, Masbate; and Kawayan, Biliran. Underwater fish visual census (FVC) was conducted to estimate densities of target fishes on the reefs while fisheries surveys using semi-structured interviews and focus group discussions were used to obtain information on the aquarium trade. Results show that target aquarium species varied across municipalities, majority of which belonged to the families Pomacentridae, Labridae, Pomacanthidae and Chaetodontidae. These families generally had low densities on the reefs, implying that fishes marketed for the aquarium trade are being sourced from areas outside the municipality. In fact, average weekly demand during peak season is significantly higher than actual densities observed on the reefs. High catch rates influenced by the demand from the aquarium trade may make this reef-dependent livelihood unsustainable in the long term. Continuous monitoring, as well as other studies (e.g. population biology of targeted species), are needed to formulate urgent regulations on the aquarium trade if these reef fishes were to persist.

DEVELOPMENT OF MICROSATELLITE PROTOCOLS FOR CORAL MADRACIS COMPLEX (Abstract ID: 28327 | Poster ID: 337)

After the declaration of the Colombian Marine Protected Area-MPA Deep Coral Natural National Park (PNNCP) in 2013, it became evident the need to develop a management plan for this MPA in the Colombian Caribbean. One of the interesting features of this MPA is that the main structural species belong to the coral complex Madracis sp (Pocilloporidae: Cnidarian) in the area: M. auretenra, M. myriaster and M. brueggemanni. This group brings a special habitat to many species of fishes and marine invertebrates in mesophotic and deep reefs within the PNNCP. However, there is little information about this ecosystem, distribution, genetic diversity and connectivity in Colombia and the Caribbean. Here we present the main results from the development of new molecular markers (microsatellites) for some Madracis species, following methods previously developed at The University of Manchester for the deep coral Lophelia pertusa. DNA extractions were carried out at the Colombian Institute of Marine and Costal Research – INVEMAR, using samples from the Cnidarian reference collection at the Marine Natural History Museum of Colombia-MHNMC (INVEMAR), collected from Tayrona Natural National Park and PNNCP. DNA extractions were also developed at The University of Manchester from Madracis corals maintained in aquariums. The new markers will allow us further ecological analysis to increase the knowledge of these Caribbean coral formations and will help us to determinate the vulnerability and resilience of these habitats to natural and anthropogenic effects this new Natural National Park.

IMPORTANCE OF SYMBIONT GENETIC STRUCTURE IN RESTORATION OF CORAL POPULATIONS (Abstract ID: 28916)

The short- and long-term success of any restoration project involving corals may depend on choosing the appropriate genetic source to be compatible with the site under restoration. Species vary in their dispersal rates and distances, and hence in the degree of genetic differentiation among populations. *Acropora palmata*, as do many species of corals, forms a symbiotic relationship with single-celled dinoflagellates of the

genus*Symbiodinium*. The symbiont provides the coral its main source of carbon compounds; however, the two organisms have different life history traits that can influence their geographic distribution. We estimated the population genetic structure of *Acropora palmata* and its dominant symbiont *Symbiodinium 'fitti'* along the Caribbean coast of Mexico, using previously designed microsatellite loci for *A. palmata* and *S. 'fitti'*, as a tool to assess genetic variation of source populations. In the animal host, we detected a single genetic cluster among 7 reefs as a result of high levels of gene flow. However, the endosymbiont showed a genetically structured population under isolation by distance with 5 clusters detected. These results suggest that sexual recruits should be introduced at an early stage so that they will take up the locally available symbionts. Furthermore, these results imply that care must be taken in choosing destination reefs for restoration efforts involving fragments or late-stage recruits so as not to alter gene flow patterns among the symbiont populations.

INTERSPECIFIC BACTERIAL COMPETETION UNDER OCEAN ACIDIFICATION SCENERIOS (Abstract ID: 29510 | Poster ID: 143)

Coral microbes have been hypothesized to promote coral health and protect the host against pathogens. Recent outbreaks of coral diseases have been correlated with higher sea-surface temperatures and ocean acidification but few studies focus on the effect of these stresses on coral commensals physiology. This study examined the impact of ocean acidification on two coral commensals' ability to prevent infection by the coral pathogen Vibrio shiloi. Beneficial bacteria Pseudoalteromonas ZJ6102 and Pseudoalteromonas euthinica were isolated from the surface of healthy Acropora cervicornis and, when challenged with V. shiloi, resulted in an antibacterial response. Competition experiments were performed by mixing equal amounts of each commensal with the pathogen in dialysis tubing maintained at high (pH=8.1) or low (pH=7.7) pH under stable temperatures (25.5°C). Colony forming units (CFUs) of each strain were calculated 24, 48 and 72 hours after inoculation. Results showed that lower pH tends to boost commensals ability to limit the pathogens growth. To test commensals ability to protect the host from bacterial infection, inoculation experiments were performed with A. cervicornis. Coral health was estimated visually and indirectly using a PAM underwater fluorometer to assess algae deterioration by the pathogen. Results showed higher photosynthetic activity for corals treated with both the pathogen and commensal compared to controls treated with the pathogen only. Studies such as these will help our understanding of coral microbial dynamics in response to environmental changes.

BRAZILIAN MPAS EFFECTIVENESS: A CASE STUDY IN SÃO PAULO (Abstract ID: 29386 | Poster ID: 641)

The establishment of marine protected areas (MPAs) in Brazil is still negligible, just over 31% of the target set by the National Biodiversity Commission to protect 10% of the coastal zone by 2020. Most of them are terrestrial area and only 1.57% of the 3.5 million square kilometers of territorial sea is represented. The coast of São Paulo State (SP) has 700 km long and a great diversity of ecosystems, which are increasingly threatened due to its strategic location in relation to major industrial centers of the country, the connection to port systems and the exploration of oil in the pre-salt Santos Basin. Only 0.7% of the territorial sea is included in three restrictive MPAs. However, before to create new MPAs it's necessary to evaluate the effectiveness of existing ones. In this sense, present study aimed to analyze the management conditions "no take" MPAs of SP. The areas were evaluated through a selection of indicators, which were organized into scenarios matrix and associated with a standard score corresponding to the best or worst possible situation to be found. The management scores attained effectiveness of 68% (Tupiniquins Ecological Station), 71% (Tupinambás Ecological Station) and 72% (Laje de Santos Marine State Park). The main common factors that compromise the complete fulfillment of the objectives of the studied areas are the lack of an integrated coastal management with other economic sectors and low government resources allocated. However, they are surrounded by sustainable use areas, which ensure certain integration of MPAs with an ecosystem approach.

FORAMINIFERAL HEALTH ASSESSMENT INDICES AND SEDIMENT GEOCHEMISTRY OF CORAL REEF-SUPPORTING TAMANDARE BAY (NE, BRAZIL). (Abstract ID: 29130 | Poster ID: 287)

This study aimed to assess spatial and temporal ecosystem health variability of water and sediment in the coral reefs of the Tamandare open embayment, located in Northeast Brazil, Southwest Atlantic Ocean, using geochemistry and benthic foraminifera as bioindicators. Sediment samples were collected at the reef base, generally built over beachrock structures, during the summer and winter of 2005. The FORAM index (FI, a foraminiferal functional group, community-based water quality assessment), and the FORAM Stress Index (FSI, which is more related to ecological affinities than to functional groups and assesses sediment or substrata quality) and geochemical data were interpreted using uni- and multi-variate analysis. This is the first application of FSI outside of Mediterranean waters. The dominance of the Quinqueloculina and Textularia genera, along with negligible numbers of living specimens, low counts of symbiont-bearing foraminifera (and thus low FI), high turbidity and high phosphorus concentrations confirm the anthropogenic influence of river inputs. All parameters suggest that the water and sediment of the Tamandare embayment are marginal for coral population settlement, and the FSI presents higher values and a more sustainable condition for summer than winter. The FI indication of marginal environmental health is not in agreement with the FSI and the currently stable coral population found over the underlying beachrock, especially of the established no-take zone. Local scientific- and community-based coral conservation initiatives have improved ecosystem health.

CHARACTERIZATION OF RECREATIONAL SPEARFISHING IN A SUBTROPICAL ROCKY REEF (Abstract ID: 29980)

Spearfishing is a highly selective activity, but the selectivity does not necessarily make it a sustainable one, as the majority of defenders of this fishing method claim. This study aimed to evaluate which traits make fished species more or less attractive to spearfishers and the relationship between fishermen expertise and characteristics of the catch in rocky reefs in the Southeastern Atlantic. The investigation was carried out in the Marine Extractive Reserve of Arraial do Cabo (23oS; 42oW). In terms of abundance, scarids was caught by most, and captured fish biomass was mainly composed of herbivores and macro-carnivorous fish. The main attributes that make a species a preferential target were, firstly, pelagic habitat, larger size and a tendency to form schools. Our study had also shown a direct relation between the fishers's experience and catch composition, where experienced spearfishers catch mainly fish with larger sizes and weight. Old spearfishers recognize that stocks of targeted fish have reduced throughout time, and clear indication that environmental reference is changing, a phenomenon global reported. Spearfishing generally means a selective fishing, but it is high dependent on fishermen. To minimize the effects of spearfishing on target species and to enhance protection of functionally important fishes, spearfishing needs restrict controls on the catch.

GOVERNANCE ANALYSIS USING THE FISH CHAIN METHODOLOGY: PNG'S BÉCHE DE MER INDUSTRY (Abstract ID: 28079)

Markets for Béche de Mer (BDM, dried sea cucumber) are vital to coastal communities in Papua New Guinea (PNG). Many of these communities are remote from trade routes and have extremely limited economic opportunities. Dried BDM is high value and shelf stable, making it one of the few commercially feasible exports from such locations. Moreover, some of the most valuable species of BDM are easily accessible from shore, meaning the fishery has been open to people without access to boats, such as women, children and old people, and so the income from BDM has been distributed relatively equitably. As ethnic Chinese markets for BDM grew over recent decades PNG's remote coastal communities came to rely heavily on this resource for cash incomes. The management system was, however, not effective and stocks collapsed. In 2009 the PNG government closed the fishery. Surveys conducted in 2015 indicate some recovery and the government is considering reopening the fishery in the near future, with a revised management plan. This project uses a 'fish chain' methodology to consider all of the various influences along the supply chain affecting governance of the fishery, including village-level cultural and economic contexts, business models for exporters and importers, and capacity issues for relevant government agencies. Findings and methods developed in this study are relevant for understanding why fisheries operate the way they do, where practice changes may be effectively encouraged or enforced, and by whom, as well as areas that are more resistant to change.

GENOMICS OF LOCAL ADAPTATION IN POPULATIONS OF ACROPORA MILLEPORA FROM THE GREAT BARRIER REEF (Abstract ID: 29490)

Local adaptation of coral populations inhabiting disparate reef environments could be the major source of genetic diversity to fuel rapid adaptation to climate change. To investigate this possibility, we performed genome scans using 2bRAD in populations of Acropora millepora from six locations along the Great Barrier Reef representing a variety of thermal and water quality conditions. We then undertook common garden and reciprocal transplantation experiments to see whether variation at the candidate loci identified by the genome scan were associated with fitness and/or gene expression variation among locations. The clearest genome scan signal, combining both high genetic divergence and elevated linkage disequilibrium, was obtained for two adjacent single-nucleotide polymorphisms (SNPs) located within a cluster of paralogous genes encoding delta-9 desaturases (d9d), enzymes that adjust the fluidity of biological membranes in response to ambient temperature. These SNPs formed a latitudinal gradient of allele frequency and were associated with elevated baseline expression of two d9d genes at a cooler, higher latitude, location. These genes also exhibited gene expression plasticity aligned with this baseline change: they were up-regulated in corals that were transplanted from a warmer to a cooler location. Thus, evolution of elevated baseline expression of these genes at a cooler location may represent a case of genetic assimilation, whereby regulatory adaptation is based on a pre-existing plastic response.

SPATIAL AND TEMPORAL SETTLEMENT PATTERNS OF SCLERACTINIAN AND BLUE CORALS IN NORTHWESTERN PHILIPPINES (Abstract ID: 29523)

The Philippines is part of the coral triangle area with the highest coral biodiversity. Coral recruitment is important in structuring reefs by coral replenishment and recovery from degradation. In this study, spatial and temporal settlement patterns of scleractinian and blue corals in the northwestern Philippines were quarterly monitored for 3 years (2006 to 2009) in four study sites (i.e. Balingasay, Malilnep, Cory Sand Bar and Caniogan) by deployment and retrieval of settlement plates every 3 months. Results showed that the settlement patterns significantly differ among years, monitoring periods, and sites. Settlement patterns decreased from year 1 to year 3 and peaked between February to May. Settlement pattern of scleractinian and blue corals coincide with the peak of spawning season observed in the study sites. Among sites, Caniogan had the highest settlement which is mostly composed of Pocilloporidae (brooders) and Others (unidentified corals). Blue corals that are also brooders were only observed at Balingasay and Malilnep probably explained by the presence of adult corals only on these sites. Results suggest that high proportion of brooders (i.e. Pocilloporidae and blue corals) may have contributed to self-recruitment on the reef. High settlement in Caniogan can be attributed to its location that is relatively embayed among sites. Therefore, coral settlement is affected by the presence of adult colonies, timing and modes of reproduction and site attributes such as exposure to wave actions.

ASSESSING CORAL REEF RESILIENCE TO OCEAN ACIDIFICATION IN THE PALAU ARCHIPELAGO (Abstract ID: 29545)

Climate change-driven shifts in ocean chemistry are projected to significantly affect the structure and function of coral reef ecosystems. Reef scientists and managers are increasingly assessing the resilience of coral reef ecosystems to climate change, yet most do not consider the effects of ocean acidification. For the first time, we present a reef resilience assessment that includes coral community tolerance to ocean acidification in Palau. Using five years of water sampling data, we mapped spatial and temporal patterns in temperature, salinity, and carbonate chemistry for the entire Palau archipelago and combined information about Palau's coastal environment with benthic community ecology and coral biology data. Archipelago-scale coupled physicochemical, ecological, and biological data allow us to map relationships between patterns in pH and coral community structure, reveal coral reef sensitivities to natural gradients in carbonate chemistry, and identify areas of potentially high resilience to ocean acidification impacts. Our results will be used to support coral reef conservation efforts in the region, specifically, identifying conservation priorities in Palau. The effective management of coral reef ecosystems in Palau is critical to support social and ecological resilience.

IDENTIFYING COST EFFECTIVE ACTIONS TO MITIGATE LAND-BASED SOURCES OF POLLUTION IN WEST MAUI THROUGH DECISION MODELS (Abstract ID: 28555)

Coral reefs are declining across the world. Causes of coral reef decline are complex, and establishing direct causal links between deleterious inputs, events, or actions, and these declines, is challenging. However, it is clear that a cocktail of land-based sources of pollution presents serious threats to coral reef ecosystems, and addressing these has become a key management challenge worldwide. In the face of high levels of uncertainty in both action feasibility and future change, decision models can facilitate improved outcomes over the long term. We applied a decision science approach to address land based pollution within a watershed planning initiative, with the objective of identifying a suite of feasible actions and policy measures that will ensure healthy coral reefs that support livelihoods over long time horizons. In West Maui, Hawai`i, nearly one quarter of all living corals have been lost in the thirteen years prior to 2008. The Watershed Planning process includes the values and objectives of local stakeholders and decision makers, and aims to quantify and explicitly address uncertainty in parameter estimates and causal relationships, and the risks, or consequences, of delayed action or failure of a given action. We present the first phase of this work.

INEQUITY IN CO-MANAGEMENT OF CORAL REEFS (Abstract ID: 28240)

Co-management has been promoted as a more equitable form of coral reef management because it provides local communities with greater power over the use and allocation of their resources. Yet co-management arrangements can exacerbate existing inequalities across regions and communities, and the benefits associated with co-management are not always equitably distributed. Here, we surveyed 790 resource users in 43 coral reef co-management arrangements across five countries to examine the benefits that resource users report from co-management, identifying departures (either losses or gains) from those of the wider community as inequity. We then evaluate how social and institutional factors contribute to actual and perceived inequity in benefits from co-management. We find that inequity is driven by contextual conditions (e.g., distance to market and population), institutional design (graduated sanctions, clear boundaries, and the rules in use), and individual socioeconomic conditions (wealth and involvement in decision-making). Managers and policy-makers can use some of these conditions, particularly institutional designs and individual socioeconomic characteristics, to inform the development of more equitable collaborative arrangements to manage and sustain coral reefs.

SOLUBLE ADENYLYL CYCLASE IS AN EVOLUTIONARILY CONSERVED PH SENSOR IN THE CORAL POCILLOPORA DAMICRONIS (Abstract ID: 29984)

Reef-building corals experience daily fluctuations in intracellular pH (pHi) due to photosynthesis by intracellular symbiotic algae of the genus Symbiodinium, yet little is know about the cellular mechanisms used by corals to detect and regulate acid/base homeostasis. Here we found that the enzyme soluble adenylyl cyclase (sAC) is essential for sensing and regulating pHi in the coral Pocillopora damicornis. Expression of sAC was detected throughout all coral tissues, including gastrodermal cells that house the Symbiodinium, and calicoblastic cells that support calcification. Application of the sAC-specific inhibitor KH7 to isolated coral cells resulted in significant and reversible intracellular acidosis in both Symbiodinium-containing and Symbiodinium-free coral cells. Furthermore, inhibition of sAC in cells exposed to light impaired pHi regulation in Symbiodinium-containing gastrodermal cells, indicating a role in sensing photosynthesis-induced pHi disturbances. Finally, sAC inhibition prevented the recovery of pHi following intracellular acidification during exposure to acidified sweater, indicating that coral sAC is also a sensor and regulator of pH disturbances from external origin. The presence of sAC in all coral cell types, together with its responsiveness to physiological pH changes, makes it an excellent candidate to sense acid/base disturbances and initiate multiple homeostatic responses. These mechanistic studies are particularly important for understanding the capacity of corals to withstand and adapt to environmental stressors such as ocean acidification.

HUMAN DIMENSIONS OF REEF MANAGEMENT PLANNING: CRITICAL ISSUES ARTICULATED BY INDIGENOUS PRACTITIONERS FROM MICRONESIAN OUTER ISLANDS: YAP STATE (Abstract ID: 29861)

Coral reefs around the world are suffering from multiple stressors, and human communities relying on reefs and associated resources are trying to manage those resources in the face of accelerating ecological change. Simultaneously, human communities and their social structures are changing, and indigenous knowledge is being eroded due to multiple factors. The One People One Reef project works collaboratively with outer island communities in Micronesia to identify traditional knowledge and management practices, provide scientific data to local practitioners, and to identify their primary concerns and issues around reef protection and management. Identification of issues surrounding reef management is the first step to better understanding how to approach ecological questions too. In 2014, we convened a Yap outer island workshop with representatives from 17 outer islands and Atolls to identify primary concerns, traditional methods still in practice, and collective recommendations. A modified grounded theory approach was used to identify patterns and key points. This presentation will outline the main findings from that workshop, with a focus on traditional management, changes in management, and identification of main areas of concern for outer island communities with respect to improved management of reefs and resources.

VERY LOCAL ADAPTATION IN CORAL THERMAL TOLERANCE LIMITS: EVIDENCE FROM 2.5 COUNTRIES, 2 OCEANS, AND 2 SPECIES (Abstract ID: 29704)

It is well known that the same species of coral from different latitudes can differ in bleaching thresholds by as much as a few degrees. This has historically been attributed to an evolutionary tuning of coral thermal limits to the conditions of their local environment (i.e. local adaptation). Recently, a growing body of evidence is finding that corals from different micro-habitats within the same reef-system separated by only 500m to 5km can differ in bleaching tolerance by as much as or more than corals from contrasting latitudes 100s - 1000s of kilometers apart. Here, we present data comparing the response of corals from three study sites to experimental heat stress: a set of shallow back-reef pools in American Samoa, a nearshore and offshore patch reef in the Florida Keys, and a back reef and fore reef in Belize. In all three cases, corals from the microhabitats with the highest amount of daily variability in temperature showed the greatest resistance to bleaching compared to conspecifics from sites with more stable temperatures. These differences were consistent despite long periods of common garden acclimation (30, 36, and 240 days for Belizean, Samoan, and Floridian corals respectively), and similar symbiont types. As a whole, these results combined with those of other recent studies suggest that the amount of thermal variability may play an important role in shaping coral bleaching thresholds and that local adaptation may be as common at within-reef scales as it is thought to be across latitudinal gradients in ocean temperatures.

TRANSLOCATION OF CORAL POPULATIONS TO ENHANCE THERMAL TOLERANCE: PERSPECTIVES UNDER THE ENDANGERED SPECIES ACT (Abstract ID: 29828)

Reef-building corals face a precarious situation of continued decline, and the recent expansion of coral species listings under the Endangered Species Act (ESA) reflects increased governmental concern and elevated conservation potential. Intra-regional translocation—informed by in situ and satellite data on current temperature regimes and model forecasts of future warming—of coral colonies predisposed to higher ambient temperatures may stave off regional coral species extinctions or the loss of reef ecosystem function by redistributing genetic thermal tolerance traits of symbionts and/or coral hosts. Although active translocation efforts are associated with inherent biological risks of vectoring invasive species and disturbing local genetic makeup, these risks can be mitigated through regulating procedures and the limiting of geographic translocation distance. Other examples of translocations of ESA-listed vertebrate and plant species illustrate the propensity for conservation efforts to reflect elevated risks when the species conservation status worsens. Using textual analysis of the ESA and case precedent, the appropriate risk thresholds are identified to ensure the continued survival of listed coral species. Under the ESA there may be a higher impetus to translocate listed coral species as opposed to non-listed species, indicating regional and management priorities. Case studies within U.S. jurisdiction are identified for potential translocation programs of listed coral species.

THE IMPORTANCE OF STRESSOR INTERACTIONS ON MACROALGAE IN URBAN ENVIRONMENTS WITH COMPLEX REGIMES OF MULTIPLE DISTURBANCES (Abstract ID: 28596)

Globally, ecosystems increasingly experience disturbance regime encompassing multiple stressors, where natural fluxes are amplified by human activities. In the urbanised, eutrophic environment of Singapore, bivariate smoothed models (GAMs) demonstrated that temperature and phosphate operate interactively, resulting in seasonal modulation of nutrient impacts on reef macroalgae. Although algae seasonal patterns were maintained, there was a noticeable reduction of persistent, opportunistic algae groups and reorganisation of dominant groups. Source of acute and chronic stresses in the system were identified and a generality in the patterns of the response of algae functional groups to these stressors was found. Both synergistic and antagonistic interactive effects were observed in species responses to the variation in the physico-chemical regime. Antagonistic interactions can mitigate deleterious effects of single stressors, conversely synergistic interactions can exacerbate single stressor effects in a non-additive manner. Understanding how these interactions operate enables a departure from the dogmatic categorisation of environmental parameters. This allows for better decision making, prioritisation in the development of ecological thresholds and setting of trigger values for management intervention.

WATER QUALITY LINKED TO ABUNDANCE AND PHYSIOLOGY OF DOMINANT SOFT CORALS IN JAKARTA BAY, INDONESIA (Abstract ID: 28311)

Declining water quality is a main reason for coral reef degradation in the Thousand Islands off the megacity Jakarta, Indonesia. Shifts in benthic community composition to higher soft coral abundances have been reported for many degraded reefs throughout the Indo-Pacific. However, it is not clear to what extent soft coral abundance and physiology are influenced by water quality. In this study, benthic community composition and water quality (i.e. dissolved inorganic nutrients (DIN), turbidity, and sedimentation) were assessed at three sites (<20km north of Jakarta) in Jakarta Bay (JB) and five sites along the outer Thousand Islands (20–60km north of Jakarta), along with measurements of photosynthetic yield and respiratory electron transport system (ETS) activity of two dominant soft corals, Sarcophyton sp. and Nephthea sp. Findings revealed highly eutrophic water conditions in JB compared to the outer Thousand Islands, with 44% higher DIN load (7.65µM/L), 67% higher turbidity (1.49 NTU) and 47% higher sedimentation rate (30.4g m-2 d-1). Soft corals dominated within the bay (2.4% hard and 12.8% soft coral cover) compared to the outer Thousand Islands (28.3% hard and 6.9% soft coral cover). Soft coral abundances, photosynthetic yield, and ETS activity were highly correlated with key water quality parameters, particularly DIN and sedimentation rates. The findings suggest water quality controls abundance and physiology of dominant soft corals in JB and may thus contribute to phase shifts from hard to soft coral dominance, highlighting the need to better manage water quality.

IMPACTS OF THE 2015-2016 EL NIÑO ON KIRITIMATI, THE WORLD'S LARGEST ATOLL (Abstract ID: 30125)

The 2015-2016 El Niño, which triggered the third ever global coral bleaching event, provided an extraordinary opportunity to rigorously examine the factors that govern reef resilience to thermal stressors. Such knowledge is crucial for developing targeted coral reef conservation strategies under climate change. Located in the central equatorial Pacific, Kiritimati (Christmas) atoll was at the epicenter of this El Niño event; the atoll was on Bleaching Alert 2 for many months. As the world's largest atoll by land mass, Kiritimati also has an unparalleled gradient of coral reef conditions: human impacts are concentrated at the NW corner of the atoll and reefs there are highly degraded, while at the other end of the atoll, the coral reefs are amongst the world's most pristine. Together, these attributes make Kiritimati an ideal location to learn about which corals can survive extreme heat stress events, which properties underlie coral reef resilience, and if bleaching impacts are minimized in areas with fewer local stressors. Here, we present new results from studies at twenty of our long-term monitoring sites across Kiritimati's

local disturbance gradient, which were conducted during six field expeditions carried out before (n=3) and during (n=3) the 2015-2016 El Niño event. We will synthesize the evidence of El Niño impacts on Kiritimati from our field data, which includes data from 500 corals tagged and tracked throughout the event, detailed photo data, in situ temperature and water quality instruments, and fisheries data.

MACROALGAL BROWSING ON A HEAVILY DEGRADED, URBANIZED EQUATORIAL CORAL REEF SYSTEM (Abstract ID: 29319)

The removal of macroalgal biomass is a key process in maintaining a healthy balance between corals and algae on tropical reefs. Numerous studies have quantified rates of macroalgal herbivory using bioassays, however most have been conducted in areas with relatively low macroalgae cover (<5%) and abundant and diverse herbivorous fish populations. This raises the question of whether these studies are representative of degraded coral reef systems where coral cover, and the biomass of herbivorous fishes are markedly lower, and algal biomass substantially higher. Here, we surveyed herbivorous fish communities and quantified their capacity to remove the fleshy macroalga Sargassum ilicifolium using bioassays on multiple reefs in Singapore; a highly degraded urbanized coral reef system exposed to chronic disturbances. Removal of S. ilicifolium biomass varied significantly among reefs (1.2–73.4% 4.5 h-1), but spatial variation was consistent between days, suggesting the strong localized effects of environment and behavior in the component species. Interestingly, despite strong spatial differences video footage revealed that a single species, Siganus virgatus, was almost solely responsible for the removal of algal biomass. Of the 5,302 bites taken from assays across all sites, S. virgatus accounted for 82.1% (4,353) of the total bites. These findings not only highlight the limited redundancy within this system, but importantly that substantial macroalgal removal occurs on these reefs and that there is a need to assess the functional roles of individual species even on degraded reefs.

INFLUENCE OF THERMAL HISTORY AND NUTRIENT ENRICHMENT ON CORAL AND SYMBIONT COMMUNITY STRUCTURE ON LAGOONAL REEFS ON THE BELIZE MESOAMERICAN BARRIER REEF (Abstract ID: 28070)

Coral reefs are increasingly threatened by rising seawater temperature and human-induced nutrient enrichment. Unclear is how spatiotemporal variations of these environmental stressors across a reefscape determine which coral species will be most successful during this climate change interval. Using a novel metric, we classified lagoonal reefs on the Belize Mesoamerican Barrier Reef as enduring low, moderate, or extreme temperature parameters (lowTP, modTP, and extTP, respectively) over the past decade using satellite-derived ultra-high resolution sea surface temperature records. Bulk nutrient concentrations were determined for each site from satellite-derived chl a proxy complemented with in-situ nutrient measurements. Reefs classified into one of the three thermal parameters were surveyed and coral tissue samples were collected to classify the symbiont community. Coral abundance, diversity, percent cover, and species richness were significantly lower at extTP sites compared to lowTP and modTP sites, which did not differ from each other. Coral community differences between extTP and lowTP/modTP sites were primarily driven by temperature differences. The influence of nutrients on coral communities was minimal. Metabarcoding of the ITS2 gene will reveal how Symbiodinium communities vary across host species and between reef environments and will elucidate how temperature and nutrients drive patterns in holobiont communities. Coral communities at extTP sites warrant additional protected status, as they may be better adapted to withstand future ocean conditions.

MICRO-RNA MEDIATED HOST TRANSCRIPTOME MODULATION IN THE CNIDARIAN-DINOFLAGELLATE ENDOSYMBIOSIS OF AIPTASIA (Abstract ID: 27840)

The functional endosymbiosis of a cnidarian coral host and photosynthetic dinoflagellate algae of the genus Symbiodinium forms the trophic and structural basis of coral-reef ecosystems. The acquisition of Symbiodinium from the environment during larval development or during the recovery from stress-induced symbiosis breakdown ("bleaching") is generally accompanied by specific alterations in host gene expression. However, the precise regulatory mechanisms modulating the cnidarian host transcriptome are not known. Here we present evidence for post-transcriptional gene regulation by miRNAs in the small sea anemone Aiptasia, a model system for cnidarian-dinoflagellate endosymbiosis. We find that Aiptasia encodes mainly species-specific miRNAs and provide evidence for recent differentiation of miRNAs within the Aiptasia genome that are commonly conserved among anthozoans. Our analysis of miRNA expression shows that both conserved and species-specific host miRNAs are differentially expressed in response to endosymbiont infection and maintenance of the algal endosymbiosis. Using cross-linking immunoprecipitations (CLIP) of Argonaute, the central protein of the miRNA-induced silencing complex, we identified miRNA binding sites on a transcriptome wide scale and find that symbiotically regulated miRNAs are modulating genes involved in Symbiodinium infection. Taken together, our findings provide evidence for an effective role of miRNAs in modulating the host transcriptome during the onset and maintenance of the cnidarian-dinoflagellate endosymbiosis.

GENETIC DATA INDICATES THAT HYBRIDIZATION BETWEEN CARIBBEAN ELKHORN AND STAGHORN CORALS IS A LIKELY MECHANISM FOR RAPID ADAPTATION (Abstract ID: 28347)

Current models predict the demise of reefs in the next 200 years. It is thus essential to identify habitats, taxa and evolutionary mechanisms that will allow some coral species to maintain their role as foundation fauna. Hybridization can provide an avenue for adaptation to changing conditions and corals hybridize with some frequency. But results may range from the introduction of just a few alleles into existing parent species via introgression, to the birth of a new, perhaps better adapted genetic lineage. Here, we concentrate on once dominant but now threatened species, Acropora cervicornis and A. palmata. In the past, hybrid colonies originating from natural crosses between elkhorn and staghorn corals were rare, and only infrequent hybrid reproduction with staghorn coral was evident, limiting the evolutionary potential of this hybrid system. New genetic and genomic data indicate that hybrids are now mating with each other, demonstrating the potential for the formation of a new species. Further, hybrids appear to be capable of mating with both staghorn and elkhorn coral, perhaps leading to gene flow between the parent species via the hybrid. Recent field observations suggest that the hybrid is increasing and its ecological role is changing throughout the Caribbean. These hybrids appear to be less affected by the disease that led to the mass mortality of their parental species in recent decades. Hybrids are also found thriving in shallow habitats with high temperatures and irradiance suggesting they may be less susceptible to future warming scenarios. Hybridization is thus a possible and probable mechanism for coral adaptation to changing conditions in the Caribbean.

GENOMIC SIGNATURES OF HABITAT ADAPTATION ARE MIRRORED BY PHENOTYPIC DIFFERENCES IN THE CORAL *POCILLOPORA DAMICORNIS* (Abstract ID: 28959)

The future of coral reefs is uncertain. Increasing environmental pressures are causing stress and decreases in coral fitness, cover and diversity are evident on reefs world-wide. The outlook depends on corals' ability to increase stress tolerance and thrive under novel, and often more extreme, environmental conditions. To provide critical knowledge of the adaptive potential of natural populations we reciprocally transplanted fragments of*Pocillopora damicornis* between environmentally distinct reef flat and slope habitats (separated by < 100 m) at two sites ca. 1 km apart at Heron Island, GBR. We detected

strong genotype by environment interactions in fitness-related traits; skeletal growth was 3.5 times higher and partial mortality was 3.2 times lower in native vs novel habitats. Field and lab experiments found higher stress tolerance in native corals from the more environmentally extreme reef flat habitat, with transplanted slope individuals achieving intermediate tolerance levels after 18 months. Analysis across 23,500 SNPs identified strong genetic differentiation between habitats and a large number of private alleles were associated with habitats but not sites. Our results are consistent with local adaptation of coral populations across very small geographical distances and reveal standing genetic variation for enhanced temperature tolerance in natural populations. Combined, our phenotypic and genomic data support a substantial adaptive potential of this coral species that should be considered in projection models under emission and natural management scenarios

EVOLUTIONARY RESCUE AND GENOMIC ADAPTATION TO OCEAN WARMING (Abstract ID: 28245)

Persistence of coral populations through warming ocean temperatures will require adaptation to new climates. Although many studies have used genomic data to examine the potential genetic basis of this adaptation by searching for climate-associated variation, few have applied their findings to predict evolution under future climate change scenarios. Here, we examine the probability of adaptation in a low latitude population of reef-building corals from Rarotonga, Cook Islands. Using candidate single nucleotide polymorphisms (SNPs) associated with thermal tolerance from a previous study in the same species, we simulate population trajectories with selective regimes reflective of warming scenarios. We find substantial capacity for adaptation to warming in the Rarotonga population, but this estimate is highly dependent on both population growth rate and the rate of warming. In addition, we show that spatially heterogeneous habitats may increase the likelihood of evolutionary rescue through assortative mating of more fit genotypes. Merging empirical genomic data with evolutionary models offers a promising method for integrating adaptive processes into predictions of species response to climate change.

RECENT BFAR INITIATIVES RELATING TO EAFM (Abstract ID: 29193 | Poster ID: 577)

This paper will present EAFM initiatives of the Bureau of Fisheries and Aquatic Resources(BFAR) as the primary agency responsible for the conservation and Management of Fisheries in the Philippines.It will include the various management plans/ programs/projects/measures for specific fisheries being implemented in various parts of the country, the recently formulated Comprehensive National Fisheries Industry Development Plan, and other related activities. The process of formulation and implementation of these plans/programs/projects/measures and how they relate to EAFM will be described.

THE ECOSYSTEM APPROACH TO FISHERIES MANAGEMENT (EAFM) FRAMEWORK IN THE CONTEXT OF FISHERIES MANAGEMENT IN THE PHILIPPINES (Abstract ID: 29333)

The Ecosystem Approach to Fisheries Management (EAFM) includes a wider scope of implementation than the fisheries management practiced in the last decades. While the conventional and traditional fisheries management mostly involved activities that focused only on the fisheries sector, the EAFM takes into consideration a broader and multi-sectoral participation; promotes good governance; and utilizes traditional and scientific knowledge to support appropriate adaptive management strategies. The Philippines is mainstreaming and integrating the EAFM concept into the management of various fisheries. In the Philippine context, several successful initiatives will be shared highlighting policy reform, institutional and structural reforms, infrastructure support, broad multi-sectoral collaboration, and promotion of the human well-being.

PROJECTING RESPONSES IN STRESSED MARINE SYSTEMS (PRISMS): MEASURING AND PROJECTING MULTIPLE LOCAL THREATS AT A GLOBAL SCALE (Abstract ID: 28379 | Poster ID: 426)

PREDICTS (Projecting Responses of Ecological Diversity In Changing Terrestrial Systems) is an ongoing collaborative project which uses a meta-analytic approach to investigate how local biodiversity typically responds to human pressures such as land-use change and infrastructure, thereby improving our ability to predict future biodiversity changes (e.g. Newbold et al. (2015) Nature 520: 45-50). The PREDICTS project has already been extremely successful at synthesising raw data from scientists worldwide in order to produce a global database of terrestrial species' responses to human pressures (now having over 3 million biodiversity records from over 27,000 sites, covering more than 47,000 species). We are now extending the methodology to shallow coastal benthic marine communities at a global scale within the 'PRISMS' project, looking at local ecological community change according to associated anthropogenic pressures (primarily land-use change). This is with the aim to compare local within-sample taxon richness, rarefaction-based taxon richness, total abundance, and compositional turnover across regional and global scales, along gradients of human pressure. The responses of reef site-level diversity to the measures of anthropogenic land-use change are modelled using generalized linear mixed effects models. Models will also be projected onto future scenarios of anthropogenic and environmental pressure variables to aid reef management.

CORAL-ALGAL DYNAMICS UNDER FUTURE CARBON DIOXIDE SCENARIOS AND EUTROPHICATION (Abstract ID: 28306 | Poster ID: 112)

Coral reefs are threatened by the consequences of increasing atmospheric carbon dioxide (CO2) leading to seawater warming and acidification, and eutrophication from crop-fertilization. Many studies suggested that algae will dominate corals in the future; however, multiple stressors provoke complex responses and their combined impacts on corals, algae and their interactions are unknown. This research focused explicitly on the synergistic effects of seawater warming and acidification under presence and absence of eutrophication on the survival of key reef organisms and their interactions under simulated present and future CO2 scenarios. Winter experiments were carried out on Heron Island, Southern Great Barrier Reef, in which Acropora pulchra coral fragments and thalli of the tropical brown algae Chnoospora implexa, both alone and in interaction, were exposed to present and "business-as-usual" pCO2 and seawater temperature (RCP8.5; + 570 µatm pCO2 and + 4°C), and to ambient and elevated inorganic nutrients (2.5 µmol L-1 ammonium and 1.25 µmol L-1 phosphate). Performance and function of corals and algae were assessed by measuring growth, productivity, pigments, and tissue nutrient content. Preliminary results showed no negative interaction between algae attached to corals under any treatment. While algae had a significant mortality after experimental mid-term, coral fragments showed growth and an increase in pigmentation in treatments with elevated nutrients. The outcome of this study will provide robust experimental evidence of the fate of future coral reefs' integrity.

NO-TAKE MARINE PROTECTED AREAS ALTER BENTHIC COMMUNITIES WITH CASCADING POSITIVE EFFECTS ON CORAL SETTLEMENT AND LARVAL AND RECRUIT SURVIVORSHIP (Abstract ID: 28020 | Poster ID: 629)

Macroalgae can harm corals via numerous mechanisms and coral larvae avoid cues from many species of macroalgae in settlement and flume experiments. However, coral larvae may not be able to avoid settlement near macroalgae with reefs globally becoming more degraded due to increasing anthropogenic stressors. We tested for the effect of substrates from a coral-dominated no-take marine protected area (MPA) compared to substrates from an adjacent fished reef dominated by macroalgae on larval settlement and recruit survivorship of the coral Pocillopora damicornis. We also tested for differences in survivorship of larvae from MPA and fished reefs when maintained in water collected from each reef. Larvae from both MPAs and fished areas initially (≤ 24 h)

avoided settlement on macroalgal-fouled substrate collected from the fished area, but no longer avoided settlement after 48 h. When out-planted to the protected or fished area, larvae from both areas experienced higher post-settlement survivorship at 4 and 26 days within the MPA than the fished area. Larvae from the fished area had lower survivorship than larvae from the MPA and this effect was exacerbated when larvae were maintained in water from the fished area compared to the MPA. These results indicate that no-take MPAs improve coral settlement and survivorship at multiple life stages. Protected areas may also select for healthier microbial communities. We are currently investigating microbial effects in the observed settlement and survivorship patterns between fished and protected reefs.

WILL YOUR DATA BE USEFUL AFTER YOU ARE GONE? U.S. FEDERAL DATA MANAGEMENT POLICIES AS RECOMMENDATIONS FOR ALL SCIENTISTS (Abstract ID: 28748)

The Public Access to Research Results (PARR) policy is being implemented across all federal agencies in the United States. It requires all data collected with federal funds be made publicly available in a timely manner. As part of it's implementation plan, the National Oceanographic and Atmospheric Administration (NOAA) has put a series of directives into place to address issues of data management, including, but not limited to, access, documentation and data citation. The Coral Reef Conservation Program (CRCP) funds the majority of projects dealing with shallow water coral reefs across different NOAA offices. These projects collect a wide variety of data from satellite derived products to in water monitoring. This range of data types along with differing office requirements provides a unique set of data management challenges. I will present an overview of how we are currently managing data within CRCP and talk about how these management practices are good recommendations for all coral reef researchers. Some of these recommendations include tools that are available to the wider research community. Data science is increasingly an important tool for resource management; this requires coral data managers to evolve how they manage and share coral data. Open access to publications and data is becoming more often a requirement rather than a recommendation, and as rigorous as scientists can be on their collection methodology, they should be equally as rigorous on how they manage their data. It is only through proper management that data can be made useful into the future.

BUILT CAPITAL AND PEOPLE PROTECTED BY CORAL REEFS GLOBALLY, NOW AND IN THE FUTURE (Abstract ID: 29593)

Climate change and coastal development are dramatically increasing risks to people and property and to losses of coastal habitats. Exposure to flooding is increasing from the combined influence of coastal storms, changes in sea levels, land subsidence, urban development, population growth and geomorphic change. The need to upgrade existing flood protection and to plan for future risks is becoming increasingly apparent, as are the costs. This is driving billions of dollars to reduce those risks, creating both threats and opportunities for ecosystems. Habitat loss will further expose communities and assets to flooding and erosion. However, there very limited estimates of the actual asset value and people directly protected by ecosystems worldwide. We combined ecological, engineering and economic approaches to estimate the benefit we get from coral reefs across the globe, by comparing the present situation with a loss of 1m in height of coral reefs globally and scenarios that account for a future of sea level rise and reef degradation. The results are revealing. For example, as compared to the flooding currently predicted for 100-year events, the loss of just 1 m in coral reef height globally would trigger added flooding of more than 16,000 km2 affecting an additional 8 million people and $US186 billion in built capital; a 92% increase in storm costs. Some of the hotspots that enjoy the greatest benefit from coral reef nowadays are in rank order from SE Asia and the Middle East. The countries that have their total built capital protected by coral reefs include many Small Island Developing States and some larger island nations (e.g., Belize, Grenada, Philippines).

ISLANDS OF SEA: THE ROLE OF ISOLATION IN SPATIAL PATTERNS OF MARINE BIODIVERSITY (Abstract ID: 29530)

Phylogeographic studies in the Coral Triangle have shown that populations of coral reef organisms are more structured than previously assumed and that isolation at small spatial scales may play an important role in forming the observed spatial patterns of genetic diversity. Isolation can affect genetic diversity due to physical barriers, irrespective of environment, and/or due to different environmental regimes. A key issue is that environmental data is generally spatially structured at multiple scales and will change over time, thereby clouding the ultimate cause of divergence and differentiation. Here we use the clearly defined spatio-temporal context of marine lakes – islands of sea - to study how gene flow corresponds with environmental gradients. Marine lakes are landlocked water bodies that maintain a marine character with coral reef organisms through narrow submarine connections to the sea. By comparing marine lakes in Indonesia, with comparable ages and sizes, but varying degrees of connection to the open sea and differing environmental regimes, we aim to test the relative contribution of dispersal limitation due to barriers versus selective environments in the formation of marine biodiversity patterns. We will present preliminary data of our study on multiple marine lineages (sponges, mussels, jellyfish) across the marine lake model system based on population genomic techniques (RADSeq). Understanding how geneflow corresponds with environmental gradients will improve predictions on adaptive capacities of species under different climate change scenarios.

CARBON AND NITROGEN FIXATION BY REEF ORGANISMS AND SUBSTRATES IN RESPONSE TO SEASONAL CHANGES (Abstract ID: 27985)

Tropical coral reefs are among the marine ecosystems with the highest C fixation rates, although they are surrounded by very oligotrophic waters. This reef paradox is not yet completely understood. However, it is evident that mechanisms must be in place allowing extraction of essential elements, particularly new nitrogen. Several key reef C-fixing primary producers (e.g. corals, macro and turf algae) and substrates (e.g. reef sands, dead corals and rocky surfaces), exhibit internal or external associations with N-fixing microbes like cyanobacteria. Such associations potentially facilitate primary production, but there are no studies that address the potential linkage between C and N fixation in coral reefs under the influence of potentially controlling environmental factors. This contribution will thus present data from a series of experiments conducted during all four seasons at a high-latitude reef location in the Northern Red Sea, thereby exhibiting strong seasonality in key water parameters. Findings revealed a widespread occurrence of N fixation by diazotrophs associated with all major groups of reef organisms and substrates and a cross-organism linkage between C and N fixation when inorganic nutrient availability in the water column was lowest. Extrapolation of our data also characterize coral reefs among the most active N-fixing marine ecosystems. This comprehensive dataset will help to gain new important insights in coral reef ecosystem functioning and resilience in a time of environmental change.

NITROGEN ACQUISITION VIA DIAZOTROPHY IN COLD-WATER, TEMPERATE AND TROPICAL CORALS (Abstract ID: 29273)

Dinitrogen ($N_2$) fixation by specialized prokaryotes (diazotrophs) represents an important source of bioavailable nitrogen (N) in the world's ocean. Among marine ecosystems tropical coral reefs have been identified as hotspots of $N_2$ fixation that may facilitate their high productivity despite being surrounded by oligotrophic waters. Recently, cold-water

coral associated $N_2$ fixation has also been demonstrated suggesting that coral-diazotroph associations are ubiquitous over large spatial and latitudinal scales. Several studies shed light on the abundance and diversity of coral-associated diazotrophic communities or quantified the amount of $N_2$fixation, while direct evidence for the uptake and metabolic usage of $N_2$fixation products by the coral host is still lacking. Thus, this talk will present a series of $^{15}N_2$ tracer experiments following the net incorporation of freshly fixed $N_2$ into the different coral compartments (tissue, zooxanthellae, skeleton, mucus) and its subsequent release into the surrounding seawater as organic and inorganic N. In addition, the uptake of fixed $N_2$ was comparatively investigated between cold-water, temperate and tropical corals to assess the specific nutritional importance of coral-associated $N_2$fixation for corals thriving in very diverse environmental settings.

LIFE BEGINS AT 40: TOWARDS RESILIENCE-BASED MANAGEMENT OF THE GREAT BARRIER REEF MARINE PARK. (Abstract ID: 29079)

The Great Barrier Reef Marine Park Authority turned 40 years old in 2015. Like middle aged humans, the future of Great Barrier Reef ecosystems is dependent upon actions that sustain health. Since 1975 the GBRMPA has been adaptively managing the Marine Park to protect the outstanding universal value of this global icon. Actions such as the original (1975) and revised (2004) zoning have minimised extractive activities and ongoing water quality improvement measures are addressing 150 years of coastal development. However, like reefs worldwide, legacy and current human and environmental pressures are challenging the capacity of GBR ecosystems to tolerate and recover from impacts. In the coming decades the increasing effects of climate change combined with existing pressures threaten to overwhelm the capacity of conventional management arrangements to protect the Reef. In response to these mounting pressures the GBRMPA is working to enhance resilience through the Reef 2050 long-term sustainability plan. The GBRMPA is partnering with Australian and international managers, researchers and non-governmental organisations to translate resilience science into practical future focused adaptive management strategies. This presentation outlines some of the ongoing strategic, tactical, stewardship, monitoring and evaluation actions that have been developed over the past decade to trial and enable resilience-based management of the world's largest coral reef system.

MACRO-INVERTEBRATE COMMUNITIES ASSOCIATED WITH HALICLONA SP. AND SPHECIOSPONGIA VAGABUNDA (PHYLUM: PORIFERA) FROM MAURITIUS (Abstract ID: 27876 | Poster ID: 294)

The macrofaunal communities associated with two distinct sponge species (Haliclona sp. and Spheciospongia vagabunda) were assessed along the east and south west coasts of Mauritius. Sponge samples were collected at a depth range of 0.5 – 2 m, dissected and the associated macrofaunal communities were collected, sorted and identified to the lowest possible taxonomic level. Faunistic associations were determined through cluster analysis using the Bray-Curtis similarity (PRIMER 6). A total of 26 macroinvertebrate species belonging to six taxonomic groups were recorded. Polychaeta was the most dominant taxa in terms of the number of individuals (51% of the total individuals) and Crustacea constituted the highest number of species (13 species). The polychaete Haplosyllis djiboutiensis and the brittle star Ophiactis savignyi were the most abundant associated species recorded. The numbers of individuals and the diversity index values were positively correlated the sponge volume. This study is among the first records on sponge-associated macrofauna in Mauritius and supports the importance of marine sponges as habitats for macro-invertebrates.

INVESTIGATING CORAL REEF GRAZING AS A NATURAL CONTROL OF INCREASED ALGAL GROWTH IN TWO HAWAI'I NATIONAL PARKS (Abstract ID: 30047)

Recent studies in Hawai'i have shown that increased coastal nutrient inputs can accelerate nuisance algal growth in coral reef ecosystems. However, in areas with sufficient grazer density, excessive algal growth may be controlled. Our study investigated the top-down effects of grazing and the bottom-up effects of benthic nutrient inputs (through submarine groundwater discharge) on algal turf growth within two Hawai'i parks (Kaloko-Honokōhau NHP and Kalaupapa NHP). Increased algal growth was significantly correlated with greater benthic nutrient concentrations at both parks. Different grazer assemblages were studied within each park with visual and video sampling, and macroalgal grazing assays reflected differences in grazer effects on algal biomass at each park. In 2013-14, algal turf grazing experiments with controlled/excluded herbivory treatments were used to document significant grazer effects on algal turf biomass, with urchin-dominated grazing at Kaloko-Honokōhau and fish-dominated grazing at Kalaupapa. These findings provide valuable information on the role of herbivores in Hawaiian marine systems and similar regional environments, and emphasize the importance of management of herbivores in tropical marine systems.

BENTHIC ALGAL GROWTH IN RESPONSE TO SUBMARINE GROUNDWATER DISCHARGE IN TWO HAWAI'I NATIONAL PARKS (Abstract ID: 30058)

Kaloko-Honokōhau and Kalaupapa National Historical Parks, experience sizable inputs of submarine groundwater discharge, which can supply large volumes of nutrient-laden freshwater from to coastal environments, potentially yielding nuisance algal growth. To investigate nearshore ecosystem responses to land-based inputs, known shoreline seeps and several randomly selected benthic stations were sampled in both parks during a four-year investigation. Nutrient concentrations were documented to be spatially and temporally variable. Generally, nutrient concentrations were not large from subtidal benthic stations compared to shoreline seep values. Results of macroalgae and algal turf growth experiments showed that algal growth varied greatly between parks and was associated with specific nutrient concentrations. Algal tissue analysis (N15) did not indicate sewage sources for available nutrients at selected benthic stations.

OPERATIONALISING THE MANAGEMENT OF CORAL REEF RESILIENCE (Abstract ID: 29127)

Coral reefs are globally imperilled, with more frequent and severe disturbance events reinforcing the ecosystem's retrogression and impacting their ability to recover. The literature often highlights that managers should aim to conserve the most resilient reefs, i.e. those reefs that are least likely to experience phase shifts because their ecological and environmental conditions. Thus far, a hurdle to protecting resilient reefs has been that resilience plays out over long time-scales and is difficult to quantify in objective-based decision-making. Our paper aims to operationalize the management of coral reef resilience in quantitative terms and present a framework to maximise both mean resilience and cost effectiveness in reef management. By understanding their past responses to disturbances, we aim to predict the reefs' future resilience. Here, we estimate the mean long-term resilience of coral reefs on a global scale based on the understanding that resilience is governed by exposure rates to multiple disturbances, the sensitivity of reefs to a disturbance, and the rates of recovery. We estimate these components on a global scale based on long-term studies, and predict long-term reef trajectories with simple stochastic models. Our approach is based on factors of resilience that can be measured and managed, providing a framework for selecting management actions on the basis of local reef ecosystem trends and financial and logistical constraints of management.

DEEP LEARNING IN THE SHALLOW SEAS: USING COLLABORATIVE PLATFORMS AND DEEP NEURAL NETWORKS TO GREATLY ADVANCE AUTOMATED ANALYSIS OF CORAL REEF SURVEY IMAGERY (Abstract ID: 28730)

Modern robotics and imaging technology enable rapid collection of large coral reef image surveys. However, the subsequent image-annotation required to extract data for ecological analysis is time-consuming and expensive, creating a manual annotation bottleneck between collected imagery and required data. We present an algorithmic framework and a collaborative platform to address this bottleneck.

The CoralNet (coralnet.ucsd.edu) image annotation platform has been freely available for 2 years. During this time, over 150,000 coral reef survey images have been uploaded as part of 288 different reef surveys, and annotated with over 4 million point annotations by 347 coral reef experts. Through the CoralNet interactive annotation tool, users already leverage automated image analysis to reduce the manual annotation work by 50%.

Using this wealth of data, we have developed the next generation automated annotation methods, using deep neural networks with 138 million parameters organized in 16 convolutional layers. Using these networks, we can further reduce the annotation burden so that, on average, only 20% of the annotation work remains for the human annotator. Remarkably, for surveys conducted with sufficient image quality, fully automated annotation is possible with *no reduction* of annotation quality compared manual annotation.

As more data is uploaded and verified, the CoralNet vision back-end will continue to evolve, creating a positive feedback loop to encourage further collaboration and enable rapid and accurate image based reef surveys.

FILTERING OF CORAL REEF FISH HERBIVORY ALONG A GRADIENT OF WAVE EXPOSURE (Abstract ID: 28012)

Quantifying the heterogeneity of ecological processes is crucial to understand spatial patterns of ecosystem function. Here we quantify the spatial variability of coral reef fish herbivory and, using a trait-based approach we measure species swimming performance, and determine whether wave exposure acts as an environmental filter of herbivore feeding function. Species with distinct feeding strategies differed in swimming performance. Although high wave exposure impairs the feeding function of 22% of species, it doubles overall herbivore feeding intensity without affecting the percentages accounted for by grazers and scrapers. The likely antagonistic effect of wave exposure on fish feeding behaviour and algal productivity makes herbivory relatively resilient to the functional impairment of less manoeuvrable species. We argue that the significance of certain environmental filters may be overridden by those stemming from selective human activities. Extending our approach to further ecological processes and factors that may supress species functions, can help refine spatial predictions of ecosystem function, and assist conservation planning aimed at sustaining resilience to disturbance.

RETENTION MECHANISMS AND SELF-RECRUITMENT IN A CORAL REEF FISH (Abstract ID: 28423)

The distance traveled and trajectories taken by marine larvae during dispersal are likely influenced by larval behaviors as well as oceanographic features. Passive retention mechanisms, such as eddies, are thought to enhance self-recruitment, that is, the return of larvae to their natal population. Exact locations of hatching and settlement of self-recruiting larvae enable tests of expected patterns of dispersal based on known patterns of water circulation. Using parentage inference based on multiple sampling years in Moorea, French Polynesia we describe spatial and temporal variation in self-recruitment of the coral reef orangefin anemonefish, evaluate the consistency of net dispersal distances of self-recruits against the null expectation of passive particle dispersal, and test the hypothesis that larvae originating in certain reef habitats (lagoons and passes) would be retained and thus more likely to self-recruit than those originating on the outer (fore) reef. Estimates of known self-recruitment were consistent across the sampling years (~ 25-27% of sampled recruits)..The vast majority (92%) of the larvae born on Moorea showed a net distance between hatching and settlement locations that was within the average maximum dispersal distance expected of a neutrally-buoyant passive particle. However, a parent of a given body size on the outer (fore) reef of Moorea was less likely than those on lagoon reefs or in passes to produce self-recruits. Our findings show that even simple dispersal models that simulate the spatial scale and direction of larval dispersal can provide insight into landscape-scale retention patterns of reef fishes.

THE PAST, PRESENT AND FUTURE OF CORAL REEFS: A FUNCTIONAL PERSPECTIVE. (Abstract ID: 28502)

Our view of the evolution of coral reefs, and fishes in particular, has been largely based on changes in the diversity of taxa. The fossil record places taxa at particular locations and points in time, while phylogenies identify relationships and the timing of divergence events. It is only when these data are considered in a functional context that we can begin to reconstruct the ecology of past reefs. The overarching goal of our research has been to develop a picture of ancient reefs as working functional ecosystems. In this way we can examine changes through time in terms of how reefs operated, rather than documenting the diversity of key lineages. In this presentation I will provide an overview of our recent research on the evolution of major functional traits in reef fishes, detailing how these traits influence the use of reefs by fishes, and how reefs have changed as a consequence. I will also examine the implications of these changes for the future of coral reefs at a global scale. Remarkably, the future of coral reefs appears to be returning to a distant past. Human activities are selectively undermining the last 30 million years of coral reef evolution, producing reefs that closely resemble their ancient counterparts.

ENVIRONMENTALLY MEDIATED MATERNAL EFFECTS IN STYLOPHORA PISTILLATA FROM THE GULF OF AQABA, RED SEA. (Abstract ID: 29387 | Poster ID: 482)

It is typically reported that 1°C above the local maximum monthly mean (MMM) sea temperature can result in coral bleaching. Despite increasing sea temperatures in line with the global rate, and recurring positive temperature anomalies, coral bleaching is rarely reported in the Gulf of Aqaba, Red Sea (GoA). Experiments conducted with the locally important *Stlyophora pistillata* sustained for 2 weeks at 5°C above MMM, resulted in few of the common bleaching signs. As a result, the GoA has been putatively identified as a refuge and a potential donor site for assisted colonisation and restoration projects. However, this prospect depends upon the continued ability for local species to adapt to further change and pass on favourable traits to enhance offspring fitness. The link between adult health and parental investment is not well understood in corals. Therefore, field sampling and experiments were conducted to investigate how the environmental experience of the parental colony influences offspring traits and how this may affect recruitment in future oceans. *S. pistillata* has colonised diverse habitats in the GoA and planulates throughout the entire regional sea temperature range (21 – 29°C). This offers

a rare chance to assess planulae fitness across *in situ* and experimental environmental gradients. Results from these studies give insights into how offspring viability is environmentally mediated and offers considerations for active restoration projects.

WATER SECURITY IN SMALL ISLAND DEVELOPING STATES: APPLYING A MULTI-SCALAR GOVERNANCE LENS TO ELUCIDATE POTENTIAL FOR 'TRANSFORMATION' (Abstract ID: 28251 | Poster ID: 557)

Water security is one of the most pressing development challenges of the Anthropocene, epitomized by the recent adoption of a dedicated water goal in the post-2015 development agenda. This agenda aims to 'transform our world'. Fundamental to such a transformation are water governance reforms. Indeed, many researchers and water management practitioners have called for a paradigm shift away from top-down command and control management towards adaptive water governance in order to enable transformation. Yet there has been limited research into the potential for such transformations in SIDS— contexts, which we argue are peculiar, and deserving of special attention. To address this gap, this paper utilizes a multi-scalar governance lens to interrogate water sector reforms in Samoa (the Pacific) and St. Lucia (the Caribbean). The multi-scalar governance lens elucidated how the actually existing complex water governance systems have arisen over time, through processes of contestation and struggle between actors at multiples scales, to fit the specific geophysical, political and cultural contexts in two case studies. The results also illustrate how, even in the unique socio-political contexts in SIDS, where state-society relations are often blurred, formal hierarchies are sometimes ill-defined, and informal relations between actors can act as limitations, there exist immanent opportunities for transformative change towards more adaptive and socially-just governance.

IMPROVING LONG-TERM CORAL REEF MONITORING IN THE WIDER CARIBBEAN REGION: INITIAL GCRMN-CARIBBEAN ACCOMPLISHMENTS (Abstract ID: 28385)

Long-term and robust coral reef monitoring coupled with strategic reporting are essential drivers for ecosystem-based management and regional policy processes. The Global Coral Reef Monitoring Network (GCRMN) report*Status and Trends of Caribbean Coral Reefs 1970-2012* highlighted the limitations of regional coral reef monitoring in the Caribbean. To address the urgent need for more effective coral reef monitoring and reporting there has been a move towards revitalizing the Caribbean component of the GCRMN. The foundation for restructuring the network was launched in August 2014, along with concrete proposals for improvements in data collection, archiving and communication. Several technical and scientific solutions have been proposed to address the lack of information and dissemination, and inconsistency in applying monitoring methods and approaches throughout the region. The first two years of the GCRMN-Caribbean has seen the confirmation of a dynamic network, which has been bolstering its presence and regional acknowledgement. An expert steering committee and members-at-large have enabled the network to achieve substantial progress. GCRMN-Caribbean integrated guidelines have been improved and tested at several sites; communication and experience sharing have increased considerably; capacity building actions have been identified and developed; and there has been collaboration with major Caribbean programmes. This paper reports on the progress towards revitalizing the GCRMN-Caribbean, its initial achievements, as well as network challenges and next steps.

EFFECTIVE DISPERSAL OF CARIBBEAN REEF FISH IS SMALLER THAN CURRENT SPACING AMONG MARINE PROTECTED AREAS (Abstract ID: 29826)

Coral reefs are deteriorating at a fast pace. Conservation measures, such as Marine Protected Areas, have been implemented to relieve some areas from local stressors and allow populations to restore to natural levels. Successful networks of MPAs can operate if the space among MPAs is smaller than the dispersal capacity of the species under protection. Here we tested the power of genome-wide Single Nucleotide Polymorphism data to estimate connectivity across populations in a series of MPAs around Puerto Rico and contrasted with 18 microsatellite markers. We found that in the common yellowhead Jawfish, *Opistognathus aurifrons* the maximum effective dispersal is 10 km. MPAs exchange migrants likely via intermediate available unprotected habitats through stepping stone dispersal. At scales > 100 km such connectivity is decreased, after the Mona Passage, making the Dominican Republic a genetic mosaic of the genetic variation from the eastern and western Caribbean. The MPA network studied is unable to maintain adequate levels of connectivity of these small benthic fishes if habitat in between them is extirpated. Given that overall reef fish diversity is driven by species with life histories similar to that of the yellowhead jawfish, managers face a challenge to develop strategies that allow connectivity and avoid isolation of populations and their extinction.

FISHING FOR ANSWERS: TRACKING YELLOWTAIL (*SERIOLA LALANDI*) MOVEMENTS AND CATCH IN THE EASTERN PACIFIC. (Abstract ID: 29871 | Poster ID: 271)

Yellowtail (*Seriola lalandi*) are large, carangid, meso-predators that migrate between sub-tropical and temperate reef systems along the North American west coast. They are seasonally abundant, corresponding to regionally elevated sea-surface temperatures; increased catches occur during periods of warm water or ENSO conditions. However, analysis of recreational catch data suggests the largest (>13 kg) individuals inhabit nearshore waters year-round. These observations suggest a structured pattern of space-use based upon physiological constraints and ontogenetic movements, with the potential for novel northward range expansions under conditions of ocean warming. This work is the first since 1960 on this widely targeted, economically important species. To examine spatial and temporal trends in the fishery, all recreational catch in southern California between 1936-2015 from all existing databases were analyzed by size, season, location, and sea-surface temperature. Catch was bi-modal with peaks at both immature and mature sizes, larger fish were caught inshore (<3 mi) while smaller fish were predominantly offshore (>3 mi). These trends varied predictably depending on season. Fish caught during winter were significantly larger than those caught during the remainder of the year. These trends motivated a comprehensive regional tagging program. Currently, the recapture rate is 21%, with time at liberty ranging from 24 hours to 24 months and recapture distance from 0-400km and suggests novel evidence of ontogenetic changes in movement.

GLOBAL PATTERNS OF FUNCTIONAL RARITY IN REEF FISH COMMUNITIES (Abstract ID: 29630)

The loss of biodiversity caused by human-mediated impacts has reached unprecedented level across all ecosystems, with rare species being by far the most threatened. Despite the importance of biodiversity to sustain ecological processes, little is known about the particular functions supported by rare species or the functional vulnerability of communities to rare species loss. Thus, assessing the spatial distribution of functional rarity would provide relevant information to the conservation of the most vulnerable species and communities within the context of intense disturbances and high uncertainty. Our extensive dataset comprised local abundances, regional occupancies and functional traits for 1,474 reef fish species. We assessed global patterns of functional rarity and implemented scenarios of functional diversity loss across 93 reef fish communities distributed across five marine biogeographic regions. We found that rare species fulfil much of the range of functional traits within reef fish communities and often perform unique roles. We identified high functional diversity erosion from rare species loss in the majority of reef fish communities, this level reaching up to 70% of functional diversity in one location. Also, rare species carry the most distinct combinations of functional traits (high distinctiveness), whereas species with low functional distinctiveness are either locally rare or common. Our results highlight the vulnerability of ecological roles supported by rare species, even in highly diverse reef fish communities.

TEMPORAL CHANGES IN THE PRODUCTIVITY AND CALCIFICATION OF SLOPE AND LAGOONAL BENTHIC COMMUNITIES ON A PLATFORM REEF (Abstract ID: 29275)

More than a quarter of a century ago, pioneering studies assessing the metabolism of coral reef communities were conducted in order to better understand the workings of

these beautiful, yet complex ecosystems. Today, studies revisiting in-situ measurements of coral reef metabolism are still very important as (i) technology has progressed and offers more precise measuring techniques and (ii) reef systems are changing through anthropogenic influences. The aim of our study was to investigate the metabolism of reef communities of 2 distinct geomorphological zones on a platform reef in the Great Barrier Reef, Australia. The sites, one at 5m on the reef slope and the other inside the lagoon, were continuously monitored for water depth, temperature, oxygen, light, $CO_2$, pH, turbidity, salinity and chlorophyll concentration using CTDs. Four times a year, in every season, in-situ incubations were conducted at both sites using computer controlled Perspex chambers connected to an autosampler. Importantly, two sides of the chambers opened between incubations to allow for water exchange and prevent depletion of nutrients/ions. Productivity, measured as oxygen flux, and calcification rates were established for representative benthic communities inside these chambers. Preliminary results suggest that there is a temporal effect on reef productivity and calcification. The findings of these incubations will also be discussed in light of the background water quality measurements.

PROGRESS TOWARD ACHIEVING SETTLEMENT AND METAMORPHOSIS OF AIPTASIA LARVAE IN THE LABORATORY (Abstract ID: 28961 | Poster ID: 200)

As the sea anemone Aiptasia gains traction as a model for investigating cnidarian-dinoflagellate symbiosis, a remaining obstacle is the inability to reproduce the complete sexual life cycle in the laboratory. Although we can obtain regular spawning and larvae production in the lab, the physical and/or chemical cues required for larval settlement and metamorphosis remain elusive. Here we report progress on two fronts: (1) identification of inductive natural products and/or bacterial isolates; (2) identification and application of neuropeptides with a role in metamorphosis. Tetrabromopyrrole, a natural product from the marine bacterium Pseudoalteromonas spp. that induces settlement and metamorphosis in coral larvae, and a Hydra neuropeptide (Hym248) each induce partial metamorphosis of Aiptasia without settlement. We are currently attempting to identify bacteria or extracts that will reliably induce both settlement and metamorphosis. To identify Aiptasia LWamide neuropeptides that might induce settlement and/or metamorphosis, we performed a thorough screen of the Aiptasia genome and available transcriptomes. At least seven putative LWamide-like neuropeptides occur in the genome and are also found in adult or larval transcriptomes. Four of these contain the "GLW" motif conserved in proteins from other cnidarians (e.g., Hym-248 from Hydra; Metamorphosin A from Anthopleura); three others, including one expressed exclusively in Aiptasia larvae, contain repetitive "GIW", "GVW" or "GFW" motifs. We are currently testing the possible roles of these neuropeptides in metamorphosis.

MARINE CONSERVATION & RESOURCE MANAGEMENT YOUTH EDUCATION - A MISSING STRATEGY IN FUTURE CORAL REEF RESILIENCE IN THE CORAL TRIANGLE? (Abstract ID: 27856)

In 1997, in a local high school in the West New Britain Province of Papua New Guinea, a volunteer biology sciences teacher commenced the development of the Marine Environment Education Program, or MEEP. With technical input from James Cook University, Australia and experienced educators, the program now reaches elementary, primary and high schools, both locally and on a wider national scale. The principal aim of the program is to help educate the country's youth in marine conservation and resource management. The course compliments PNG Department of Education primary & secondary curricula in biology and environmental sciences while exposing students to actual field visits to coral reefs and other marine ecosystems. MEEP has now been thoroughly field tested within Coral Triangle conditions, marine environments and communities, and is further evolving even after a period of 19 years. With this background and historical development, is there a more co-ordinated approach for marine conservation and resource management youth education within the Coral Triangle by all CT countries? Can MEEP be part of a solution to coral reef resilience? The future of marine resource management within this region will depend in part on the present and future youth generations and their understanding of sustainable use of their marine resources. Is it time for more Coral Triangle countries to engage in this strategy for future resilience of coral reefs? Mahonia Na Dari Research and Conservation Centre (Guardian of the Sea), Kimbe Bay, PNG where the program is based, believes it is.

NON-CONSUMPTIVE EFFECTS OF NATIVE AND INVASIVE PREDATORS ON RECRUITMENT OF CORAL-REEF FISHES (Abstract ID: 28838)

Coral-reef fishes are particularly susceptible to predation during their transition from pelagic larvae to reef-associated juveniles. Larvae of some species detect cues from predators and avoid settling nearby. However, it is unknown whether recruits alter their settlement habitat in response to invasive predators and how other potentially mediating factors, including predator diet and interactions among conspecific recruits (e.g., competition, facilitation), influence these patterns. We conducted manipulative field experiments to test for non-consumptive effects of native and non-native predators on the settlement of Caribbean coral-reef fishes. There was no effect of predator presence or conspecific density on the recruitment of bicolor damselfish (*Stegastes partitus*) to standardized patch reefs. In contrast, there were ~52% fewer mahogany snapper (*Lutjanus mahagoni*) recruits to reefs with a native predator (graysby grouper, *Cephalopholis cruentata*) compared to predator-free control reefs and reefs with an invasive predator (red lionfish, *Pterois volitans*) regardless of predator diet. These results suggest that snapper recruits may use species-specific cues to recognize native predators and are naïve to cues from an invasive predator. However, on nights with extremely high recruit densities there was approximately equal recruitment of snapper to all reefs regardless of predator presence, suggesting that intraspecific interactions among recruits may limit the non-consumptive effects of predators at high conspecific densities.

MODEL FOR SUSTAINABLE HARVEST TO ASSIST COMMUNITY-BASED RESOURCE MANAGEMENT (Abstract ID: 29698)

Fisheries worldwide are in decline due to exploitation, anthropogenic pressures, habitat loss, and changes in climate. Here, we present a single-species assessment model that uses resource monitoring data collected by the 'Opihi Partnership, which involves communities, scientists, NGO, and GO, to evaluate the ability to sustainably harvest 'opihi (*Cellana spp*., limpets) at different times and locations. 'Opihi are culturally and economically valuable to the Hawaiian Islands and its people, so it is imperative to ensure that this fishery is sustainable. The life history characteristics of 'opihi are used to build assumptions into the model regarding spawning characteristics, growth rates, and size at reproductive maturity. The model accepts 'opihi size distribution and population density data and returns a recommendation of whether harvest, under current legal regulations, would be offset by the maturation of juvenile 'opihi. We then tested the model with data from 'opihi makaiauli (*Cellana exarata*) from two islands, Mokupāpapa and Mokumanamana, in the Papahānaumokuākea Marine National Monument (PMNM), which are ideal because neither is subject to harvesting. The model predicts that when challenged with unrestricted harvest within the legal size limits, the recruitment-limited site could not sustain harvest and the recruitment-saturated site can only sustain seasonal harvest. There is also the potential for this model to extend to other broadcast spawners such as sea urchins, mussels, abalone, clams, and oysters.

CHANGE DETECTION IN A CORAL REEF ENVIRONMENT IN THE ARABIAN GULF USING MULTISPECTRAL REMOTE SENSING (Abstract ID: 28583)

The United Arab Emirates (UAE) borders the Arabian Gulf. The coasts and islands that flank Abu Dhabi, the UAE's largest emirate, host important marine habitats such as coral reefs. These reefs are subject to pressures from urban and industrial encroachment and from climate change. The current study aims to detect the change in a reef environment of Dalma Island, located 42 km off Abu Dhabi, between 2013 and 2015. Satellite remote sensing-based monitoring of such ecosystem presents a challenge due to the attenuation of light through the atmosphere and the water column, as well as the spectral similarity of its benthic components. Our method proposes a combination of different remote sensing techniques that include image segmentation, non-linear feature analysis (kernel feature extraction) and ensemble learning methods (Random Forest); consisting of spectral-spatial methods vs. pixel-based methods. Change detection is fulfilled using the Iteratively Reweighted Multivariate Alteration Detection method that performs an automatic radiometric normalization and factors out the side effects of varying acquisition conditions. The achievement of the adaptation of these methods to the region of concern demonstrates the operational role of multispectral remote sensing in coral reef monitoring.

THE EFFECT OF FLUORESCENT PIGMENTS DIVERSITY ON UV INDUCED DAMAGES IN HERMATYPIC CORALS (Abstract ID: 28654)

Solar radiation includes both vital photosynthetic active radiation (PAR), and harmful ultra-violet radiation (UVR). Corals at the photic zone are exposed to UVR that induces different physiological damages including two abundant DNA lesions: cyclobutane pyrimidine dimers (CPDs) and 6-4 photoproducts (6–4PPs). Such DNA damage may lead to cell death and coral degradation. Coral reefs are known to poses a variety of fluorescent proteins (FPs), which are extensively used as visual markers in biomedical research, yet, their biological function is still poorly understood. Whereas it has been shown that FP production is influenced by light and, therefore, provides photoprotection against radiation (whether UVR or PAR), the role of fluorescence in preventing direct DNA damage has not yet been studied. In this study, different natural fluorescent morphs of the same coral species, coupled with translocation experiments and observations both in-situ and ex-situ were used in order to investigate the changes in coral fluorescence and UVR protection abilities. We characterized excitation and emission spectra of different FPs, quantified fluorescence levels, and analyzed UVR induced DNA damage in both host and algal symbiont. We found that the expression of fluorescence can change under different light regimes (either by photoconversion or expression levels) and that UVR induced DNA damage varies in relation to the coral's FP arsenal, thus, suggesting that a certain FP might give an advantage is UVR exposed environments.

SPATIAL AND TEMPORAL VARIATION IN NEAR-SHORE MARINE ASSEMBLAGES AROUND THE US VIRGIN ISLANDS (Abstract ID: 29392 | Poster ID: 315)

While many Caribbean marine habitats have degraded in recent decades due to Diadema outbreaks, excess nutrients, coral bleaching, overfishing etc., most attention has been given to larger off-shore reef habitats. However, coastal near-shore marginal habitats interspersed with corals can support high biodiversity including juveniles of many coral-reef species. These habitats are especially prone to human-caused degradation and often are the ones most visited by tourist and arguably are an equally important tourism asset and potential nursery. We report here on a study conducted in 2003/4 and followed up in 2013 on the benthic habitat cover at sites adjacent to St. John and St. Thomas, US Virgin Islands. With the help of Earthwatch volunteers, we enumerated rocky habitat cover types and distribution and size of benthic fishes and how this related to changes in coral and other live cover. Overall coral cover declined at all sites between 2004 and 2013 although there was minor recovery of some species (e.g. *Acorpora palmata*and *Millepora spp*.). Some fish species abundances seem to be tightly linked to changes in coral cover (for instance the three-spot damselfish *Stegastes planifrons* seemed to follow changes in *M. annularis* abundance among sites and through time). We will briefly touch on the costs and benefits of citizen science data acquisition and among site and across-decade trends in the above benthic characteristics.

PREVALENCE OF POACHING BY RECREATIONAL FISHERS IN THE GREAT BARRIER REEF MARINE PARK, AUSTRALIA (Abstract ID: 27795)

Though the Great Barrier Reef Marine Park is widely considered the best managed coral reef in the world, law enforcement records show a rapidly increasing trend in detected offences and non-compliance by recreational fishers. However, the actual level of illegal fishing by recreational fishers is currently unknown, as are the reasons for why recreational fishers poach (i.e. fish in no-fishing zones). Here, we estimate poaching by recreational fishers in no-fishing zones of the Great Barrier Reef Marine Park, Australia using a mixed methods approach. Specifically, we surveyed 265 fishermen and conducted 60 underwater visual censuses to quantify discarded fishing gear inside and outside no-fishing zones. Our study revealed three key results: 1) the level of non-compliance among fishers is between 3 and 18%; 2) poaching activities were often concentrated in poaching hotspots; and 3) the highest rated perceived motivations to poach were because fishing is better in no-take zones, and a low probability of detection. Thus, efforts to reduce poaching in no-fishing zones via the information deficit communication model (i.e. telling fishermen that green zones work) are unlikely to reduce poaching activities. Overall, our results indicate a rising trend of recreational fisher non-compliance that could threaten the efficacy of one of the world's best-managed marine protected areas.

POSITIVE SELECTION AND DIFFERENTIAL GENE EXPRESSION SUPPORT ECOLOGICAL SPECIATION BETWEEN THREE SYMPATRIC SPECIES OF GRUNTS (GENUS: HAEMULON) (Abstract ID: 28717)

Understanding the genomic basis of adaptation is essential for discerning how divergence takes place. This is particularly relevant for groups conformed by sympatric species that have broad geographic ranges. This is the case of the genus *Haemulon*, where five species pairs overlap in the Tropical Western Atlantic. Here we studied the transcriptomes of three closely related species of grunts: *H. carbonarium*, *H. flavolineatum* and *H. macrostomum*. Branch-sites models revealed over one hundred orthologs under strong positive selection, while gene expression assays identified 1258 differentially expressed genes between the three species. Moreover, 43 genes were found to be both under positive selection and differentially expressed. Major differences were found in genes related with signal transduction, metabolic pathways, gene regulation and reproductive traits. Positive selection was also found in the FGF1 gene, which is related with the development of the feeding apparatus in fishes. Considering that overlapping species of grunts are known to have dietary partitions, and that these correlate with differences in feeding structures, this study supports the case for ecological speciation in the genus *Haemulon*.

SPATIO-TEMPORAL CHANGES OF THE REEF COMPLEX OF PROVIDENCE ISLAND, COLOMBIAN CARIBBEAN: AN ASSESSMENT FROM THE SEASCAPE PERSPECTIVE (Abstract ID: 28117)

Changes in coral reefs composition, richness, and distribution are not easy to quantify in most reef systems. This is the case of the reef complex of Providence Island because the limited spatial and temporal coverage of the traditional monitoring programs do not allow observing changes at seascape level. We assessed those seascape units (SU) changes within this shallow reef complex by comparing two satellite images: Ikonos (2000) and Quickbird (2012). The SU were classified by an object oriented method, and validated using field points. We found that 90% of the SU became fragmented or transformed after 12 years, mainly in the west. The SU composition changed due to macroalgae and cyanobacteria dominance and the local extinction of corals. This led to an increase in SU richness, but with time spatial homogeneity will prevail. A decrease in the extension of the SU dominated by corals was evident: two SU with live coral cover >30% disappeared due to the death of Acropora and the increase of cyanobacteria. To the east and south, the SU were fragmented and transformed to other SU that had more macroalgae than calcifying organisms. These shifts led to a loss of 10.4% of coral reef area and 37.7% of live coral (3.2% annual mortality rate). The results show that the reef complex has deteriorated, losing its calcifying potential due to the replacement of live coral by macroalgae, cyanobacteria and dead coral. This will lead to a decrease in coral accretion, biodiversity and ecosystem services. Satellite analysis gives us a better tool to understand the magnitude of reef changes.

GENOMIC SIGNATURES OF PRE-ADAPTATION AND POST-INVASION RAPID ADAPTIVE EVOLUTION IN THE BLUESPOTTED CORNETFISH, A MEDITERRANEAN LESSEPSIAN INVADER (Abstract ID: 29913)

Biological invasions are increasingly creating ecological and economical disasters both on land and in aquatic environments. For over a century, the Mediterranean Sea has steadily been invaded by Red Sea species (called Lessepsian invaders) via the Suez Canal, with a current estimate of approximately 450 species. The bluespotted cornetfish, *Fistularia commersonii*, considered a "Lessepsian sprinter", entered the Mediterranean in 2000, and by 2005 had invaded the entire basin from Israel to Spain. The situation is unique and interesting both because of its unprecedented rapidity, and by the fact that it took this species approximately 130 years to migrate from the Red Sea into the Mediterranean. Using genome scans, with restriction site associated DNA (RAD) sequencing, we evaluated neutral and selected genomic regions for Mediterranean vs. Red Sea cornetfish individuals. We found that little neutral changes were detectable among populations.

However, almost half of the genes associated with the 47 loci under selection were related to disease resistance and osmoregulation. Due to the short time elapsed from the beginning of the invasion to our sampling, we interpret these changes as signatures of pre-adaptation, where Red Sea individuals that carried those traits were primed to successfully invade the Mediterranean. Such genomic regions are therefore good candidates to further study their role in invasion success.

MORPHOMETRIC AND GENETIC DIFFERENTIATION OF ACANTHOCHROMIS POLYACANTHUS IN THE PHILIPPINES (Abstract ID: 29240 | Poster ID: 187)

Acanthochromis polyacanthus (spiny damselfish) is a model organism in dispersal for its lack of pelagic larval stage. Performance differences have been attributed to divergence in morphological traits among population. Genetic analyses have also documented the differentiation in Acanthochromis polyacanthus across color morphs and within color morphs from different populations in Australia. In this study, we explored the morphometric and genetic differentiation of spiny damselfish in the Philippines. Principal component and multivariate analysis of variance at 20 landmark points were evaluated for 160 individuals from Davao del Norte, Davao Oriental, Sarangani, and Batangas. Geometric morphometrics by generalized procrustes analysis revealed morphological disparities among populations. Genetic analysis of the COI gene from a subset of 73 individuals also reveals variation across the 4 populations. Our results suggest that Acanthochromis polyacanthus in the Philippines can be differentiated per population. The absence of pelagic larval stage may have attributed to the significant morphological and genetic differences among populations. However, since there is no obvious mechanism for dispersal for this species, whether this divergence is a result of a plastic response to environment or genetic adaptation remains a mystery. Keywords: Acanthochromis polyacanthus, morphometrics, COI gene

EFFECTS OF UNBURNT COAL DUST ON A CORAL, REEF FISH, AND SEAGRASS SPECIES (Abstract ID: 29570 | Poster ID: 466)

Thousands of coal loaded vessels, carrying up to 150,000 t of coal regularly transit through coral reef ecosystems in Australasia, the Indo-Pacific and Caribbean regions each year. Coal particles and dust are physically abrasive, block light penetration into the water column and contain potentially toxic hydrocarbons and trace metals. Consequently, reef organisms such as corals, can be at risk from suspended and deposited coal particles that might result from ship loading or spill events. Despite this risk, the effects of suspended and deposited coal on tropical marine organisms of high conservation value remains largely unknown. This study conducted a series of controlled experiments exposing three taxa abundant in tropical marine ecosystems (the coral *Acropora tenuis*, the reef fish *Acanthochromis polyacanthus*, and the seagrass *Halodule uninervis*) to a range of suspended coal dust (< 63 µm) concentrations (0-275 mg/L) over 28 d. Results demonstrate that chronic coal exposure can cause considerable lethal effects on corals, and reductions in seagrass and fish growth rates. Coral survivorship and seagrass growth rates were inversely related to increasing coal concentrations (≥ 38 mg/L) and effects increased between 14 and 28 d, whereas fish growth rates were similarly depressed at all coal concentrations tested. This investigation provides novel insights into direct coal impacts on key tropical taxa for application in the assessment of risks posed by increasing coal shipments in globally threatened marine ecosystems.

WHY DOES THE RED SEA REGION HAVE SO MANY ENDEMIC SPECIES? AN EVOLUTIONARY AND ECOLOGICAL CONNECTIVITY PERSPECTIVE (Abstract ID: 29725)

The Red Sea and seas of the Arabian region represent a unique environment with strong latitudinal gradients in water temperature, salinity, and nutrient load that may act as ecological barriers to larval dispersal and the eventual settlement of marine fauna. We conducted broad-scale surveys of reef organisms employing modern taxonomic (i.e., integrated molecular and morphological studies) and phylogeographic approaches at multiple sites throughout the region. This presentation will explore which groups of reef-associated animals have high levels of endemism in the region. Establishing patterns of biodiversity and biogeography in the Arabian region is one of the first steps towards understanding the underlying drivers of adaptation to the unique Arabian environments. For some taxonomic groups, we have also explored genetic and genomic patterns to help understand how the distributions of these organisms originated, how the distributions are maintained, and the capacity that various population have for adaptation to continued global change. The findings also shed light on ecological and evolutionary connectivity patterns. Future work will integrate local larval dispersal observations, species distributions, genetic data, and large-scale oceanographic models to further understand the role of the Red Sea in the general context of Indo-Pacific biogeography.

LETHAL AND SUB-LETHAL IMPACTS OF DREDGE RELATED STRESSORS ON CORALS (Abstract ID: 28529)

The impacts of sediments on coral reefs are under intense scrutiny, with increased coastal development globally. Numerous dredging operations have facilitated this development and can generate large quantities of suspended sediments that can affect nearby coral populations. Sediments released into the water column result in three proximal stressors to corals; firstly the suspended sediment can clog filter feeding apparatus, secondly it attenuates light, reducing levels available for photosynthesis, and lastly it may fall out of suspension and smother corals. In order to appropriately manage the impacts of dredging-related stressors on corals, cause-effect pathways followed by dose-response relationships need to be determined. A series of experiments were conducted to partition the impacts of suspended sediment and light attenuation on coral, and then determine low light thresholds for corals. These experiments have provided insight into the impacts on a suite of health indicators including mortality, colour, chlorophyll fluorescence, respiration rates, along with chlorophyll and lipid concentrations, providing information on both lethal and sub-lethal impacts. These experiments have determined that light is the major stressor on coral health rather than suspended solids, and that extended periods of reduced light are detrimental to coral health for both adults and juveniles. These results demonstrate that, excluding sediment deposition, measuring light levels is an effective way to monitor the stress on reef corals during dredging projects.

HORMONAL TRIGGERING OF CORAL REEF FISH METAMORPHOSIS (Abstract ID: 29992)

In coral reef fish, the larva to juvenile transition occurring while recruits colonize the reefs has been acknowledged as a metamorphosis for more than 70 years. Indeed, this shift from pelagic to benthic life is accompanied by major changes suited to the new reef environment. However, physiological and hormonal processes that could occur and trigger this transition remain unknown in coral reef fish. Here, we hypothesized that thyroid hormones (TH) are triggering coral reef fish metamorphosis, as evidenced in temperate and commercial fish species like flatfishes and sea breams. By capturing larvae at their arrival into the reefs of Moorea, French Polynesia, we observed a TH peak at metamorphosis in a surgeonfish, Acanthurus triostegus, and a batfish, Platax orbicularis. We also showed a TH decrease in 3 other species from different families, suggesting that their TH peak may occur before reaching the reefs. In A. triostegus, neuromast development and guts lengthening were observed along metamorphosis. Daily hormonal treatments on A. triostegus recruits exhibited that enhancing the TH pathway leads to both early neuromast development and early gut lengthening, while interrupting this pathway leads to delays in these changes. Overall, these results suggest that coral reef fish metamorphosis seems to be a classical TH-triggered metamorphosis. Knowing the ability of pollutions like pesticides to disrupt such endocrinal processes, it is of great interest to better characterize this metamorphosis facing global change and its importance in larval recruitment.

COLLATERAL DAMAGES OF THE CORALLIVOROUS GASTROPOD DRUPELLA CORNUS ON CORAL MICROBIAL ASSOCIATES (Abstract ID: 28573 | Poster ID: 147)

The grazing activity by specific marine organisms represents a growing threat to the survival of many scleractinian species. For example, the recent proliferation of the corallivorous gastropod Drupella cornus now constitutes a critical case in all South East Asian waters. If the damaging effects caused by this marine snail on coral polyps are relatively well known, the incidence of grazing on coral microbial associates might also potentially impair the defense mechanisms and nutritive properties of their bacterial and viral epibionts. In this study, we tentatively compared the main ecological traits of coral-associated bacterial and viral communities living in the mucus layer of Acropora formosa and Acropora palmata, between healthy and predated individuals (ie colonized by D. cornus), in the Bay of Nha Trang (Vietnam). Although some samples are still under analysis, preliminary results seem to show a substantial impact of the presence of the gastropod on a variety of ecological markers (abundance, diversity, respiration, metabolic capacity, life strategy, etc.) for both viral and bacterial communities, whatever the species considered. Finally, our results suggest that predation, beyond its direct deleterious mechanical effects to corals, might be also able to cause significant alterations in their symbiotic microbiota, which may subsequently promote the emergence of opportunistic pathogenic infections.

INVESTIGATING ACUTE *MONTIPORA* WHITE SYNDROME: POTENTIAL CAUSATIVE AGENTS, ENVIRONMENTAL DRIVERS, AND THE IMPORTANCE OF CORAL HEALTH (Abstract ID: 28131 | Poster ID: 153)

Disease is a threat to coral reefs and exacerbates the widespread impacts of climate change. Moreover, environmental stressors can increase prevalence of coral diseases. Outbreaks of the tissue loss disease acute *Montipora* white syndrome (aMWS) have occurred in *Montipora capitata*, a major reef-building coral in Kaneohe Bay, Hawaii, which may have been triggered by sewage runoff associated with rainfall and pre-existing stress from a chronic tissue loss disease (cMWS). One of the potential etiological agents of aMWS is *Pseudoalteromonas* sp. OCN003, a strain isolated from diseased *M. capitata*. Under controlled conditions, 20% of the healthy fragments exposed to OCN003 developed acute tissue loss within 3 weeks post-inoculation. When fragments already compromised by cMWS were exposed to OCN003, 60% of the fragments switched to acute tissue loss within 4 days post-exposure. Thus, OCN003 is more successful as a secondary pathogen in laboratory experiments. Infections of cMWS are observed year-round, while aMWS outbreaks have only occurred during the rainy winter months. Bacterial communities of samples from healthy and diseased *M. capitata*during an aMWS outbreak were analyzed with high-throughput sequencing. Sequences from the family Enterobacteriaceae dominated all samples, which were similar to species that inhabit the human gastrointestinal tract, suggesting sewage and/or freshwater input. This study describes the first*Pseudoalteromonas* sp. pathogenic to coral and possible bacterial communities consistent with anthropogenic stressors associated with a fatal coral disease.

SHIPPING AND MARINE PILOTAGE: ARE THERE SUFFICIENT SYSTEMS IN PLACE TO PROTECT VULNERABLE MARINE ECOSYSTEMS? (Abstract ID: 29946)

Like other vulnerable marine ecosystems, many coral reefs are situated in areas adjacent to busy shipping routes and ports. High risk-industries, including those carrying risks to the marine environment such as oil extraction and shipping, require many layered controls in place in order to prevent catastrophic accidents. Accidents can cause widespread environmental damage, as well as economic costs and loss of human life. We still do not fully appreciate the long-term impacts of catastrophes such as the grounding of the Exxon Valdez in Alaska, and the Deepwater Horizon oil spill in the Gulf of Mexico. One risk control employed by the shipping industry is marine pilotage – the utilization of an experienced mariner familiar with a local area to direct itinerant foreign or unfamiliar vessel's crew through the hazardous and dynamic environments of ports, coastlines, and reefs. The organization and engagement of marine pilots varies at national and international levels, influenced by many factors including regulatory frameworks and legislation. Here we present the usage of coastal pilots in the Great Barrier Reef for the central benefit of shipping safety and environmental protection. With projected growth in shipping traffic, we discuss strengths and limitations of the current system. Catastrophic accidents in sensitive marine areas can have severe and lasting impacts, thus a zero-accident goal requires a different approach to more conventional risk or exposure management.

WHICH FACTORS DRIVE CORAL REEF FISHERIES: ECONOMICS, ENVIRONMENT OR RANDOMNESS? (Abstract ID: 28104 | Poster ID: 265)

Coral reef environments support a significant proportion of commercial fishing activities, and are very important for the small-scale sector. These fisheries are essential for income generation and food security of millions of people. Importantly, the targeted reef species are associated with higher market values when compared to fishing resources in other habitats. In addition, this resource are easy to access, making them less costly to catch. Hence, the main goal of this study is to identify the main drivers of reef fisheries for the small-scale sector. This knowledge is useful for developing effective management plans that can economically benefit the fishers while ensuring the sustainability fish and fisheries. A time series of landing data was used jointly with ex vessel price data and environmental variables to conduct our analysis. Multivariate and Bayesian analysis are performed to evaluate the possible association between species habitat and economic factors. Specifically, we investigated the link between the temporal variation of important commercial reef fish abundance, their ex vessel fish price and the associated environmental characteristics of the coral habitats. If it turns out that coral reef fisheries are driven mainly by economic factors, managers will be able to choose a management instruments, for instance, the use of seasonal closure carefully. On the other hand, if environmental factors were more important, then climate change mitigation, for instance, will become a bigger issue for managers' to deal with in order to better protect reef fish supply.

PERCEPTIONS IN SMALL ISLAND MARINE RESOURCE MANAGEMENT (Abstract ID: 28003 | Poster ID: 594)

Transformation to sustainable lifestyles demands integrative, inter- and transdisciplinary approaches of science and stakeholder engagement. In these processes perceptions, values and social norms play key roles in shaping behavioural outcomes. Often, environmental degradation and its far reaching impacts are consequences of human behaviour such as environmental pollution and resource overuse. Understanding collective human behaviour is thereby key for tackling global challenges. Taking the example of community- based marine resource management (CBMRM), this paper combines ecological and psychological views on the challenges of participatory processes and calls for an explicit integration of behavioural science expertise in transformational endeavours. Societies and ecosystems do not change independently from each other, hence, a truly transdisciplinary and workable approach is necessary whenever human beings aim at sustainable interactions with ecosystems. This paper dissects factors that affect stakeholder perceptions, pathways and interpretations of information, and how these shape social norms, and translate into behaviour. In making these factors explicit, we aim for a workable approach for people working in sustainable resource use and management.

MITIGATION OF THERMAL AND LIGHT STRESSERS ON A MAURITIAN REEF BY TROPICAL CYCLONIC CONDITIONS (Abstract ID: 29532)

Coral reef ecosystems are threatened due to global warming leading to widespread coral bleaching. This study examined coral bleaching over 3 months (November to January) during 3 years (2010-2013) in the dominant coral species, *Acropora muricata*, within the coral reefs of Belle Mare, Mauritius in the South Indian Ocean at a finer scale including three zones, namely near the coast (Z1), in the middle of the lagoon (Z2) and on the reef flat (Z3). Data loggers were deployed next to the monitored coral colonies to record *in situ* temperature and light levels. For the periods November 2010 – January 2011 and November 2011 – January 2012, higher prevalence of temperatures above 30°C and 31°C occurred at Z1 than Z2 and Z3. However, bleaching occurrence was reversed, i.e., *A. muricata* colonies did not bleach at Z1 but bleached, starting in November, at Z2 and Z3. During November 2012 and January 2013, temperature and light recordings were lower and almost no coral bleaching occurred compared to the previous two years. Tropical cyclonic conditions in the vicinity of Mauritius included only two tropical disturbances occurred in January 2011, three cyclones occurred between December 2011 and January 2012, and five cyclones, passing closer to Mauritius, occurred between October 2012 and January 2013. These findings indicate that increased frequency of tropical cyclonic conditions coinciding with the beginning of coral bleaching occurrence period mitigate thermal and irradiance stresses, and reduce bleaching effects on coral reefs.

SOCIO-ECONOMIC IMPACTS OF EXPANDED HABITAT PROTECTION IN PULLEY RIDGE, FLORIDA GULF COAST (Abstract ID: 29666)

The Gulf of Mexico Fisheries Management Council designated Pulley Ridge as a HAPC in 2005. Although Pulley Ridge is in relatively intact ecological condition, its rarity and connectivity with the broader marine area lead agencies to believe that its protection is necessary. A small portion of the Pulley Ridge is banned for bottom trawling, but the agency is considering expanding its reach. The commercial fishers are extremely sensitive to new or additional management actions as some of them are still recovering from the Florida Keys sanctuary regulations of the 1990s. This paper is an attempt to understand how the additional HAPC designations may influence commercial fishers by analyzing their perceptions towards the new regulation, current harvests, and their economic connections with different coastal zones of the Florida Gulf coast. A survey of 50 commercial fishers is conducted. The secondary data on species-wise and vessel-wise catches, and their flow to various port destinations are analyzed. The economic impacts that the reductions in fish catch in the Pulley Ridge have on various economic sectors of the region are also analyzed using a regional input-output model. The results indicate that the HAPC expansion in Pulley Ridge will have some negative impacts on a couple of fishing destinations in the Florida Gulf coast. However, the real management challenge emanates from the negative experience the stakeholders suffered during the past regulations. Efforts toward educating them about the long-term benefits of the current HAPC is therefore essential.

INFLUENCE OF TEMPERATURE VARIATION ON QUORUM SENSING SIGNAL PRODUCTION BY BLACK BAND DISEASE HETEROTROPHIC BACTERIA (Abstract ID: 29578)

Black band disease (BBD), one of the most aggressive and complex coral diseases, is comprised of four functional groups of bacteria (photoautotrophs, sulfide oxidizers, sulfate reducers and heterotrophs) causing disease progression. The heterotrophs have been shown to produce quorum sensing (QS) signal molecules, comprising of acyl homoserine lactones (AHLs) known to be involved in pathogenesis of numerous bacterial diseases worldwide. BBD infects corals when sea water temperature exceeds 28°C. Hence the primary goal of this research was to examine the effect of temperature on AHLs produced by heterotrophs from BBD to assess a potential role of QS in BBD pathogenesis. 156 bacterial isolates from BBD, 38 from surface mucopolysaccharide layer (SML) of healthy corals (HSML), and 36 from healthy SML of BBD infected corals (BSML) were tested for production of AHLs by a reporter strain bioassay. 24 QS positive heterotrophs were further exposed to varying temperatures (24°, 27°, 30° C) to determine the role of temperature on AHLs using LC-MS/MS. Out of eight AHLs that were discovered, 3OHC4 was the most abundant AHL (produced by 17 of 24 isolates), shadowed by C6 (13 out of 24 isolates). Statistical analysis showed a species specific AHL variation profile, and that 3OHC4, 3OHC5 and 3OHC6 were most significantly affected. Influence of temperature variation was more significant on a global level than on an individual species level for specific AHLs. 16S rRNA gene sequencing revealed that most of the QS positive isolates were vibrios. The results from this research will assist in decrypting the mechanism and etiology of one of the most destructive and intricate coral diseases.

ARE WE APPROACHING A LIMIT OF RESILIENCE TO REPEAT BLEACHING OF CORAL COMMUNITIES IN MAYOTTE, SW INDIAN OCEAN? (Abstract ID: 29252)

The island of Mayotte is in the core of a high marine biodiversity center for the Indian Ocean, bathed by an intermittent gyre and dynamic meso-scale eddies that result in high variability of water conditions, but within a relatively narrow temperature band. High levels of coral bleaching on the island have been documented 3 times (1983, 1998 & 2010) and a fourth is imminent in 2016. The 2010 bleaching event was severe (SST at +0.59C), affecting 52% of corals, with a final mortality estimated at 32%. Bleaching was strongly zone-dependent, with the hottest regions in the north suffering significantly higher bleaching and mortality than cooler regions in the south. Acropora was the dominant genus, and dominated the bleaching response, followed by Pocillopora, Montipora and Porites. Bleaching and mortality were strongly size-dependent, with larger colonies more susceptible than smaller ones. The 2016 bleaching event is expected to be severe (SST predicted at +0.84C), though the absence of bleaching in 2014 and 2015, which were also record hot years equivalent to 1998, suggest some adaptation and acclimation has occurred. Data will be collected using the same methods as in 2010, using 25*1 m belt transects to record the condition of all hard corals (genus, size and degree of bleaching, mortality and disease). We will focus on genus, size and region influences on bleaching and mortality, and differences between the 2010 and 2016 events that may indicate adaptation to increasing temperatures or the increasingly frequent major bleaching events affecting Mayotte.

FROM MONITORING TO COMMUNITY-BASED MANAGEMENT: RESULTS FROM THE 'OPIHI PARTNERSHIP (Abstract ID: 29886)

The 'Opihi Partnership, composed of community, academic, governmental and non-governmental organizations, was constructed under a paradigm where all stakeholders are equal. The stakeholder members seek to understand and ultimately see the replenishment of the highly sought after endemic limpets. There are several reasons for the success and longevity of the 'OP: incorporation of indigenous and western sciences, long-term commitments from partners, each partner benefits from membership, and yearly trips by members to Papahānaumokuākea Marine National Monument are but a few. The 'OP started with the modest goal of counting 'opihi. This effort spawned numerous outreach and educational events, a mountain of data, and ultimately, action. Due in part to their experiences in the 'OP, members have moved toward actively managing not only their 'opihi, but a plethora of marine resources. Here we present a summary of results and successes of the 'Opihi Partnership. We further describe how the 'OP model can be generalized to the reef ecosystem level.

A FUNCTIONAL ANALYSIS OF ALGAL ASSEMBLAGES ON THE GREAT BARRIER REEF TO ESTIMATE EFFECTS ON CORAL COMMUNITY DYNAMICS. (Abstract ID: 28402)

We combine knowledge of macroalgal functional traits with abundance data from 960 surveys of macroalgae on the Great Barrier Reef in a novel approach to assess effects of macroalgal assemblages on coral community dynamics. Cluster analysis of the survey data identified 75 key macroalgal genera that contributed to 13 repeatedly observed macroalgal assemblages. For these 75 genera we estimated the strengths of 24 traits likely to influence corals. Traits were selected for relevance to: the potential for an

assemblage to establish; competitive impacts on corals; impacts on coral recruitment; potential to modify habitat; influence on stability of a macroalgal bloom. We combined the abundance of genera present in each assemblage with the trait dataset to estimate the effects of each macroalgal assemblage. Measures of functional diversity and community weighted mean were used to estimate the likely ecological effects of each of the 13 Great Barrier Reef macroalgal assemblages. In this way we combined data from field surveys with the predictive strength of trait analysis to estimate likely community trends. We suggest that benthic surveys which pay attention to localized macroalgal traits can provide insight to future community interactions, impacts to coral recruitment, trends in abundance of macroalgae and stability of macroalgal blooms, thus can provide valuable guidance to management decisions.

RESPONSES OF TWO SCLERACTINIAN CORALS TO METAL POLLUTION AND OCEAN ACIDIFICATION (Abstract ID: 29880)

Metal pollution affects many reefs worldwide and while the effects of ocean acidification alone or in combination with warming on coral metabolism have been extensively investigated, none of these studies consider that corals might be already affected by other anthropogenic inputs, such as metal pollution. Here we tested in laboratory conditions the combined effect of ocean acidification and cobalt concentrations on two corals: *Stylophora pistillata* and *Acropora muricata*. Two pH levels (8.02 and 7.75) and two cobalt concentrations (natural, 0.03 µg $L^{-1}$ and polluted, 0.2 µg $L^{-1}$) were tested during five weeks in aquaria. For both species, cobalt input decreased significantly their growth rates by 28%, while it stimulated their photosystem II. By contrast, low pH did not affect their growth rates. The effect of higher cobalt concentrations (1.06±0.16 µg $L^{-1}$) on *A. muricata* was also measured *in situ* using benthic chamber experiments. At this concentration, cobalt decreased both coral growth and photosynthetic rates. Even if no interaction between pH and cobalt concentration have been revealed in our study, it is likely that coral colonies, for which growth rates decrease when submitted to a moderate cobalt input, will be weakened if they are subjected to additional threats (i.e temperature, other metal pollution). To confirm or cancel these conclusions, additional benthic chamber experiments have been performed on the same coral species to test the impacts of realistic nickel inputs.

BOLSTERED PHYSICAL DEFENSES UNDER NUTRIENT ENRICHED CONDITIONS MAY FACILITATE A MACROALGAL SPECIES IN THE SOUTH PACIFIC (Abstract ID: 28962 | Poster ID: 280)

Human manipulations of top-down and bottom-up processes, through nutrient enrichment and overfishing, on coral reefs can cause a shift from dominance by corals to macroalgae. Turbinaria ornata, a brown macroalga, is rapidly expanding in range and habitat across the South Pacific, but the relative importance of nutrient input and herbivory pressure, or an interaction between the two, in controlling its accumulation is previously unknown. Therefore, we investigated the impact of nutrients and herbivory on Turbinaria ornata. We conducted: 1) a mesocosm experiment assessing relative nutrient limitation, 2) a field experiment comparing importance of nutrients (+/-) and herbivory (+/-) to biomass accumulation, and 3) an herbivory assay and toughness test comparing enriched and ambient thalli to assess changes to anti-herbivory defenses. We found no evidence of growth being nutrient limited in T. ornata; rather than stimulating growth, nutrient addition deterred herbivores. However, when physical structure was removed, enriched algae were preferred, with consumption rates 25-fold those of unenriched algae. Additionally, enriched thalli were tougher than ambient thalli, suggesting physical defenses were bolstered by nutrient enrichment. We found a unique interaction where nutrients inhibit herbivory and facilitate T. ornata biomass accumulation. This has important consequences to coral reefs, as nutrient enrichment may allow T. ornata to become more prevalent on reefs in areas where it was once controlled by herbivory, possibly at the expense of coral species.

THE SEA ANEMONE *EXAIPTASIA* AS A MODEL FOR CORAL MICROBIOME STUDIES (Abstract ID: 27935)

A plethora of human diseases and much of human physiology have been elucidated by studies using animal models. So too knowledge of scleractinian corals, in particular the role of *Symbiodinium*, has been advanced by studies with the coral model *Exaiptasia*. Other models could include the close scleractinian relative the Corallimorpharia and scleractinian coral cell cultures. All models are symbioses between an animal and a dinoflagellate (*Symbiodinium*), but there are numerous distinguishing attributes which allow the researcher to select one model over the others. For example, *Exaiptasia* can occur in the aposymbiotic state which is appealing when attempting to reveal the role of *Symbiodinium* in coral phenotypes. *Exaiptasia* and Corallimorpharia have several traits in common like relative ease of lab culture, ability to obtain a large number of clonal polyps, demonstration of both sexual and asexual reproduction and formation of stable symbioses with a range of *Symbiodinium* species. However, there is much more information on the biology and ecology and prolific genomic and proteomic data on *Exaiptasia* compared to Corallimorpharia. Apart from assessments of coral bacterial pathogens, coral models have seldom been used in coral fungal, prokaryote or viral studies. To address this paucity, we have grown Great Barrier Reef sourced *Exaiptasia*for 12 months in the laboratory. We will report its identity, the *Symbiodinium*types it harbours and features of its prokaryotic microbiome.

CORALME: A MODERN SYSTEM FOR TIME-EFFICIENT DETAILED ANNOTATION OF LARGE CORAL REEF IMAGE DATASETS IN AN OPERATIONAL SETTING (Abstract ID: 29697)

CoralMe is a collaborative open-source system dedicated to underwater coral reef image annotation, with an emphasis on interactive and time efficient segmentation and recognition techniques. The primary objective of the library is to connect ecological monitoring initiatives with cutting-edge computer vision techniques through a lightweight, extensible, interoperable and robust system. Our contribution is twofold. First, CoralMe offers a set of basic functionalities focused on automation that can be used in a number of way, such as providing an enhanced user experience to speed up the task of manual annotation, or to build a fully automated coral recognition model using existing data. Second, CoralMe's functionalities can be extended to support new algorithms with little effort, rendering technological advances made by the computer vision community readily available to marine ecology efforts. This is made possible by its architecture consisting in a MATLAB backend service easily extensible by computer vision researchers, as well as a front-end API that makes use of the standard JSON-RPC communication protocol to allow CoralMe's integration to any existing software. CoralMe bridges the gap between expert annotation and computer vision engineers, contributing to faster development of reliable and precise measurement of coral resilience.

BRYODIVERSITY IN REEFAL ENVIRONMENTS - WHAT CAN WE EXPECT THE FUTURE TO HOLD? (Abstract ID: 28809)

The Phylum Bryozoa has been given inadequate attention in the tropical habitats, including the reefal zones. Any estimates of biodiversity for this phylum are quite inadequate at present, by comparison with the more spectacular groups. The reasons for this knowledge gap include: the lack of discrimination of similar forms using optical microscopy; the difficulty of field sampling of the most diverse habitats within the reef ecosystem and the poor geographic spread of detailed sampling campaigns. Historical studies which enthusiastically aggregated large synonymies have made biogeographic analysis practically impossible at present. It would be desirable to estimate the biodiversity for bryozoans from each of the regions of coral-reef habitats, and to include similar estimates for adjacent shelf and deeper-water environments. However, several drawbacks make current estimates premature. In particular, sampling by SCUBA of rubble-encrusting species has rarely been attempted. Important studies based upon major sampling programs have provided monographs; however the taxonomic work is in need of modern revision using scanning electron microscopic methods. Estimates of bryozoan diversity derived from extrapolation from detailed sampling at extremely few sites suggest that locations may be host to up to about 200 species. Wider regions possibly attain up to 500 species. Tropical reef environments world-wide potentially encompass 2000 to 4000 species, at least double what is known at present.

WHEN MISMATCHES DON'T MATTER: THE EFFECTS OF DIVERGENT ECOLOGICAL AND ECONOMIC SCALES IN COASTAL FISHERIES. (Abstract ID: 28968)

Conservation management decisions are often implemented at the scale of human communities, rather than the scale of the most relevant ecological dynamics. Research frequently points out the loss in efficiency that results from such scale mismatches. However, the scale of management is influenced by social, economic and political constraints on management actors; by the higher implementation costs of spatially-variable management plans; and by the independent behaviour of actors. While it is clear that objectives can be better achieved if management and ecological scales are aligned, it is not clear whether such benefits are large enough to justify the costs of alignment, or how alignment can be achieved in multi-actor contexts. On Manus Island in Papua New Guinea, small customary tenure areas define the scale of harvest decisions, but the populations in each area are demographically connected by pelagic larval dispersal. Using genetic parentage analysis, we quantify the extent of this scale mismatch for the commercially valuable serranid P. areolatus. Game-theoretic analyses show that the scale and strength of dispersal should disincentivise sustainable harvesting behaviour, since dispersal allows individual communities to externalise the costs of overharvesting to adjacent communities. Despite these mismatched scales, communities in southern Manus have created a tribal network for management and negotiation, emphasising the importance of social capital in avoiding suboptimal outcomes or the need for top-down governance.

INNOVATIONS AND ADVANCEMENTS OF FISHERY-INDEPENDENT, VISUAL MONITORING OF CORAL REEF FISHES FOR ECOSYSTEM-BASED MANAGEMENT (Abstract ID: 29612 | Poster ID: 578)

Reef management requires detecting population change and the effectiveness of management intervention at small and large spatial scales. Innovations in 36 yr advanced non-destructive, diver-based visual monitoring of Florida reef fishes to support ecosystem and length-based assessments. Shifting from an experimental design to a random stratified survey allowed expanded coverage to the entire Florida shallow water (<30m) reef track (1081 km2). Circular plots efficiently provided habitat data and species composition, abundance, size structure, and habitat distributions for ~275 observed exploited and non-exploited reef-associated fish species. Improved digital benthic maps facilitated defining habitat strata and quantification of georeferenced sample units and domains. NITROX SCUBA increased bottom time and GPS navigation ensured precise sample location. Sampling was optimized by a two-stage, stratification based on depth, habitat type, management zone, and region. Advances include standard habitat classification based on habitat patchiness and relief, optimization based on sample variance of 5 exploited fishes in 4 families, and use of mean exploited length for sustainability. Iterative analyses of past data refined stratifications and future sample allocation for increased efficiency and precision. Adopting a single standard method by multiple institutions allowed pooling of limited resources to achieve wide geographic coverage and ecosystem-level assessments of change within and outside MPAs, and influences of hurricane disturbance, fishery regulations, and invasive fish.

UNDERSTANDING THE INDO-PACIFIC BIODIVERSITY GRADIENT THROUGH COMPARATIVE PHYLOGEOGRAPHY OF BRITTLESTARS (Abstract ID: 28314)

Understanding the mechanisms underlying biodiversity patterns is of crucial importance in evolutionary and conservation biology. Here, we analyzed 15 widespread Indo-Pacific brittlestar species using mitochondrial and nuclear sequences, and microsatellite markers, to investigate the origin and evolution of biodiversity in the Indo-Pacific coral reefs, with a focus on the effects of past climate changes on population demography and speciation dynamics. Using Bayesian dating, Bayesian skyline plots, tests of simultaneous divergence and expansion, and recent approaches of scenario testing, we revealed numerous cryptic speciation events, an evolutionary hotspot in the South western Indian Ocean, shared demographic responses to past events among species, and connectivity patterns across the distinct Indo-Pacific biogeographic provinces. These results helped pinpointing areas of evolutionary importance and past glacial refuges and overall, shed light on the effects of past climate fluctuations on these reef organisms' population dynamics.

COMPARING MESOPHOTIC AND EUPHOTIC REEF FISH SIZE, FEEDING GUILD COMPOSITION, DIVERSITY AND ENDEMISM IN THE AU'AU CHANNEL, HAWAII. (Abstract ID: 27973)

Mesophotic reefs (30-150m) are understudied habitats. Little is known about the fish assemblages that occur at mesophotic depths and this dearth of information limits the ability to understand and manage potential resources. Mesophotic reef assemblages in the Au'au Channel between the islands of Maui and Lanai in the Hawaiian Islands were compared with neighboring euphotic reef fish assemblages surveyed during 2007-2011. Using three different survey methods for the mesophotic and one method for the euphotic, approximately 7,000 mesophotic and 800 euphotic fish individuals were identified and their standard length estimated. In general, mesophotic fish were greater in both body length (12.5 cm versus 7.0 cm) and mass (233 g versus 86 g). Fish in five of seven feeding guilds were larger on the mesophotic reef although planktivores were larger on euphotic reefs. Mesophotic fish assemblages had greater species richness (92 versus 66 species) and endemism, but euphotic fish assemblages were more diverse (Simpson's Index of Diversity: 0.93 versus 0.86).

QUANTIFYING CHEMICAL CHANGES IN THE "HEARTBEAT" OF A CORAL REEF ON TETIAROA ATOLL, FRENCH POLYNESIA (Abstract ID: 29577 | Poster ID: 240)

Anthropogenic carbon emissions have increased the threat of ocean acidification in coral reef ecosystems and could translate to crippling losses in marine biodiversity and other coastal ecosystem services. The ability to decode the complex and dynamic biogeochemical signal of ocean acidification in reef environments will dramatically increase our ability to identify the early signs of reef dissolution and manage the impacts of ocean acidification in reef ecosystems. To capture the fine temporal changes in reef chemistry that result from increasing ocean acidification, we have created a reef observation network on Tetiaroa Atoll, French Polynesia. Limited human impacts on this location make it an ideal setting for investigations of acidification on a pristine and mature reef environment. Our experiments feature instruments that monitor seawater pH, dissolved oxygen, and salinity at 15-minute intervals. We also conducted a series of 24-hr to 48-hr experiments to capture hourly variability in reef alkalinity, dissolved inorganic carbon, and nutrients. Preliminary analyses reveal a reproducible daily pattern in which oxygen and pH diverge in the early evening, suggesting a pulse of reef dissolution during this time. This phenomenon implies that certain portions of the reef may be more susceptible to dissolution and degradation than others. We aim to continue quantitative decomposition of our rich biogeochemical dataset collected over the last two years. The ultimate aim is to quantify the rate of atoll growth or decline in the context of increasing ocean acidification.

PHOTOCONVERTIBLE CORAL FLUORESCENT PROTEINS: AN ADAPTATION TO THE LIGHT CLIMATE AT MESOPHOTIC DEPTHS? (Abstract ID: 28591)

The high-level expression of green fluorescent protein (GFP)-like pigments in mesophotic corals suggests an important biological function for this protein group other than the photoprotective role assigned to their homologues in shallow water cnidarians. Photoconvertible fluorescent proteins (PCFPs), which undergo a green-to-red spectral shift upon ultraviolet (UV) irradiation, are commonly found in mesophotic and depth generalist species, thus providing an opportunity to investigate alternative functions. Due to rapid attenuation of UV by the water column it is unknown, however, whether photoconversion can occur throughout the depth range of PCFP-containing corals. To assess the feasibility of PCFPs as an adaptation to the mesophotic light field, we investigated the spectral dependence of photoconversion both*in vivo* and *in vitro*. Exposing live coral colonies to different light spectra in a mesocosm experiment showed that photoconversion depends entirely on the presence of near-UV wavelengths. Using field irradiance

data from the Red Sea, we showed that photoconversion of purified proteins can occur down to mesophotic depths and is thus feasible as a deep-water adaptation. These findings provide new insights into the biology and ecology of mesophotic corals, as well as the function and regulation of coral fluorescent proteins.

VERTICAL CONNECTIVITY ON ATLANTIC AND PACIFIC REEFS: A GENOME-WIDE ASSESSMENT OF SIX DEPTH-GENERALIST CORAL SPECIES (Abstract ID: 29091)

Mesophotic coral ecosystems can act as important refuges against disturbances affecting shallow reefs. Consequently, they have been hypothesized to aid in shallow reef recovery by acting as a source of propagules. However, to date, this assumption of vertical connectivity has only been tested for three different scleractinian coral species. Here, we summarize the results of vertical connectivity assessments for six different depth-generalist coral species (*Agaricia fragilis, Agaricia lamarcki, Stephanocoenia intersepta, Acropora aculeus, Seriatopora hystrix* and*Pachyseris speciosa*) from various locations in the Western Atlantic (Bermuda, Bonaire, Curacao) and Indo-Pacific (Great Barrier Reef, Coral Sea, Papua New Guinea). Using a modified RAD-seq approach that comprehensively removes endosymbiont contamination, we characterized genome-wide variation (~20,000-150,000 SNPs) across ~1,500 individuals from paired shallow (10-15 m) and deep (40-60 m) populations sampled at different locations and/or regions. Brooding species all exhibited genome-wide differentiation by depth, indicative of varying degrees of adaptive divergence. In contrast, differentiation in broadcasting species was mostly observed across geographic regions and not by depth. These results establish the first broader pattern demonstrating a contrasting potential for vertical connectivity based on reproductive mode, and allow us to move towards a more generic characterization of connectivity between shallow and mesophotic coral reefs.

HABITAT LOSS REDUCES THE ABUNDANCE AND SPECIES RICHNESS OF CORAL REEF FISH RECRUITS REGARDLESS OF HABITAT CONFIGURATION (Abstract ID: 29202)

Habitat loss is a spatially complex process that not only reduces the total amount of habitat available, but also changes the spatial configuration of the remaining habitat. This may involve substantial increases in the degree of fragmentation (i.e. subdivision) and isolation of habitat patches, however the influence of these configuration changes relative to those of habitat loss are unknown. In this study we measured the independent and interactive effects of habitat loss, fragmentation, and isolation on the abundance and species richness of coral reef fish recruits. Replicate experimental seascapes were constructed with either control or a 50% reduction in habitat cover and cross-factored with two levels of fragmentation (9 or 18 habitat patches) or isolation (3m or 15m spacing between patches). Recruitment was surveyed after three months and data was pooled across patches to provide a seascape-level estimate of effects on total fish abundance, species richness, and individual species. Habitat loss resulted in a 60% decline in total abundance and 25% decline in species richness, regardless of levels of fragmentation or isolation. Most species declined with the 50% reduction in habitat, but exhibited variable responses to changing habitat configuration. Overall, most species were unaffected by fragmentation but responded positively to increased isolation, though this positive effect was in some cases restricted to treatments with higher habitat cover. These findings emphasize prevention of habitat loss for reef fish conservation in a changing world.

OUTCOMES AND LESSON'S LEARNED AFTER 14 YEARS OF COMMUNITY-BASED CO-MANAGEMENT INITIATIVES ON FIJI'S CORAL COAST. (Abstract ID: 29796)

Community-based resource management can be an effective approach for biodiversity conservation and replenishing depleted reef fish stocks, particularly on Pacific islands whose indigenous communities have significant control over their resources. The customary fishing rights owners in Fiji's Coral Coast district of Korolevu-i-wai began marine co-management activities with the Fiji Locally-Managed Marine Areas Network in 2002. In 2005, this effort was bolstered by the integration of a community-based supporting organization that has facilitated the implementation of a suite of research, capacity-building, and community-development programs. While no-take and fished control sites had >35% macroalgal cover and <10% coral cover in 2004, the no-take protection provided by the relatively-small (<1 km2) tabu areas established as part of the marine management plan was sufficient to remove macroalgal cover and promote coral community recovery in the tabu areas, but not in adjacent fished areas. By 2012, coral cover in tabu areas exceeded 50% and tabu areas had 500% more coral cover, 50% more coral species, 50% more food fish species, and 500% more food fish biomass than adjacent fished areas which now have >70% macroalgal cover. Simultaneously targeting community development priorities and economic needs strengthened support for resource management and conservation actions. Strong traditional governance and inclusion of a broad suite of stakeholders have been key factors for the success of community-based resource management initiatives.

PATTERN AND PROCESS IN TROPICAL FISH EXPATRIATION POLEWARD FROM THE GREAT BARRIER REEF (Abstract ID: 27948)

I summarise patterns of recruitment and persistence of coral-reef fishes along the SE Austrian temperate coastline establishes over a 16-year monitoring period. Recruitment intensity in southern locations is weakly related to East Australian Current (EAC) strength, with temporal patterns differing among key families (Chaetodontidae, Pomacentridae, Acanthuridae) and among the over 100 species recorded to date. A key bottleneck to population establishment at higher latitudes is winter water temperature, and recruitment and establishment of these species is related to site wave exposure. Life history characteristics of species and families also are good predictors of high latitude recruitment. Expected changes to EAC strength and sea surface temperature along this coastline are linked to measured patterns in growth and pelagic dispersal to suggest changes in the dynamics of this process under climate change.

THE SUNSCREEN SHEEN: AN ASSESSMENT OF THE PRESENCE AND QUANTITY OF ORGANIC UV-FILTERS IN THE WATERS OFF WAIKIKI BEACH (Abstract ID: 28928 | Poster ID: 464)

Organic UV filters are known endocrine disruptors that interfere with larval and embryonic development, reproduction and gender determination in marine invertebrates, fishes, rodents and humans. They find their way into the environment via plastic and personal care product waste. When humans enter the ocean after applying sunscreens with organic UV-filters as their active ingredient they eventually wash off, directly entering the marine environment. In 2015, the state of Hawai'i received over 4.8 million visitors, over 3.6 million spending time on O'ahu, home to the famous Waikiki Beach and many other beaches that experience high visitor frequency, most of whom use sunscreen products with organic UV-filters. Few studies have attempted to quantify the presence of organic UV-filters in the nearshore waters of O'ahu. The present study aims to detect and quantify the following organic UV-filters: avobenzone, homosalate, octocrylene and oxybenzone in an effort to understand their prevalence and persistence in Waikiki's nearshore waters. Water samples will be collected on and 60cm below the surface at various locations along Waikiki Beach every three hours from 0600-2400. Analytes will be extracted using reverse phase solid phase extraction and analyzed using triple quadrupole liquid chromatography/mass spectroscopy. By detecting these organic UV-filters, we hope to spread awareness of the possible effects these compounds might have on biological systems, specifically nearby coral reef communities that experience constant exposure due to high visitor frequency.

DESIGN OF CLIMATE CHANGE ADAPTATION MEASURES FOR A CORAL LAGOON BEACH IN MAURITIUS (Abstract ID: 29263 | Poster ID: 449)

Mon Choisy in northwestern Mauritius is an economically important public beach enjoyed by locals and tourists. Chronic erosion has resulted in the loss of up to 20 m of beach width in 40 years and is likely to increase in coming years due to global sea level rise, severely impacting beach amenity and economic viability. In 2014, the Government of Mauritius and UNDP, supported by the Adaptation Fund, initiated a project to analyze the causes of erosion at Mon Choisy and provide rehabilitation options. A comprehensive technical assessment incorporating physical and biological surveys, instrumental data collection and calibrated numerical modeling suggest that the erosion is caused primarily by the interruption of sediment supply from existing coastal works and the degradation of coral and seagrass habitats due to anthropogenic and natural factors, resulting in increased wave energy penetration into the lagoon, sediment mobility

and decreased production of coralline sand. Remedial measures proposed include the removal of *Casuarina* trees, beach reprofiling and replanting with native sand binding and coastal forest species, sand nourishment, low crested breakwaters for wave energy dissipation, seagrass rehabilitation, and the designation of a Voluntary Marine Conservation Area. While these measures may reduce erosion and result in a more resilient beach, they do not address the underlying causes of the erosion, highlighting the need for funding agencies to consider longer term programs with broader reach in order to fully address the threats to coral lagoon beaches.

POPULATION ECOLOGY OF THE RED SEA LIONFISH *PTERIOS MILES* IN ITS NATIVE RANGE (Abstract ID: 27952)

Research of the lionfish introduction into the western Atlantic and Caribbean seas has revealed this species to be the most successful marine fish invader ever documented. To better understand the potential ecological reasons for this unprecedented invasion, we studied various population parameters of *Pterois miles* in its native habitat by tagging 36 individuals among a fringing reef in Egypt in October 2014. Initial recapture success exceeded 60% of fish tagged, but gradually declined to 10% by November 2015. Mean juvenile growth rates ranged from 7.8 to 10.2mm per month in summer, while adults (TLmax 32cm) had relatively constant growth rates of about 4mm per month throughout the year. In August, several adults had ripe gonads indicating that reproduction was about to take place. Site fidelity was strong with 50–100% of fish being recaptured at the initial tagging site while the remaining fish were recaptured within a 60m radius. To identify potential biotic constraints in the Red Sea, juveniles (TL <10cm) were caught and released near potential predators. Stonefish, moray eels, and several groupers ignored lionfish. Other groupers exhibited aggressive behaviors and continuously attacked until lionfish swam upwards into the water column using the current to drift away. Actual predation was not observed, suggesting habitat competition plays an important role in lionfish distribution. These observations provide new insights into population ecology of lionfish in their natural habitats that can improve our understanding of the distributions of invasive populations.

THE SCLERACTINIAN CORAL FAUNA OF MOOREA (FRENCH POLYNESIA) : STABILITY OVER TIME VERSUS ENVIRONMENTAL DISTURBANCES ? (Abstract ID: 28532)

An inventory of the scleractinian coral fauna in the reefs surrounding the island of Moorea (French Polynesia) was conducted in 1978 by Kühlmann and the results published by Chevalier & Kühlmann (1983). In order to provide a reference collection for the research on coral reef being presently conducted at the CRIOBE, a comprehensive sampling survey was carried out in 2012, around Moorea, including most sites visited 34 years earlier by Kühlmann. In the intervening period numerous changes have affected the reef environment. These include direct and indirect anthropic disturbances, most of them linked to a sharp increase in the resident and transient (tourist) population, resulting in a general anthropisation of the shoreline, including landfill and coral sand and rock extraction. Further, several significant natural disturbances have taken place during that period, such as episodes of severe Acanthaster infestations, recurrent bleaching events, cyclones and protracted episodes of abnormally low sea level. Yet the qualitative comparison of the results obtained 34 years apart indicates very little overall difference in scleractinian diversity. Indeed, except for two species not found in 2012 but whose presence has been ascertained on the nearby island of Tahiti, the species lists are almost identical. The only notable difference is recorded for the family Acroporidae, particularly the genus Acropora. Hypotheses as to the mechanisms underlying relative stability of the scleractinian fauna around Moorea are presented, and consequences for reef management are discussed.

DENSITY DEPENDENT HABITAT SELECTION DICTATES DISTRIBUTION OF REEF FISH FOLLOWING HABITAT LOSS (Abstract ID: 28497)

Habitat loss governs the distribution of species on a coral reef by altering the availability of resources. While we know that complete loss of habitat has severe negative effects on reef fish communities, we know relatively little of how species respond to patchy disturbances. This is surprising given that many threats facing coral reefs have a species bias, and therefore result in a mosaic of dead and live corals. In this study we investigated how an ongoing outbreak of the crown-of-thorns seastar affected the distribution of a common reef fish, *Pomacentrus moluccensis*. We identified reefs with a range of coral damage and recorded densities of fish on plating *Acropora*colonies. We found that densities of *P. moluccensis* on live coral colonies were greater with increasing proportions of dead coral. In addition, we describe how fish start occupying dead coral when >50% of colonies on a reef were dead. We suggest that the loss of habitat causes crowding on remnant live coral until some fish are forced to choose less preferred dead colonies. We then conducted a choice experiment to investigate if density dependent habitat selection was the mechanism underlying this pattern. When presented with the choice of two colonies, fish were more likely to choose a near empty alternate colony when the other colony was severely crowded with conspecifics. This study is the first to demonstrate density dependent habitat selection during an ongoing disturbance event and adds to the growing body of work outlining how reef fish communities are affected by disturbances.

EXAMINING THE WIDE BAND FREQUENCY RESPONSES OF COMMON REEF FISHES- COMPARISONS BETWEEN MODELS AND MEASUREMENTS (Abstract ID: 29418)

Many heavily exploited fishes are crucial to the ecosystem function of reefs. A central challenge to quantifying change in coral reefs and their ecosystem services is the acquisition of spatially and temporally appropriate data to examine patterns in diversity and abundance of coral reef fishes, and in particular exploited target species. Wideband acoustic technology offers a promising tool that might allow inference at relevant taxonomic and spatiotemporal scales. Using the boundary element method with high-resolution computed tomography data, we examine numerically modeled acoustic scattering responses (12-250 kHz) of dominant reef fishes across a range of orientations. The modeled wideband scattering responses are compared with in situ measurements of wideband scattering from reef fishes obtained using the Simrad EK80 echosounder. Preliminary analyses suggest that wideband scattering responses in this frequency range are sensitive to the fine-scale morphological variations among common reef fish species. Further analysis will give insight into the appropriate frequency domain to examine the efficacy for taxonomic resolution.

QUANTIFYING PROJECT IMPACTS AND MITIGATION OFFSETS BY PARTITIONING ECOSYSTEM FUNCTIONS AND SERVICES (Abstract ID: 28998 | Poster ID: 688)

Federally permitted projects that result in significant and specific loss of resources important to the human or aquatic environment are required to mitigate for that loss. The difficulty of defining linkages between project activities and their effects often leads to a controversial accounting of ecosystem value. Particularly on large public projects, selection of the type and scale of mitigation is often negotiated as final permits are either granted or denied. A rubric is needed to fairly balance the environmental cost of development against the benefits of mitigation using a common currency. This two-fold problem requires a correct assessment of the environmental impacts of development and the appropriate design of mitigation to offset losses. The 2008 Compensatory Mitigation rule does not require compensation for the loss of specific resources, but rather for aquatic resource "types, functions and services". Here we propose a methodology that focuses upon defining ecosystem functions and services threatened by proposed projects, and selection of the mitigation type and quantity needed to maintain ecosystem balance. Using the framework from the Millennium Environmental Assessment (MEA, 2005), the impact site is parsed into 27 ecosystem categories divided between Regulating and Support Functions, and Provisioning and Cultural Services. Analysis of each category allows the actual likely project impacts to be standardized in common terms. Knowledge of the specific ecosystem functions and services impacted enables resource agencies to select mitigation options that match the values and quantities of ecosystem functions and services jeopardized by the proposed project.

MICROBIAL METABOLIC SHIFTS DURING IN-SITU DEVELOPMENT OF CORAL BLACK BAND DISEASE (Abstract ID: 29044)

Black band disease (BBD) is a virulent, globally-distributed infectious disease characterised by a darkly pigmented polymicrobial band at the interface between apparently normal coral tissue and freshly exposed skeleton. Microbial taxonomic profiles for BBD

have been extensively characterised, but the underlying microbial metabolic functions that contribute to anoxic and sulphide-rich microenvironments within the lesion and govern its pathogenicity have not been documented. Combined metagenomic and metatranscriptomic profiling of microbial lesions at two stages in BBD development were sampled from replicate coral colonies: 1) a less-virulent precursor stage termed cyanobacterial patches, and 2) a fully developed BBD lesion. The development of BBD pathogenicity is linked to relative increases in production of sulfide within the lesion by sulfate-reducing bacteria, and to photosynthetic CO2-fixation by cyanobacteria. The latter play a pivotal role in pathogenesis by introducing organic carbon in addition to nutrients derived from dead coral tissue. Furthermore, heterotrophic bacterial degradation of organic carbon produced by cyanobacteria represents a key mechanism for the depletion of dissolved oxygen within BBD lesions to levels harmful to underlying coral tissue, especially in the absence of light. The increased mechanistic understanding of BBD development provided by this 'omic'-based study highlights the complexity of microbial interactions within the polymicrobial communities involved in the pathogenesis of BBD.

LATITUDINAL VARIATION IN SPAWNING SYNCHRONY OF ACROPORA CORALS (Abstract ID: 28955)

Reproductive synchrony is a feature of many plant and animal populations. High reproductive synchrony between species of scleractinian corals is known to occur in a wide range of locations in the world. Levels of synchrony are, however, variable between locations. It has often been suggested that the synchrony is driven by environmental variables correlated with latitude, such as water temperature, insolation and photoperiod. We here develop a method to quantify spawning timing and synchrony, and apply it on a large dataset that compiles Indo-Pacific Acropora reproductive data from 152 reefs in 17 countries between the latitudes 35°S and 35°N. We then test the hypothesis that the spawning synchrony in Indo-Pacific Acropora species correlates with latitude. We found no correlation between synchrony and latitude, which further supports the hypothesis that synchronous spawning is a feature of all speciose assemblage. Although it is well-accepted that variables such as water temperatures and lunar cycles strongly influence the seasonality and timing of coral reproduction, the exact factors that determine the level of synchrony within and among populations remain to be identified, potentially involving factors other than environmental ones, such as socio-biological or ecological ones.

EFFECTS OF OCEAN WARMING AND CO2-INDUCED ACIDIFICATION ON CALCIFICATION OF FOUR CARIBBEAN REEF-BUILDING CORALS (Abstract ID: 28700)

Rising atmospheric carbon dioxide (pCO2) has caused ocean temperature to increase and pH to decrease, raising concerns about the health of marine organisms. Corals are particularly vulnerable to these stressors, likely due to their narrow thermal tolerance and use of carbonate ions in calcification, although response patterns vary across taxa. We conducted controlled laboratory experiments for approximately 90 days to investigate the independent and interactive effects of ocean warming (28, 31 C) and acidification on the calcification rate and skeletal properties of four keystone Caribbean reef-building corals (*Pseudodiploria strigosa, Siderastrea siderea, Porites astreoides, Undaria tenuifolia*) collected from the Belize Mesoamerican Barrier Reef. Aragonite saturation states of 3.9, 3.2, 2.2, and 0.7 constrained by total alkalinity measured via closed-cell potentiometric titration and dissolved inorganic carbon measured via coulometry, were attained by sparging natural seawater with air-CO2 mixtures formulated at 280, 400, 700, and 2800 ppm pCO2, respectively. Temperature and pCO2 were fully crossed with three-fold treatment replication. Calcification rates for all species exhibited a generally decreasing trend with increasing pCO2, although this trend was not always linear. The negative effects of pCO2 were more pronounced at 28C than at 31C. Notably, three of the species exhibited net skeletal dissolution in the treatments that was undersaturated with respect to aragonite, with only *S. siderea* producing skeleton on a net basis under these conditions.

ACROPORA CERVICORNIS TRANSPLANTS AS FISH HABITAT AND AS A POSITIVE INFUENCE TO FISH RECRUITMENT ON CARIBEAN REEFS (Abstract ID: 30139)

No-take MPAs have been established widely as a fisheries restoration measure and to reestablish the ecological balance essential to coral reef health over time. However, where Caribbean Acropora cervicornis corals have become locally extinct, they do not return on their own through larval recruitment processes. For such situations, staghorn Acropora transplantation may be required in order for the natural balance of the MPA to be obtained, resulting in restored fish and invertebrate populations by increasing vital branching coral habitat. From the perspective of evaluating coral transplantation as a potential coral reef and fisheries management tool, the specific impacts of coral transplantation on fish populations is of fundamental importance, particularly for reefs suffering from algal overgrowth or other ecological imbalance due to low fish numbers. If a lack of fish is related to a lack of habitat, Acropora transplantation could potentially be important in reestablishing fish populations that would then help reestablish a broader ecological balance and lead to conditions more conducive to recovery. Specific interactions between coral transplants and fish recruits are investigated in this study, focusing on the following questions: 1. what fish families, size, and numbers do coral transplants on rock, rubble, or sand, or seagrass substrates provide?, 2. does proximity to the reef (<3m, >30m) or substrata effect fish numbers, diversity, or initial recruitment size to coral transplants?, and 3. does the relative number of fish recruits influence coral health or growth? https://www.facebook.com/C4Conservation/

REPLACING BARBIE'S NOTEBOOK: HOW DIGITAL TECHNOLOGY IS REVOLUTIONIZING DATA COLLECTION IN SMALL SCALE FISHERIES (Abstract ID: 30054)

The collection of fisheries data from small scale fisheries has historically been a challenge for national governments. The technical and financial investment required to sustain data collection across scores of communities whose fishers target complex multispecies fisheries, often with a low catch value has not been an obvious priority when allocating limited national budgets. In the last few years however the advent of low cost cloud computing and the widespread adoption of smart phones in rural areas means that the technology exists to revolutionize data collection and vastly improve the ability and cost effectiveness of collecting, analyzing and disseminating fisheries information at national scales. Here, I present case studies from both the Caribbean and South East Asia where a simple to use data collection system built around a mobile App, a solar powered vessel monitoring device and a digital registration system, have been deployed across large geographic areas to capture high resolution data on a range of small scale fisheries. I explore the challenges presented by moving record keeping from note books to the cloud, the need for careful design in technology to overcome barriers in literacy and language, and the development of data management pipelines and automated systems to collate, analyze, interpret and disseminate data in near real time. The approach is rapidly increasing our understanding of how fishers use the seascape and coral reef resources, empowering decision makers at all levels and enabling science to underpin small scale fisheries management.

EVALUATING TRADE-OFFS BETWEEN FISHERIES HARVEST AND CORAL REEF RESILIENCE (Abstract ID: 29926)

Reef fisheries are required to take an ecosystem approach to their management, yet informing management with policies that avoid ecosystem impacts is challenging in highly complex systems, particularly if the target species serve an important ecosystem function. Caribbean coral reefs provide a classic example where herbivorous fish are an important fishery but depletion can elicit cascading impacts that lock reefs into degraded states. To date, scientists have recommended bans on parrotfish exploitation but this simply isn't politically or economically feasible in the majority of countries. A fisheries policy is needed that permits exploitation while limiting the impact on reef resilience. We modelled the impacts of a parrotfish fishery on the future state and resilience of Caribbean coral reefs, enabling us to quantify the trade-offs between harvest and ecosystem health. We find that implementation of a simple and enforceable size restriction of > 30 cm provides a win:win outcome in the short term, delivering both ecological and fisheries benefits leading to increased yield and greater coral recovery rate for a given harvest rate. However, maintaining resilient coral reefs even until 2030 requires the addition of harvest limitations (< 10% of virgin fishable biomass) to cope with a changing climate and induced coral disturbances, even in relatively healthy reefs today. Managing parrotfish fisheries is not a panacea for protecting coral reefs from climate change but it can play a role in sustaining the health of reefs and high quality habitat for reef fisheries. http://www.marinespatialecologylab.org/

SOCIAL RESILIENCE AND THE BUSINESS CASE FOR INCREASING INVESTMENT IN WASTEWATER TREATMENT: THE IMPORTANCE OF INTEGRATING EFFECTS ON NATURAL CAPITAL (Abstract ID: 30019)

Natural capital is Earth's stock of natural assets, including land, air, water and living organisms. For many developing nations, the quantity and quality of key ecosystem services that flow from natural capital (e.g. drinking water, fisheries, and tourism) continue to decline due to the negative impact of wastewater pollution. It is becoming more broadly understood that the degradation of natural capital can have significant impacts on the long-term environmental and economic resilience of a community. Therefore, in an effort to strengthen support for investment in critically needed wastewater infrastructure, economic analyses are expanding to include both traditional elements (e.g. the cost of various wastewater treatment alternatives) and elements related to natural capital (e.g. the value of ecosystem services). However, coral reefs and other natural resources also have a quantifiable cultural value, and their degradation erodes cultural natural capital – a critical component of a community's social resilience. This is reflected in a global paradigm shift in international development priorities, with capital investment decisions resting increasingly on a more thorough assessment of project impacts that accounts for the link between social resiliency and a community's economic and environmental resilience. Our paper seeks to demonstrate that project stakeholders can leverage a business case approach to evaluating wastewater infrastructure projects with a focus on conserving existing, and creating new, natural capital.

LOW BUT STABLE REEF SHARK POPULATION ABUNDANCE AND DENSITY AT AN UNFISHED CORAL REEF (Abstract ID: 28401)

Baseline population estimates are lacking for many marine species, especially large predators such as reef sharks. The grey reef shark (Carcharhinus amblyrhynchos), which is listed as Near Threatened on the IUCN Red List of Threatened Species, is highly mobile and therefore particularly difficult to monitor. We used spatial capture-recapture (SCR) models, which incorporate movement effects, to produce the first spatially explicit, baseline population abundance and density estimates of grey reef sharks at Palmyra atoll, a remote, unfished U.S. National Wildlife Refuge in the central Pacific Ocean. We estimated a mean density of 17-21 grey reef sharks/km2, which translates to a total population size of 6261-8344 sharks at Palmyra. Shark abundance was stable through the course of the eight-year study, and shark distribution was non-uniform giving rise to density hotspots. Our density estimate is at least an order of magnitude lower than previous estimates at Palmyra based on data from spatially limited underwater diver surveys. Pristine coral reef locations have been characterized as having 'inverted trophic pyramids', yet this concept may be based on potential overestimates of apex predators from visual surveys in these systems. In addition, the insights from this study suggest adjusting reef shark recovery targets, as present targets are likely unrealistic and therefore impossible to achieve. At the same time, harvest quotas warrant similar downgrading to prevent continued overexploitation of reef sharks.

USING BIOCRITERIA AND THE BIOLOGICAL CONDITION GRADIENT TO PROTECT CORAL REEF ECOSYSTEMS (Abstract ID: 28688 | Poster ID: 616)

Biological assessments (surveying the presence, number, size and condition of fish, corals, algae, plants, and other biota) provide important information about the health and integrity of coral reef ecosystems. Biological criteria are a way of describing the qualities that must be present to support a desired condition in a waterbody and serve as the standard against which assessment results are compared. A Biological Condition Gradient (BCG) provides explicit characterization of how attributes of the biological system change as human disturbance increases, establishing clear and scientifically defensible narratives for different levels of biological condition. Comparing results of biological assessments with BCG thresholds is an effective approach for evaluating the integrity of coral reef ecosystems, weighing management options and communicating status and goals. Decision-makers can use the BCG to determine which level most appropriately describes the current condition of their reefs and what conditions are desired, and can set easily communicated, quantitative goals for achieving those conditions. A variety of coral reef management activities can be supported by combining biological assessment and a coral reef BCG: these include water quality standards and condition status (excellent, good, fair, poor), pollution management (point source and non-point source), dredge-and-fill permitting, risk assessment to aquatic life from hazardous waste sites, risks to threatened and endangered species, environmental impact assessment and fisheries.

LARGE-SCALE, LONG-TERM INTERDISCIPLINARY ECOSYSTEM ASSESSMENT AND MONITORING OF THE U.S. PACIFIC ISLANDS TO SUPPORT ECOSYSTEM-BASED MANAGEMENT AND CONSERVATION (Abstract ID: 29028)

Effective ecosystem-based management and conservation of coral reefs requires information about what ecological resources are available, where those resources are located, how and why those resources are changing over time, how those resources are utilized and valued by people and communities, and how human activities, including climate change, are effecting the sustainability of the ecosystems. Since 2000, NOAA's Coral Reef Ecosystem Program, in partnership with Federal, State, and Territorial agencies and academic and non-governmental institutions, has been mapping, monitoring, and conducting applied research to provide these types of information to support sustainable management of the coral reef ecosystems of Hawaii, American Samoa, Guam, the Northern Mariana Islands, and the U.S. Pacific Remote Islands as the Pacific implementation of NOAA's National Coral Reef Monitoring Program. Triennial surveys at over 40 island ecosystems monitor the abundance, diversity, size, and condition of corals, other invertebrates, algae, fishes, and microbes, as well oceanographic and environmental conditions and human uses influencing them. Use of systematic and consistent methods across diverse gradients of biodiversity, oceanographic conditions, and human uses and impacts allows an unprecedented opportunity to perform comparative biogeographic and socio-ecological analyses. We will discuss how these analyses can inform efforts by fisheries and coastal resource managers to effectively implement ecosystem-based management to achieve a balance between ecological and human well-being.

HERBIVOROUS GRAZING IN A NEW DIMENSION: THE IMPORTANCE OF MICRO-TOPOGRAPHIC COMPLEXITY (Abstract ID: 27994)

On coral reefs, the grazing pressure exerted by herbivorous fishes is a major determinant of benthic community structure. Using a trait-based experimental approach, we demonstrate that previous schemes of herbivore functional diversity are missing a key component of coral reef consumer-producer dynamics. Specifically, we show that micro-topographic refuges and the functional identity of herbivores that are able to exploit resources within

these refuges strongly affect benthic community development. Within refuges, benthic communities are grazed by a small suite of functionally similar species, which only crop the apical portion of algae. In contrast, surfaces outside of refuges are grazed by a wide range of species from various functional groups, including species that extract the entire epilithic algal matrix or its particulate component. This functional filtering results in two separate grazing regimes, which create distinct coexisting benthic assemblages: assemblages within refuges are diverse, supporting several types of algae as well as juvenile scleractinian corals, while communities outside refuges feature low diversity assemblages dominated by simple filamentous turfs. These results suggest that, although limited to the scale of a few centimeters, micro-topographic refuges mediate the biotic control of benthic community development by affecting grazer functional diversity. Given the importance of coral reef consumer-producer dynamics, these results provide valuable information for the management of herbivore functional diversity in a changing world.

PRELIMINARY RESULTS FROM SENTINEL 2 MSI IMAGERY FOR CORAL REEF MAPPING APPLICATIONS (Abstract ID: 29460)

ESA's recently launched Sentinel 2 mission offers several desirable features for routine coral reef monitoring, including global coverage in coastal regions (20 km off the coast) with a 5-day revisit time, and 10 m resolution in visible wavelengths. In addition to providing data continuity to previous reef mapping from SPOT and Landsat missions, sensitivity analyses demonstrate that Sentinel 2 may provide more accurate mapping for coral reef applications. The ESA-funded Coral Reefs SEOM project (Scientific Exploitation of Operational Missions) aims to apply Sentinel 2 's capabilities to develop and validate coral reef composition and condition mapping and monitoring products. During the project, mapping and change detection of reef geomorphic zones and dominant benthic types, bathymetry and water column properties retrieval will be assessed over a range of different coral reef types. The algorithms developed in the SEOM project will be distributed as a set of open source software modules providing a validated processing chain for coral reef remote sensing. These tools will enable uptake of Sentinel 2 imagery for coral reef mapping and monitoring applications among the user community. With this presentation we aim to gather community feedback on the proposed monitoring products, present the study sites and discuss some preliminary results, including a comparison of physics-based bathymetry mapping between Sentinel 2, Landsat 8 and other imagery sources.

DIVERSITY AFFECTS DISEASE TRANSMISSION IN CARIBBEAN CORALS (Abstract ID: 28769)

Coral disease can have devastating consequences for coral reef communities. There are several characterized diseases, including black band and white plague that affect multiple species of reef-building corals. In the Caribbean, species susceptibility to black band and white plague appears to vary among regions and outbreaks of disease are associated with different dominant species. Understanding how species susceptibility varies is important to predicting the future impacts of disease and may help to identify risk factors. This study tracked the prevalence of coral disease among multiple sites over an extended time period and examined the spatio-temporal patterns of species-susceptibility. Laboratory transmission experiments were completed to support whether field patterns indicated true variation in susceptibility or were solely a function of species density. Our results suggest that white plague and black band preferentially affect highly abundant orbicellids and *Siderastrea siderea*, respectively, but that this is a result of greater susceptibility and not just proportionally greater densities of the host species.

DEEP ON THE CHEAP: ACCESSIBLE AND COST-EFFECTIVE METHODS FOR QUANTITATIVELY SURVEYING MESOPHOTIC CORAL REEF ECOSYSTEMS (Abstract ID: 29665 | Poster ID: 333)

An array of recent technological advancements has allowed broader scientific access to mesophotic coral ecosystems (MCEs). These reefs are now known to function in support of fisheries, serve as regional larval sources, and act as potential refuges for reef organisms. There is still a great deal unknown about these systems, including their global distribution. Although our collective understanding of MCEs has greatly increased in recent history, the costs of requisite technologies for accessing these environments—i.e., technical SCUBA, ROVs and AUVs—often hinders their study. We have developed a highly accessible and boat launched remote camera system that provides a rapid and cost effective approach to identify, quantitatively describe and monitor MCEs. We have undertaken three investigations using these techniques—on the north and south shelves of St. Thomas and within the Buck Island Reef National Monument, St. Croix, USVI. We have used this system to identify benthic structure of MCEs at depths between 30 and 100 m with and without high-resolution bathymetry. Equipment costs range from $500 to $3500 USD depending on desired depth and data requirements. We found that a crew of three people can sample 25 to 50 points daily depending on conditions and travel time. Post-processing of benthic photographs identifies coral species, macroalgae, sponge and cyanobacteria coverage. We discuss the broader applicability of these methods in remote regions and areas lacking high-resolution bathymetry and advanced SCUBA capabilities.

MOVEMENTS OF THE REEF MANTA RAY (MANTA ALFREDI) IN THE RED SEA USING SATELLITE AND ACOUSTIC TELEMETRY (Abstract ID: 28019 | Poster ID: 519)

Populations of mobulid rays are declining globally. Understanding the movement ecology of these rays remains an important priority for devising appropriate conservation measures throughout the world's oceans. We sought to determine manta movements across several temporal and spatial scales with a focus on quantifying site fidelity and seasonality in the northern Farasan Banks, Red Sea. We fitted manta rays with acoustic transmitters and pop-up satellite archival transmitting (PSAT) tags, including four with GPS capability. All acoustically tagged individuals traveled frequently among high-use receiver locations and reefs and demonstrated fidelity to specific sites within the array. Estimated and realized satellite tag data indicated regional movements <200 km from the tagging location, largely coastal residency, and high surface occupation. GPS-tagged individuals regularly moved within the coastal reef matrix and showed fidelity to the high-occupancy sites identified by acoustic tagging. We also tested the accuracy of several geolocation models to determine the best way to analyze our light-based satellite tag data. We documented significant errors in light-based movement estimates that should be considered when interpreting this data. Despite some error in satellite tag positions, combining results from PSAT and acoustic tags in this study yielded a comprehensive representation of manta spatial ecology across several scales, and such approaches will inform the design of appropriate management strategies for manta rays in the Red Sea and tropical regions worldwide.

CORAL PLASTICITY AND HOLOBIONT DYNAMICS UNDER THERMAL STRESS: INTRAPOPULATIONAL, INTERPOPULATIONAL AND INTERSPECIFIC VARIABILITY (Abstract ID: 29194)

In the context of global change, corals will be submitted to an increase of sea surface temperatures that will certainly reach values never experienced previously in their lifetime. In order to better predict the future of these animals of great ecological importance under this unusual thermal stress, we need to better understand the mechanisms

of coral's thermotolerance. In this work, we performed a comparative thermotolerance experiment for two coral species: *Pocillopora damicornis*, a tropical scleractinian coral, and *Corallium rubrum*, a temperate coral from the Mediterranean Sea. For each of these species we compared the response to thermal stress for individual genotypes of two populations which have experienced in their life history high or low annual thermal variations. As corals are metaorganisms, living in close association with complex microbial communities and/or symbiotic zooxanthellae (for *P. damicornis*), we followed the transcriptomic response of the cnidarian host (by RNAseq) and the dynamic of the associated microbiota (using 16S metabarcoding) at the upper limit of the thermotolerance of these different species / populations / colonies. These comparative analyzes of the thermal stress response of the coral holobiont have allowed us to identify potential similar molecular mechanisms existing between these two ecologically and phylogenetically distant species, as well as differences within the same species between populations experiencing different thermal regimes.

SWELL AS A HIGH FREQUENCY DRIVER OF MACROALGAL COVER AND CORAL-MACROALGAL INTERACTIONS ON CARIBBEAN CORAL REEFS (Abstract ID: 30033)

Compromised Caribbean stony coral health due to tactile interactions with reef-associated macroalgae has long been observed. Elucidating primary physical and biological components driving local macroalgal benthic cover and coral-macroalgal tactile interactions requires high frequency, longitudinal data collection. We used a seven-year high frequency (monthly) data set of biophysical variables and macroalgal dynamics to determine the primary factors driving intra-annual changes in coral-macroalgal tactile interactions on 4 shallow (6-20 m) reefs in St. Thomas, US Virgin Islands. We found that both macroalgal benthic cover and prevalence of coral-macroalgal interactions were primarily negatively related to wave-driven turbulence, which likely forcibly dislodges macroalgae. Acute and chronic wave-driven decreases in macroalgal cover and coral-macroalgal interactions fit patterns related to location along the insular platform, depth, frond fragility, and relative attachment strength of dominant site-associated macroalgal species. Furthermore, any relationships between macroalgal cover/coral interactions and a suite of physical parameters including temperature, pH, sedimentation, turbidity, PAR, inorganic nutrients and chlorophyll were either minimal or influenced directly by wave turbulence. This study suggests that in coral reefs where macroalgae are major benthic components, macroalgal abundance and interactions with corals can be tied to water motion, providing another mechanism whereby moderate wave-driven turbulence might favor coral health and reef growth.

ECOLOGICAL AND MORPHOLOGICAL TRAITS PREDICT DEPTH-GENERALIST FISHES ON CORAL REEFS (Abstract ID: 27776)

Ecological communities that utilise similar habitats may exhibit functional convergence despite significant geographic distances and taxonomic dissimilarity. On coral reefs, steep gradients in key environmental variables (e.g. light and wave energy) restrict some species to shallow depths. We show that depth-generalist reef fishes are correlated with two species-level traits: caudal fin aspect ratio and diet. Fishes with high aspect ratio (lunate) caudal fins produce weaker vortices in the water column while swimming, and we propose that 'silent swimming' reduces the likelihood of detection and provides an advantage on deeper reefs with lower light irradiance and water motion. Significant differences in depth preference among trophic guilds reflect variations in the availability of different food sources along a depth gradient. The significance of these two traits across three geographically and taxonomically distinct assemblages suggests that deep water habitats exert a strong environmental filter on coral reef fish assemblages.

LIGHT MEDIATES THE PHOTOSYNTHETIC RESPONSE OF A CRUSTOSE CORALLINE ALGA TO OCEAN ACIDIFICATION, AND CONSEQUENCES FOR OTHER PHYSIOLOGICAL PROCESSES (Abstract ID: 29477)

Photophysiology has multiple potential avenues through which it could be affected by future ocean acidification (OA). Since photosynthesis influences energetic budgets as well as important physiological processes, including calcification and respiration, understanding how it is affected by OA is important for predicting the response of autotrophic taxa to OA. To determine whether light, through its influence on photosynthesis, could mediate the effect of OA on an important coral reef calcifier, experiments were conducted on a crustose coralline alga, Porolithon onkodes. In each experiment, two pCO2 levels (ambient and elevated) were crossed with three experimental light treatments. Calcification, respiration, net photosynthesis, and photochemical efficiency (Fv/Fm) were measured, and photosynthesis-irradiance curves were constructed. Interestingly, there was inhibitory effect of OA on some aspects of photophysiology in P. onkodes (photochemical efficiency), but neutral (maximum gross photosynthesis), and even facilitative effects on other aspects (light-use efficiency), and many of these effects were modulated by light. Additionally, unlike post-illumination respiration, dark-adapted respiration was two times higher under elevated pCO2. This indicates that photosynthesis may mitigate the stimulatory effect of OA on respiration. Finally, although light did not alter the negative effect of OA on calcification, the responses of photosynthesis and respiration could constrain the distribution of this species to a narrower range of light environments in the future under OA.

INFORMING CATCHMENT MANAGEMENT PLANS TO IMPROVE COASTAL WATER QUALITY: AN APPLICATION OF NUMERICAL MODELS AND OBSERVING SYSTEMS IN THE GREAT BARRIER REEF (Abstract ID: 28638 | Poster ID: 533)

Declining water quality on the Great Barrier Reef (GBR) has been linked to a long-term decline of coral cover within the GBR World Heritage area. GBR reefs are naturally exposed to river runoff carrying nutrient and suspended sediment loads, but historical and current land-use practices have enhanced the delivery of terrestrially derived material in to the marine environment. Regional water quality improvement plans are a primary mechanism to manage and improve riverine coastal water quality, through actions in the source catchments targeted at reducing sediment and nutrient delivery into streams, rivers and ultimately the marine receiving waters. Hydrodynamic and biogeochemical models currently being applied to the GBR as part of the eReefs project provide a valuable tool for identifying, quantifying and communicating the spatial impact of discharges from various rivers into the GBR lagoon. Using hindcast simulations of historic wet seasons, river-tagged passive tracers were released from major rivers discharging into the GBR to provide a quantitative identification of high or extended exposure of spatial regions to river plumes. Simulated river exposures were coupled with estimated river nutrient loads to inform a spatial risk analysis of reef exposure to terrestrially derived pollutants. This modelling provided a quantitative basis for prioritizing catchments for management attention, and has informed the refinement of regional water quality improvement plans. http://aims.gov.au

DIVERSITY AND ABUNDANCE OF DECAPOD MACROCRUSTACEANS IN REEFS DIFFERING IN STRUCTURAL COMPLEXITY AND SUBSTRATE TYPES (Abstract ID: 28795 | Poster ID: 293)

Decapod crustaceans are a major component of biodiversity and food webs in tropical coral reefs, but most depend on structured shelter for survival. Therefore, reef decapods might be affected by the ongoing loss of architectural complexity of Caribbean reefs. We analyzed diversity and abundance of decapods in two reefs (Limones and Bonanza) in Puerto Morelos (Mexico). Both reefs were similar in length, distance from the coast, and depth range, but Limones was more structurally complex due to greater acroporid growth, mailny over the crest zone. However, due to sampling constraints, our study was limited to the back-reef zone. Using transects, we assessed structural complexity in this zone using the rugosity index and HAS (habitat assessment score), estimated habitat types cover using AGRRA protocols, and quantified all visible decapods. Although structural complexity at the back-reef zone did not differ significantly between reefs, diversity

and abundance of decapods were higher in Bonanza, which exhibited a greater variety of substrate types. Three of the most abundant decapods occurred in close association with certain substrates, e.g., Calcinus tibicen (Anomura) with Millepora complanata, Domecia acanthophora (Brachyura) with Acropora palmata, and Mithraculus coryphe (Brachyura) with rubble. Our results provide a baseline for future comparisons and suggest that, in coral reefs, local diversity and abundance of decapods are modulated by the diversity of substrate types coupled with structural complexity and the establishment of commensal and other types of association.

DYNAMICAL MODELING OF COUPLED SOCIETAL-CORAL REEF SYSTEMS (Abstract ID: 29889)

Societal-coral reef relationships are often rooted in ecological context, historical legacies, coastal heritage, and place-based socio-cultural traditions. These relationships have a nonlinear, dissipative character across spatio-temporal scales that render the coupled whole a complex dynamical system. Complex systems can exhibit feedback loops, preferred configurations (attractors), threshold-induced transitions (bifurcations), self-organization, emergence and other rich behaviors. As a complement to discipline-focused approaches, we take an initial step towards gaining insight into the societal-coral reef complex system by combining a dynamically based modeling approach with a set of complexity-based tools for analyzing model results. Coral reefs are simulated with a continuum partial differential equation model that has been upscaled from a spatially explicit cellular model. Modeled coral reefs are linked, via a fish population model, to fishing societies represented by agent-based models. Societal decision-making occurs either with utility functions that couple local fishing to a global fish market or with a heuristic decision-tree (transcending delineation of resources by value) in a traditional subsistence fishery. System behavior is characterized by emergent dynamics, attractors and bifurcations, and also by using nonlinear spatio-temporal forecasting to probe phase space. The dynamical contrast between a subsistence and a market-based fishery will be presented, and implications for management will be discussed.

WILL WE MANAGE TERRESTRIAL POLLUTANT RUNOFF SUFFICIENTLY TO SAVE THE GREAT BARRIER REEF IN THE FACE OF CLIMATE CHANGE. (Abstract ID: 28036)

The Great Barrier Reef is in severe decline with coral cover down 75% since the 1960s and seagrass in decline. Causes of the decline are catchment pollutant runoff, climate change and fishing. Under current management the decline continues. In response to a UNESCO request to the Australian Government to show how the government planned to address the dire situation the 2050 Long Term Sustainability Plan (LTSP) was produced. The Plan is widely criticized by scientific and conservation groups as completely inadequate for its purpose. A major component of the Plan is action to manage water quality by better management of agriculture (beef grazing & cropping). Pollutant load targets are set – a reduction of 50% in fine suspended sediment loads and 80% in nitrogen loads in priority areas by 2025. A reliable estimate of funding required to implement management practices sufficient to achieve the targets is a minimum of A$780 million over the decade. This funding is unlikely to be available from Australian and Queensland Government sources. It is also unclear whether the improved management options currently available will be sufficiently effective in reducing loads by the required amounts. In the current situation it is highly unlikely the targets will be met by 2025 and "sufficient" resilience provided to Reef ecosystems to prevent further declines in the face of increasing climate change impacts. Our hope is for large increases in funding in the near future and rapid, widespread farmer uptake of innovative practices which sharply reduce sediment and nutrient losses from farms.

CORAL REEF FISHES USE MANGROVE-DERIVED CHEMICAL CUES TO DIFFERENTIATE SETTLEMENT HABITATS (Abstract ID: 29254)

While coral reef fishes are known to use chemical cues derived from terrestrial vegetation to locate settlement habitats, whether these cues originate from the vegetation itself or rather from associated microbial communities has not been determined. Mangroves are a ubiquitous component of tropical coastal ecosystems, with stands frequently growing adjacent to coral reefs. As mangrove leaf fall often peaks during periods of high fish recruitment, cues from these leaves may represent an important source of settlement cues. In flume trials, both Indo-Pacific (Fiji) and Caribbean (Belize) reef fishes exhibited the ability to distinguish the odor of leaves from healthy versus polluted reefs. The strongest preferences were shown for fallen, submerged leaves suggesting a microbial influence. The results of a patch reef study indicated that reef-associated mangrove leaves can directly affect levels of recruitment. Recruitment was highest on patch reefs paired with the odor of healthy-reef mangrove leaves and lowest when paired with the odor of polluted-reef mangrove leaves. However, when microbial communities were artificially removed from these leaves any difference in recruitment was not seen. These results suggest that reef-associated vegetation, and specifically the microbial communities associated with plant material, can provide recruiting fishes with an important source of information regarding both the location and health of nearby settlement habitats.

RECOVERY TRAJECTORIES OF REEF FISHES FOLLOWING LARGE-SCALE DISTURBANCES SUGGESTS A HIGH DEGREE OF RESILIENCY AND IMPORTANCE OF HABITAT AVAILABILITY AND QUALITY (Abstract ID: 30072)

Many significant impacts threatening coral reefs worldwide occur at the landscape scale and result in long-lasting changes to live coral cover and reef architecture. While short-term monitoring efforts have proved useful at documenting the immediate changes that occur following such a disturbance, longer-term studies often are required to disentangle the independent and combined effects of the loss of live coral and reduction in habitat complexity on reef-associated communities. The reefs surrounding the island of Moorea recently experienced two large disturbance events, an outbreak of the crown-of-thorns seastar and large waves associated with a cyclone, which significantly reduced the cover of live coral and reef topographic complexity at an island-scale. In the 2-3 years immediately following these events, total abundance of reef associated fishes declined, overall fish biomass increased and species richness remained virtually unchanged. These results were due primarily to the substitution of very abundant, small-bodied, coral dependent species by larger bodied species of mobile herbivores. Recent data indicates that as live coral cover has increased, the species composition of the associated fish community has begun to return to its pre-disturbance state suggesting a high degree of resiliency. Recovery of populations of coral dependent species has occurred in an ordered manner related to the increasing size of newly recruited corals indicating that habitat availability and quality play a key role in structuring communities of reef associated fishes.

VERMETID GASTROPODS AND ALGAE REDUCE CORAL GROWTH VIA CHANGES IN THE PHYSIO-CHEMICAL ENVIRONMENT AND MICROBIOME (Abstract ID: 28190)

Interaction modifiers alter the intensity of pair-wise interactions between other species. On coral reefs, macroalgae interact with corals, and the strength of this interaction can influence shifts from coral-dominated to algal-dominated communities. Other organisms can potentially modify the effects of algae on corals. For example, the nets of the sessile vermetid snail,*Ceraesignum maximum*, decrease coral growth and survival. These nets also may exacerbate the environmental conditions that lead to deleterious effects of macroalgae on corals. Using a combination of field and lab studies, we tested if (and to what extent) *C. maximum* modifies the effects of algae on coral growth by changing environmental conditions and altering the coral microbiome. Growth of corals (as measured by linear extension and calcification) declined in response to the combined effects of algae and vermetids. Vermetid nets reduced flow and led to changes in the oxygen microenvironment, even in the presence of high water flow. Potentially fueled by retention of microbial substrate (e.g., DOC) under nets, bacterial diversity and the relative abundance of Vibrios increased in the presence of vermetid nets. These results indicate that vermetids exacerbate the effects of algae on coral growth potentially via changes in physio-chemical conditions and microbial communities. Thus the presence of *C. maximum*has the potential to degrade reefs. However, in 2015, there was a recent mass die-off of *C. maximum* in French Polynesia. This die-off may lead to healthier corals and promote reef recovery.

TRACING THE IMPACTS OF LAND-USE CHANGE TO CORAL REEF FISHERIES (Abstract ID: 29108)

Coral reef fisheries are important for the livelihoods of millions of people, yet are threatened by both overfishing and land-based inputs of nutrients and sediment. Integrated coastal planning requires linking land-uses to their impacts on fisheries, but quantifying these linkages is hindered by the diffuse and displaced impacts of land-uses on fisheries. We quantify the impacts of land-use change to a coral reef fishery in Fiji. Using statistical models that link land-cover maps, river run-off, reef habitat and fish biomass, we are able to link land-use change in catchments to resultant impacts on reef fisheries. The models indicate that stricter fishery management could improve fish biomass, but is critically constrained by poor water quality on numerous of reefs. Catchment management in several critical areas could improve fish biomass. Maps that quantitatively link land-uses in catchments to the productivity of fisheries offer a powerful tool to inform coastal planning.

OCEAN ACIDIFICATION HAS NO EFFECT ON CORAL BLEACHING OR RECOVERY FOR SCLERACTINIAN CORALS (Abstract ID: 28729)

While effects of OA on hermatypic coral calcification are species-specific, the effects of OA on Symbiodinium photosynthesis are equivocal. Through the measurement of growth (calcification) and changes in photophysiological parameters (production, absorption) of the 2 scleractinian corals O. faveolata and P. astreoides, that were exposed to combinations of elevated pCO2 and temperature, the present study aims to establish an energetic model capable of quantifying future hermatypic coral calcification rates using autotrophic energetic inputs as predictors. Neither photosynthetic production or absorbance properties for O. faveolata was affected by pCO2 or temperature. P. astreoides also showed no effect of pCO2 on photosynthetic production or absorbance properties, but at high temperature (31.0 C), a significant reduction of 77% was seen for photosynthetic production and a reduction of 63% in absorbance properties. To further quantify the effect of OA on photophysiological function, P. astreoides that "bleached" at high temperature were allocated to ambient and high pCO2 treatments, at ambient temperature (27.0 C), where they were allowed to recover. Photosynthetic production recovered to ambient levels in 4 weeks, with no difference in recovery rates between ambient or high pCO2 treatments. Our goal was to increase the understanding of metabolic costs of OA and create a predictive model for future tropical reef systems, in an attempt to further our understanding on the effects of global climate change, as well as aiding in the management of current emission scenarios.

INFORMING CORAL REEF MANAGEMENT DECISIONS AT FOUR U.S. NATIONAL PARKS IN THE PACIFIC USING DATA FROM A COMPREHENSIVE, LONG-TERM MONITORING PROGRAM (Abstract ID: 29639 | Poster ID: 625)

Effective management of coral reefs is challenging with local and global stressors. Robust monitoring data are critical to reef management. In 2006, the Pacific Island Network Inventory and Monitoring program of the U.S. National Park Service implemented monitoring protocols at four national parks in Hawai'i (Kaloko-Honokōhau National Historical Park [KAHO], Kalaupapa National Historical Park [KALA]), Guam (War in the Pacific National Historical Park [WAPA]), and American Samoa (National Park of American Samoa [NPSA]). Benthic marine community, marine fish assemblage, and land-based surface and groundwater quality protocols used a split panel sampling design to collect data on ecosystem "vital signs" and processes at replicate sites per park. Vital signs include coral species richness, percent coverage of benthic substrate types, fish abundance, fish biomass, and water quality variables. The value of these data is highlighted in three case studies that describe how the monitoring data have been used to manage an array of issues at the parks. First, reef areas at NPSA and WAPA vulnerable to Acanthaster planci outbreaks were identified to determine whether, and where, to focus culling efforts. Second, data were used at KALA to delineate zones with high fish biomass that were sensitive to fishing activities and warranted increased management. Third, surface water quality and groundwater data at KAHO were used to take management action that mitigated land-based threats to coral reefs. Comprehensive monitoring enables informed decision-making for resources.

OVER A DECADE OF CHANGE IN SPATIAL AND TEMPORAL DYNAMICS IN HAWAIIAN CORAL REEF COMMUNITIES (Abstract ID: 29021 | Poster ID: 713)

The Hawai'i Coral Reef Assessment and Monitoring Program (CRAMP) was established in 1999 to describe spatial and temporal variation in Hawaiian coral reef communities in relation to natural and anthropogenic factors. In this study, we analyzed changes over a 17-yr period (1999 to 2015) based on data from 64 permanent reef stations at 32 sites in the main Hawaiian Islands. Overall mean statewide coral cover, richness, and diversity did not vary significantly since the initial surveys, although local variations in coral cover trends were detected. The greatest proportion of stations with significant declines in coral cover was found on the island of Maui (0.4), while Hawai'i Island had the highest proportion of stations with significant increases (0.67). Shallow (<5 m) stations experienced the majority of significant increases and decreases. Trends in coral cover at some stations varied over time due to acute (e.g., crown of thorns outbreak) and chronic (e.g., sedimentation) disturbances. Stations with increasing coral cover with the potential for recovery from disturbances were identified for possible management actions in the face of future climate change. Increasing water temperature in 2014 and 2015 has resulted in major coral bleaching events with associated mortality. Temperature models predict severe bleaching events to increase in frequency and intensity in coming decades with concomitant decline in Hawaiian corals. Trends reported in this study provide a baseline that can later be used to test this predicted decline associated with future warming.

THE FUTURE OF COMPETITIVE CORAL REEF DYNAMICS: EFFECTS OF ELEVATED TEMPERATURES AND OCEAN ACIDIFICATION ON THE PHYSIOLOGY OF ACROPORA-HALIMEDA INTERACTIONS (Abstract ID: 29075 | Poster ID: 278)

Competition for limiting resources, specifically between coral and macroalgae, is critical in determining the structure and function of coral reef ecosystems. Global changes arising from greenhouse gases, notably the speed and scale at which these changes are occurring, are pushing coral reefs into conditions they may not have experienced in the past 420,000 years. These stresses have begun altering ecosystem dynamics, often favouring the superior competitor with deleterious effects to the functions and services of these systems. Here, coral-algal competition was examined temporally via an orthogonal design that investigated the effects of anticipated RCP8.5 seawater temperatures and/or ocean acidification on the calcification, production, and tissue properties of the staghorn coral Acropora and the calcifying macroalgae Halimeda. Seasonal field monitoring revealed Acropora-Halimeda interactions were one of the most abundant coral-algal interactions on the southern Great Barrier Reef, where Halimeda is commonly observed growing at the bases or among the branches of Acropora. In winter, RCP8.5 projected warming quadrupled Halimeda calcification, but only in the absence of RCP8.5 acidification, highlighting the adverse effects of multiple stressors. Remarkably, there were no significant harmful effects on the calcification of either organism due to their physical interaction in winter, suggesting that coral-algal relationships are more complicated than the believed dominance of macroalgae, and may in this case, be a commensal or mutualistic interaction.

HOW DO THEY DO IT? AN EXPLORATION OF THE MOLECULAR UNDERPINNINGS OF IMMUNE PRIMING IN THE SEA ANEMONE*EXAIPTASIA PALLIDA*. (Abstract ID: 29531)

Coral disease outbreaks have been rapidly increasing on reefs worldwide, and our understanding of how corals respond to disease-causing agents remains limited. Our recent work has shown that the anemone *Exaiptasia pallida* possesses a transient form of immune priming lasting for up to one month. In this phenomena, a sublethal exposure to the coral pathogen *Vibrio coralliilyticus* protects the anemone from subsequent encounters, in comparison to naïve hosts. In the present study, we aimed to identify genes involved in the immunological priming response. Four weeks post-priming, both

primed and unprimed animals were exposed to a bacterial challenge, whereas a control group was not inoculated with bacteria. Primed and unprimed hosts were sacrificed for RNA extraction just prior to bacterial challenge, and again four hours following bacterial challenge in both primed and unprimed hosts, as well as with untreated controls animals. RNAseq analysis was conducted to a depth of 10 million reads per biological replicate (n=3). The analysis revealed a gene expression response associated with immune priming. We discovered 11 differentially expressed genes (FDR corrected p≤ 0.05) between primed and non-primed treatments. The molecular response associated with immune priming indicates varied changes in cellular regulation involving biological processes including immune effector processes, defense response to pathogen, and regulation of apoptotic processes. We propose a model to explain the molecular mechanism mediating immune memory in this early-diverging metazoan.

AN OUNCE OF PREVENTION: BUILDING RAPID RESPONSE CAPACITY TO MINIMIZE IMPACTS OF ACUTE REEF IMPACTS ON GUAM (Abstract ID: 29119)

Early response to acute coral reef impacts such as coral bleaching and disease, crown-of-thorns starfish outbreaks, and vessel groundings, can prevent further impacts, facilitate restoration, and provide valuable information to improve long term outcomes. As these events are often unexpected, managers should build partnerships and capacity before an acute event occurs. This is especially important for managers on small islands as local capacity is limited and support may be days or weeks away. Coral reef managers and scientists on Guam have developed a Reef Response Team composed of government agencies and the University of Guam. The team collaborates with a regional network of coral reef managers and receives funding, training, and technical assistance from federal agencies. The team also relies on community reporting as an early warning system. Rapid response to acute impacts allows managers to document impacts, evaluate potential management interventions, and gain valuable lessons or information from the event. Early response to recent ship groundings allowed managers to minimize impacts to sensitive coral reef habitats and sea turtle nesting beaches and lessons learned are now being applied to contingency planning for spill and grounding response. The team also responded to the 2013 coral bleaching event in Guam and assessments and follow-up monitoring will inform reef management strategies. Case studies from Guam, response challenges facing small islands, and recommendations for improving response capacity will be discussed.

CITIZEN SCIENCE TO IMPROVE COMMUNITY ENGAGEMENT: CONSIDERATIONS, CHALLENGES, AND RECOMMENDATIONS FROM THE GUAM COMMUNITY CORAL REEF MONITORING PROGRAM (Abstract ID: 28951 | Poster ID: 731)

The Guam Community Coral Reef Monitoring Program (GCCRMP) works with community members to collect data on reef health and improve community engagement in management. Led by NOAA staff in Guam, the program works with numerous partners, including government, education, and community organizations, to address local management priorities. Over 1,200 residents have participated in the GCCRMP and the program has grown from a simple citizen science project to a more comprehensive science based community conservation program. It began in 2012 with benthic habitat and macroinvertebrate monitoring, but has since diversified to attract new members and sustain member involvement. The GCCRMP now also includes socioeconomic monitoring, stewardship opportunities, and reef impact reporting. In addition, GCCRMP has established strong partnerships with the educational community through service learning and student internship opportunities. Members have investigated the benefits of marine preserves on macroinvertebrates and helped document coral bleaching in 2013 and 2014. The GCCRMP has demonstrated that citizen science can be a powerful tool to improve community engagement and support coral reef conservation efforts. It has also shown the importance of setting reasonable objectives, developing simple methods that can provide reliable data, building partnerships, and communicating effectively. This presentation will describe the evolution of the GCCRMP including successes, challenges, and recommendations for others seeking to establish citizen science and community engagement programs.

POSITIVE MPA EFFECTS AFTER 8 YEARS OF CONSERVATION EFFORT AT REUNION ISLAND (INDIAN OCEAN) (Abstract ID: 29380)

Coral reefs at Reunion Island fringe less than 10% of the coastline and are a focal point for traditional fisheries, recreation and tourism. The increasing demand on the services they provide has led to conflict among users and societal debate. Their degradation, documented since the 1970s, is mainly due to land-derived pollution and overexploitation. To reduce direct human impacts, the Réunion Natural Marine Reserve (RNMR) was created in 2007. It comprises 3 protection levels: general protection zones open to traditional and recreational fishing (45% of surface area), no-fishing zones (49%), and restricted-access sanctuaries (6%). The effectiveness of this marine protected area (MPA) was assessed following a classic BACI design, comparing data from a baseline study prior to its establishment to data collected after 8 years of reinforced protection. Positive MPA effects existed within sanctuary zones on fore reef slopes, showing increases in total fish biomass (+67%), fishable biomass (+78%), biomass of families targeted by traditional fisheries (+900%) and a slight rise in fish diversity (NS). Here, coral cover remained stable or increased, while a general decrease in coral cover and diversity occurred on reef slopes outside sanctuaries along with a strong increase in algal turfs on all monitoring sites. The MPA produces significant biological responses respective of protection levels and the positive outcomes may contribute to a wider acceptance of the necessary constraints of an MPA among local users and representatives.

DIRECT VISUALIZATION OF MOTILE BACTERIAL PATHOGENS TARGETING THEIR CORAL HOST (Abstract ID: 29744)

The infection of corals by pathogenic bacteria is an important contributor to the worldwide demise of coral reefs. These bacteria are always motile, yet the mechanisms by which they migrate towards the coral and land on the surface remain unclear. Dense carpets of epidermal cilia allow corals to generate strong vortical flows, which in addition to enhancing nutrient and oxygen exchange, represent a hostile hydrodynamic environment for motile bacteria and hinder their pursuit of chemical cues emanating from the coral. Using high-speed imaging coupled with dual-wavelength epifluorescent microscopy, we tracked individual cells of the coral pathogen Vibrio coralliilyticus in the immediate vicinity of a scleractinian host, Pocillopora damicornis. We simultaneously determined the bacterial trajectories and the fluid flow produced by the coral's cilia with micrometer precision. This allowed us to directly quantify the ability of the bacteria to target and ultimately reach the coral surface. We find that the strong ciliary flows significantly, but not entirely, impede bacterial navigation towards the coral surface due to (i) the disruption of chemical gradients guiding the bacteria, and (ii) the hindrance of directed swimming by hydrodynamic forces produced by the ciliary flows. Direct visualization of bacteria swimming in the vicinity of the coral host and making initial contact with the coral surface is a powerful approach to shed light on these important precursor steps to infection.

SYMBIONT COMPOSITION AND DENSITY CHANGE WITHIN TWO MURICEA SPECIES OF THE FLORIDA KEYS ACROSS A BLEACHING EVENT (Abstract ID: 28987 | Poster ID: 354)

Coral bleaching (the loss of the algal symbionts) due to increased sea surface temperatures has led to increased mortality of many scleractinians. However, bleaching among octocorals is less common. We monitored Symbiodinium type and densities in two octocorals within the genus Muricea across the Florida Keys 2015 bleaching event. Muricea elongata colonies were tagged and sampled in May, September and November 2015, and colonies of Muricea atlantica were sampled in September and November. Cell densities and symbiont type were determined for each species. Cell densities were significantly different from month to month, with the lowest densities occurring in September, establishing that both species did indeed bleach. Based on cell counts, as well as visual observations, September Muricea atlantica colonies were more severely bleached than Muricea elongata. Preliminary results indicate that both host species harbored strains within the Symbiodinium B184 phylotype. Based on 4 microsatellite loci these species harbor at least 4 (M. atlantica) to 8 (M. elongata) symbiont genotypes, which

differed between host-species. In most cases symbiont genotypes did not change across the bleaching event. These studies are ongoing and additional samples will be collected and analyzed in February and May 2016. These preliminary results suggest that the different bleaching response may be due to the variation in symbiont genotypes between host species implying that a species-specific approach might be needed to address the possibility of an ecosystem composition shift in the Florida Keys.

LIVING ON THE EDGE: REGIONAL EXTINCTION RISK OF CORAL-DEPENDENT FISHES IN A MARGINAL GULF (Abstract ID: 30006 | Poster ID: 301)

The Arabian Gulf is rich in marine biodiversity and resources that serve to provide important ecosystem functions. However, multiple human and environmental impacts, including coastal development and recurrent bleaching events, have led to the degradation of coral habitat in the Gulf. Fishes dependent on coral reef habitat for survival are thus potentially at an inherently greater risk of regional extinction than species not relying on coral habitat. Despite this, the diversity of coral-dependent fishes within the Gulf and the regional effects of coral degradation on these species had yet to be quantified. Using primary literature and expert knowledge, the coral-dependent fishes of the Gulf were identified and comprehensive data on each of their regional distribution, population status and trends, life history characteristics, and major threats were collated to assess their risk of extinction under the IUCN Red List Regional Categories and Criteria. All coral-dependent fishes with sufficient data to assess were listed at elevated risk of extinction because of the limited area and degraded and fragmented nature of coral habitat in the Gulf. Collaborative efforts among all Gulf States are thus necessary for efficient and effective management and protection of the coral habitats and their associated communities within this globally important region.

CORRELATING SYMBIODINIUM DENSITY AGAINST THE FIELD BLEACHING ASSESSMENT SCALE TO QUANTIFY REDUCTION IN SYMBIODINIUM ABUNDANCE ON REEFS OF HAWAI'I ISLAND (Abstract ID: 29844)

Coral bleaching data from field assessments are being extensively collected in the face of a current El Niño event that resulted in significant warming of coral reef habitats worldwide. Although many field assessment protocols determine prevalence and severity of coral bleaching in different ways, the field data are seldom extrapolated to biological measures such as actual density reduction of Symbiodinium in coral tissues. The present research correlated Symbiodinium density of three Montipora species across the scale of bleaching severity used by the Hawai'i Division of Aquatic Resources during the 2015 mass coral bleaching event at Wai'ōpae, Hawai'i Island. The density of Symbiodinium in "completely bleached" was 17.3-50.6% and in "pale bleached" tissue was 46.4-107% of that in "healthy" tissue among the three species of Montipora. The Symbiodinium density data were combined with field monitoring data to extrapolate the extent of reduction in the abundance of Symbiodinium due to coral bleaching at the population scale. Having symbiont density values associated with the bleaching scale allows translation of field bleaching data to a measure of biological functionality to assess the impacts of bleaching on coral holobiont physiology and photosynthetic capacity for the whole reef.

HOW A CORAL PATHOGEN FIGHTS VIRAL INFECTIONS? (Abstract ID: 28037)

The majority of known bacteria are equipped with an immune system that prevents infection by viruses and mobile genetic elements. Foreign intruders are identified via a short fingerprint of their DNA that is stored as a template in the bacterial genome, the so-called "clustered regularly interspaced short palindromic repeats" (CRISPR). We demonstrate that the dominant cyanobacterium in the black band disease mat, is equipped with such a CRISPR immune system. Analyzing CRISPR templates reveals previous bacteriophage infections and provides insights into interactions between viruses and the pathogenic cyanobacteria. Our results suggest that the black band disease mat is a hot spot for viral infections and that cyanobacteria are in a constant arms race with bacteriophages. This presentation summarizes the cyanobacterial CRISPR system and associated DNA fingerprints stored in the cyanobacterial genome. A role for viruses in black band disease has not been previously considered.

GEOMORPHOLOGY AND HOLOCENE EVOLUTION OF KIMBERLEY CORAL REEFS (Abstract ID: 27916)

The Kimberley Bioregion (North West Australia) is characterised by the largest macrotides of any tropical region in the world (about 11 m), frequent tropical cyclones and high-turbidity. Despite these challenging environmental conditions, the region is also known for extensive and diverse intertidal coral reef habitats. While the area has been recognised as an international biodiversity hotspot, it is still poorly investigated, compared to other reefal ecosystems in Australia, primarily due to its extreme remoteness and lack of infrastructure. A combination of remote sensing, sub-bottom profiling and associated sedimentological work produced a reef geodatabase, providing the first detailed geospatial study of coral reefs within the bioregion. More than 800 reefs have been documented and a geomorphic classification scheme for the Kimberley reefs was developed and includes a new "high intertidal" geomorphic class of reef. Reef coring shows that reef growth began soon after the post-glacial flooding of the antecedent substrate. High-resolution acoustic data, acquired along selected reefs, showed that pre-existing substrate has influenced the successive reef morphology. Global sea-level changes, controlled by ice age fluctuation events, provided a signal which is recorded in successive stages of the reef growth, separated by hiatuses. Two acoustic reflectors can be distinguished, marking the boundaries between Holocene (Marine Isotope Stage 1, last 12,000, 10-20 m thick) and Last Interglacial (MIS5, 125,000 ago, 12 m thick) reefs and an ancient Neoproterozoic rock foundation.

HOME IS WHERE THE WAVES ARE: CORALS IN GUAM'S EXPOSED REEF FRONTS ARE RESILIENT TO LOCAL STRESSORS BUT VULNERABLE TO REGIONAL WARMING (Abstract ID: 29170)

High coral cover and diversity are typical of Guam's wave-exposed reef-front habitat. This is in contrast to deeper coral communities that have experienced significant declines in cover associated with *Acanthaster planci* outbreaks. Regular exposure to moderate wave energy may mitigate the effect of some stressors, but few data have been available to empirically test this claim. Using data collected at 45 shallow (5 m) sites during a major bleaching event in 2013, Guam's reef front communities were characterized and assessed for bleaching prevalence. These communities generally exhibited high coral and crustose coralline algae cover and low macroalgae and cyanobacteria cover. The stress-sensitive genera *Acropora* and *Montipora* were in greater abundance along exposed coasts, while the stress-tolerant genera *Porites* and *Leptoria* were more abundant along leeward coasts. In comparison, deeper (15 m) communities assessed during NOAA PIFSC towed-diver surveys in 2011 were homogeneous around the island, with low coral and crustose coralline algae cover and higher cyanobacteria and macroalgal cover. While reef front communities appear to be more resilient to local-scale stressors, bleaching prevalence data indicated they were highly impacted by a regional warming event. The substantial number of taxa shared between reef front and lower slope coral communities suggests that the reef front may serve as refugia for some species. However, the vulnerability of reef front communities to thermal stress may diminish their future ability to provide suitable refugia and aid in recovery of Guam's deeper communities.

LET THE REEF BE YOUR GUIDE: AN ADAPTIVE APPROACH TO MONITORING ON GUAM (Abstract ID: 29106)

Long-term coral reef monitoring programs provide ecological observations essential for both management and research. Effective monitoring programs are question-driven,

achieve sufficient statistical power and confidence, and evolve as new information is obtained. On Guam, a long-term coral reef monitoring program was established to answer managers' questions pertaining to the effectiveness of marine protected areas and watershed management activities, and to assess spatial and temporal patterns in the resilience of Guam's reef systems to climate change-associated impacts. The program uses a split-panel, random-stratified sampling design coupled with standard reef monitoring protocols along with adaptive site boundary determination that is informed by natural environmental regimes. An adaptive approach to site boundary delineation has been critical in determining appropriate stratification and achieving a desired level of statistical power. We demonstrate how benthic habitat homogeneity increased once natural environmental regimes were accounted for. As a result of reformed site boundaries, statistical power ($\Delta = 0.30$, $\alpha = 0.05$) increased multifold for broad level benthic cover categories, including an increase from a power of 0.25 to 0.76 for hard coral cover. Our results highlight the importance of incorporating adaptive capacity into monitoring programs to better focus upon the ecological questions of interest. This effort lends itself to many other monitoring programs that desire to evolve as new information becomes available, and focus on priority questions with increased statistical power.

THE ROLE OF QUORUM SENSING IN THE PATHOGENESIS OF THE CORAL PATHOGEN VIBRIO CORALLIILYTICUS STRAIN OCN008 (Abstract ID: 29870 | Poster ID: 166)

Vibrio coralliilyticus strain OCN008 has been described as a causative agent of acute Montipora White Syndrome (aMWS), a tissue loss disease affecting the Hawaiian reef building coral Montipora capitata. In laboratory infection trials, infection by the pathogen was cell-density dependent, suggesting that quorum sensing is involved in virulence. The genome of OCN008 appears to encode three quorums sensing pathways described in Vibrio harveyi, LuxP, LuxN and CqsS pathways. Levels of HapR, the high cell-density master regulator common to all three pathways, were shown to be cell density dependent. Deletion of the genes, luxP, luxT, or hapR, from OCN008 attenuated virulence by approximately 50%. Additionally, the production of exoenzymes responsible for lipolytic, proteolytic, and hemolytic activity was greatly reduced in luxP and hapR mutant strains, but not in a luxT mutant. Interestingly, deletion of the gene, aphA, the low cell density quorum sensing regulator, also attenuated virulence by 50% but did not affect exoenzyme activity. Taken together, these results suggest that the expression of certain virulence factors in OCN008 is regulated by quorum sensing and relies on the LuxPQS sensor/synthase pathway. Activation of the LuxPQS pathway at high cell density suggests that a high concentration of bacteria is a requirement for expression of certain virulence factors and full virulence of the pathogen. The infection trial results with the AphA mutant highlight the precisely coordinated manner in which virulence factors must be expressed for a successful infection to occur.

OVERFISHING, NUTRIENT POLLUTION, AND TEMPERATURE INTERACT TO DISRUPT CORAL REEFS DOWN TO MICROBIAL SCALES (Abstract ID: 29453)

Many stressors, such as local overfishing and nutrient pollution may reduce coral reef resilience by increasing coral-algal competition. Algal competition reduces coral recruitment, growth, and survivorship by several mechanisms, including disruption of coral microbiomes, which may increase pathogen outbreaks, especially during times of thermal stress. Using a multi-year field experiment, we show that overfishing and nutrient pollution disrupt species interactions down to microbial scales, shifting reefs towards algal dominance, and killing corals by sensitizing them to predation, thermal stress, and bacterial opportunism. Excluding herbivorous fishes from reef plots increased algal abundance >4-fold and intensified coral-algal competition. This destabilized coral microbiomes, elevated putative pathogen loads, and increased coral disease >2-fold and coral mortality >8-fold. Adding nutrients also increased algal cover and killed corals by turning normally benign parrotfish predation deadly - a surprising outcome linked to microbial shifts on bitten corals. Thermal stress exacerbated the impact of local stressors, further disrupting microbiomes of unhealthy corals and concentrating 80% of coral mortality in the warmest seasons. However, mortality increased with thermal stress only if herbivores were removed and/or nutrient pollution increased; corals in control plots grew despite similar temperature profiles. These results show how altering important trophic interactions can fundamentally reorganize ecological communities down to microbial scales.

INSIGHTS INTO CORAL RECOVERY BASED ON SYMBIONT STATE AND ENVIRONMENTAL CONDITION IN THE TEMPERATE, FACULTATIVELY SYMBIOTIC CORAL ASTRANGIA POCULATA (Abstract ID: 28812)

Understanding the dynamics of coral health and the coral-algal symbiosis are becoming increasingly important to coral reef conservation. Here, we examine wound healing as a proxy for coral colony resilience and its potential contribution to coral reef recovery. We used the temperate, facultatively symbiotic coral Astrangia poculata to explore the role of symbiosis (involving Symbiodinium psygmophilum) and the impacts of environmental condition- via changes in temperature (9, 18, 24°C) and food availability (with or without ad libitum feedings of copepods)- on the healing ability of experimentally wounded colonies. Regardless of environmental condition, symbiotic corals exhibited a significant healing advantage over aposymbiotic colonies. Overall, recovery success increased with temperature and with prey availability. This analysis suggests that, with or without the potential for heterotrophy, a relationship with Symbiodinium promotes higher tissue replacement and integrity. Regardless of symbiont state or whether the colonies were fed, we observed minimal decline in total colony tissue cover and no difference between symbiont states under fed and starved conditions. This suggests that colonies in both symbiont states may preferentially allocate energy towards colony integrity when a wound is inflicted. Lastly, significant reductions in healing ability occurred under cold temperatures, suggesting that, in temperate corals- as might be expected- recovery and survivability are more greatly impacted by winter conditions than by exposure to high temperature.

UTILIZING INNOVATIVE THREE-DIMENSIONAL RECONSTRUCTION TECHNIQUES TO ENHANCE ECOLOGICAL AND BIOLOGICAL STUDIES OF CORAL REEFS (Abstract ID: 28924)

The structural complexity of reefs plays a major role in the biodiversity, productivity, and functionality of coral reef ecosystems. 3-dimensional (3D) analyses vastly improve quantification of the structural complexity of coral reef habitats. We used Structure-from-Motion (SfM) photogrammetry techniques to create 3D reconstructions of Hawaiian coral reefs. The resulting models were integrated into geospatial software in order to quantify metrics pertaining to 3D complexity that are known to affect ecosystem biodiversity and productivity. The 3D structural properties of the reconstructed reefs were statistically analyzed to determine how each coral species and abiotic feature contribute to the structural complexity of the benthic environment. Plating and branching corals exhibited the highest surface complexity, slope, and curvature ($p<0.01$). Temporal analyses were also conducted to assess the impacts of acute disturbances on the volume and 3D architectural complexity of coral communities. Loss of live coral cover was found to directly correlate with reductions in both habitat complexity and volume. Furthermore, these techniques were used to map disease lesions on affected coral colonies in a 3D framework. The lesions exhibited statistically distinct clustering across the surface of the affected colonies, thus providing useful information for characterizing disease epizootiology. These innovative techniques can be utilized for an array of research purposes to improve our understanding of how changes in coral composition and habitat structure affect ecosystem processes.

MITIGATING THE LOSS OF STAGHORN ACROPORA FROM BLEACHING MORTALITY, USING RESILIENT POPULATIONS (Abstract ID: 29989)

Guam's coral reefs assemblages have experienced bleaching events in rapid succession within the last five years, resulting in unprecedented losses of coral. In particular, bleaching events in late 2013 and June 2014 lead to catastrophic coral death with 100% mortality in some areas. Shallow populations of staghorn *Acropora* corals are confined to reef flats on Guam and suffered from high mortality in these bleaching events. Staghorn corals serve an important ecological role in coral communities due to their ability to create thickets and structurally stable habitats, but are highly susceptible to bleaching. This study aims to conserve Guam's staghorn corals by growing and outplanting coral fragments. After examining the remaining staghorn populations around the island, some have shown recovery and resilience to bleaching. From these populations, approximately 700 fragments of *A. aspera, A. acuminata, A. muricata,* and *A. pulchra* were collected and

placed in an *in situ* coral nursery. Fragments have shown positive net growth and will be compared to source population growth rates. Additional fragments from resilient source populations will be transplanted to experimental plots on reef flats and monitored for growth and thicket formation in order to identify optimal transplant sites. Finally, nursery-grown fragments will be outplanted to enhance reef recovery in sites suffering from significant mortality.

PERMITTING OF A PIER IMPROVEMENT PROJECT IN HONOLULU HARBOR, OAHU, HAWAI'I (Abstract ID: 28952 | Poster ID: 564)

Hawaii Department of Transportation-Harbors Division (HDOT-H) proposed improvements to two existing piers in Honolulu Harbor. The initial design met the needs of HDOT-H. To comply with the Hawaii Environmental Policy Act and permitting requirements for the Department of Army (DA) permit, AECOS, a local environmental consulting firm, was hired to conduct a biological survey and calculate impacts. The survey found the project would have significant impacts to coral colonies, corals proposed (at that time) to be listed on the Endangered Species Act, and potential acoustic effects on sea turtles and marine mammals. As part of the DA permit, pre-permit consultations were initiated with federal resource agencies and all parties eventually advised that the project would not be permitted as designed. The project was re-designed such that it would have minimal environmental impacts. While impacts would still occur with the new design, in light of the drastic reduction in direct impacts, natural resource agencies approved the DA permit without requiring mitigation. A coral transplant plan was required (and implemented) to avoid impacts. Several years after the initial contract had been let, construction has just begun. From our perspective, we offer the following to improve the permitting process: (1) conduct a biological survey prior to issuing the design contract to better guide the design and (2) establish a mitigation bank to facilitate the permitting process and result in effective implementation of the three steps of mitigation.

LONG-TERM CORAL REEF MONITORING NEAR A COASTAL TECHNOLOGY PARK IN HAWAII (Abstract ID: 29270 | Poster ID: 690)

The Natural Energy Lab of Hawaii Authority (NELHA) is a state agency in Kailua-Kona focused on research, education, and commercial activities that support sustainable industry development in Hawaii. NELHA construction included large pipelines on the Keahole Point reef to pump cold sea water from a depth of 914 m for research. Since 1989, yearly monitoring has been conducted on benthic biota and fish communities to address impact concerns on the areas widely recognized abundant and diverse near shore marine resources. At six survey sites (three with pipelines and three without) coral abundance and diversity indices were estimated along 50 m transects at depths of 5, 10, and 15 m representing three different habitat zones. Results have shown a gradual increase in coral cover over time (currently 54%) with Pocillopora meandrina (11%) and Porites lobata (35%) always among the dominant species and 11 others making up the remaining 7%. No significant difference between sites or habitats was observed. The fish community was monitored at the same sites and depths with 25 m transects. While the species composition of the fish community was highly variable from year to year, no significant overall changes in species richness (S), evenness (J') or diversity (H') were identified during an 18-year period, with the exception of 2012 in which methods were altered, resulting in an outlier sample. The results of benthic biota and fish studies support the conclusion that the reef community adjacent to the NELHA facility does not appear to be significantly impacted by human-mediated inputs.

THE FLORIDA REEF RESILIENCE PROGRAM, 10 YEARS OF A PUBLIC-PRIVATE PARTNERSHIP ON THE FLORIDA REEF TRACT (Abstract ID: 29858)

The Florida Reef Resilience Program (FRRP) is a collaborative effort among managers, scientists, conservation organizations and reef users to develop resilience based management strategies for coping with climate change and other stresses on Florida's coral reefs. The FRRP originated in 2005 from discussions among Australia's Great Barrier Reef Marine Park Authority, the State of Florida, the US National Oceanic and Atmospheric Administration and The Nature Conservancy. Since its inception, The Nature Conservancy has coordinated the steering committee of the FRRP, guiding the collaborative effort between fourteen different organizations representing state agencies, federal agencies, universities and NGO's. One of the most important accomplishments of the FRRP has been the increased collaboration between multiple jurisdictions. This has enabled managers to look beyond their jurisdictions placing their respective sites within the context of the entire Florida Reef System. Two efforts of the FRRP, which have been instrumental in fostering this working relationship, have been the Disturbance Response Monitoring Program and support for management planning processes. The DRM has demonstrated how these multiple partners are able to work collaboratively to accomplish results that are much greater than their individual sites while contributing to a greater understanding of the reef tract as a whole. The scientific knowledge and data gathered from this comprehensive coral monitoring has been an invaluable resource to inform the management processes along the Florida Reef Tract.

THE CAYMAN ISLANDS CORAL REEF RESTORATION EXPLORER (Abstract ID: 29918)

The Cayman Islands Coral Reef Restoration Explorer utilizes multiple models of ecosystem services provided by Coral Reef ecosystems to guide restoration efforts to maximize these services. The ecosystem services models include: tourism, coral connectivity and coastal defense. The Restoration Explorer allows for the planning of coral and mangrove restoration with the focus on enhancing a particular environmental service. The tourism model data represents the number of Photo User Days (PUDs) to estimate the amount of recreation and tourism occurring around the Cayman Islands. The resulting analysis gives an indication of the areas that are most important for tourism. The coral connectivity model used NOAA's Real Time Ocean Forecasting System (RTOFS) ocean circulation model and regional coral reef data to simulate eight coral spawning events from 2008-2011, applying a 30-day pelagic larval duration and 20% mortality rate. Larval dispersal patterns were analyzed between reef units across jurisdictional marine zones in order to identify spatial relationships between larval sources and destinations within countries and territories across the region. Ocean current data were acquired from the NOAA. The Coastal Defense model uses standard engineering techniques to help users estimate how and where to restore or conserve critical habitat, reducing wave impacts and increasing the resilience of the local community and infrastructure.

PHYLOGENETIC DIVERSITY OF CEPHALOPODA (ANIMALIA:MOLLUSCA) WITHIN THE RED SEA (Abstract ID: 29076)

The Red Sea is a geologically young sea (~5 mya) with a relatively understudied ecosystem compared to other major reef ecosystems. The diversity of Cephalopoda within the reef ecosystems of the Red Sea remains poorly characterized. Cephalopods are found in all the world's oceans, from shallow water to the abyssal plains, and are commonly used as fish bait and consumed by most coastal communities. Despite their abundance and common consumption, the there are few reports of cephalopods within the Red Sea. A small number of field guides have reported a total of 9 octopus, 3 cuttlefish, and 8 squid species based on either sightings or photo ID, but little information is found in published scientific literature for Cephalopoda in the Red Sea. We collected cephalopod specimens within the Saudi coastline of the Red Sea to investigate Cephalopoda species diversity and distributions. Samples were photographed for morphological identification, and then tissue samples were subsequently analyzed utilizing the DNA marker cytochrome oxidase subunit I. We will present results of an integrated morphological and molecular examination of our samples in the context of previously described species. The Red Sea region is known for high endemism in some groups; this study will contribute to an understanding of the role that the Red Sea plays in biodiversity and biogeography of the broader Indian Ocean.

THERMAL-STRESS REFUGIA FOR CORALS: OBSERVATIONS IN MESOPHOTIC COMMUNITIES OF APO REEF, PHILIPPINES (Abstract ID: 29070)

On top of local scale coral mortalities, climate change induced mass coral bleaching has alarmingly reduced reefs worldwide over the last decades. Coral bleaching, which is pri-

marily caused by anomalous changes in sea surface temperature and irradiance, is commonly reported for euphotic reefs (<20 m) while still generally viewed as less prevalent in mesophotic reefs (≥30 m). However, more studies are needed to determine whether mesophotic coral communities are indeed less susceptible to bleaching. In May 2015, we studied the prevalence of bleaching in coral communities at shallow (~5 m) and mesophotic reefs (~30 m) at three sites in Apo Reef (Mindoro), which at the time of study was in the 'Bleaching Watch' level of NOAA's Coral Reef Watch Program. Based on in situ measurements, sea surface temperatures of the shallow reefs were 2°C higher than the mesophotic reefs in all sites. Bleaching occurred in only one of three sites. A shallow reef of this site registered 31°C and had higher bleaching prevalence among Acropora corals; acroporids were however uncommon at the mesophotic reef. Seriatopora corals also had higher bleaching prevalence at the shallow than at the mesophotic reef. These initial results suggest that deeper sites may serve as refugia for coral communities from thermal stress, and warrants further monitoring of more sites, especially in relation to predicted El Niño-associated sea surface temperature anomalies. Studies on genetic connectivity and other ecological factors between shallow and deep reefs may provide insights on the resilience of reefs in the face of thermal stress events.

ARE MESOPHOTIC REEFS SAFE FROM EXPLOITATIVE FISHING? (Abstract ID: 29083 | Poster ID: 325)

Reef fish communities are faced with various disturbances, of which destructive and unsustainable fishing practices pose the most direct and immediate impacts. Marine protected areas (MPAs) are among the management measures used to mitigate such impacts, although for pragmatic reasons MPAs are typically located in shallow and more accessible reefs. In the Philippines, reef fish communities at depths >20 m are poorly known and there are no published studies on the potential of deep reefs as refugia from fishing mortality. Here we assess the differences in the structure of reef fish communities (1) between protected areas in deep reefs (25–38 m) and in shallow reefs (8–15 m), and (2) between protected and unprotected deep reefs through underwater fish visual census (FVC). FVCs were conducted at three protected deep reefs (Culasi, Antique; Bayauan, Southern Negros; and Apo Reef, Mindoro) and three nearby protected shallow reefs (Libertad, Antique; Siit, Southern Negros; and Apo Reef, Mindoro). FVC was also conducted in three unprotected deep and shallow reef (Mati, Davao; Calatagan, Batangas; Abra de Ilog, Mindoro). Preliminary results indicate that fish community abundance and biomass are higher in protected deep reefs than in protected shallow reefs. Moreover, the fish community abundance in protected deep reefs is also higher than in unprotected deep reefs; thus deep reefs are also vulnerable to fishing pressure when left unmanaged. Overall, these provide initial indications that protected deep reefs can effectively protect reef fish communities and highlights the importance of extending MPAs to cover mesophotic reefs.

THE ROLE OF MATERNAL NUTRITION ON OOGENESIS AND LARVAL DEVELOPMENT IN THE CORAL-EATING CROWN-OF-THORNS STARFISH, ACANTHASTER PLANCI (Abstract ID: 29143)

Populations of crown-of-thorns starfish, Acanthaster planci, are predisposed to major fluctuations in abundance due to immense fecundity, high fertilization rates, and short generation times. Variation in environmental and biological conditions that result in fluctuations in larval survival and development can have pronounced effects on recruitment rates and population dynamics. Past studies on A. planci have primarily focused on the direct effects of larval nutrition, while the role of maternal nutrition on reproduction and larval development has been overlooked. In many echinoderms, egg size, fecundity, egg quality, and even larval quality can vary with the nutritional history of adults. To examine the effects of maternal nutrition on gametogenesis and larval development of A. planci, we maintained females on varied diets: starved, preferred coral prey (i.e. Acropora spp.) and non-preferred coral prey (i.e. Porites). Fed starfish increased in weight, had heavier gonads and pyloric caeca, and produced larger eggs compared to starved females. Starfish that fed exclusively on Acropora spp. produced bigger larvae with larger stomachs that developed normally and much more rapidly compared to those from Porites-fed and starved females. Because food quality (coral community structure) and quantity (coral abundance) vary widely between adult A. planci populations in coral reefs, any effect of maternal nutrition on larval quality and survivorship may influence the overall reproductive success of A. planci and help explain marked fluctuations in abundance.

RECRUITMENT PATTERN OF JUVENILE REEF FISHES IN PUJADA BAY, MATI CITY, PHILIPPINES (Abstract ID: 29504 | Poster ID: 252)

This study was conducted in an attempt to investigate the relationship of benthic attributes to the abundance of fish recruits. A total of 99 transects were surveyed in two sites within Pujada bay from January 2015 to November 2015. Results have shown that species richness was consistently higher inside the MPA (Tamisan) though not significantly different from a non-MPA site (Catmonon). Moreover, both sites were predominated by Pomacentrids. The pattern of abundance of recruits inside the sanctuary peaked during inter-monsoonal period (April, May and October) while peak of recruitment in non-MPA site was during the Northeast monsoon and extended a bit until April. Comparing the relationships of the different benthic composition with the total abundance of recruits, no significant difference was found. This supports the idea that recruits settle randomly in reefs and thus, stochastic in nature. However, with a closer observation for the abundance of pomacentrid recruits alone, during the Southwest monsoon (June-September) the abiotic component (sand and rubble) showed significant relationship with recruit abundance for both sites. Similar pattern was observed during the inter-monsoonal phase in non-MPA site, Catmonan. In Tamisan MPA, hard coral cover showed significant relationship with Pomacentrid abundance. Hence, recruits may also be dependent on the benthic conditions and composition of reefs. In any case, Tamisan as an MPA was showing good contribution for the reefs in Pujada Bay.

DRIVERS OF REDISTRIBUTION OF FISHING AND NON-FISHING EFFORT AFTER THE IMPLEMENTATION OF A MARINE PROTECTED AREA NETWORK (Abstract ID: 27931)

Marine protected areas (MPAs) are now a common tool in marine spatial planning (MSP) for conserving marine biodiversity and managing fisheries. However, the use of MPAs in MSP often neglects – or simplifies – the redistribution of fishing and non-fishing activities inside and outside of MPAs following their implementation. This redistribution of effort can have important implications for effective MSP. Using long term (14 years) aerial surveys of boats at the California Channel Islands, we examined the spatial redistribution of fishing and non-fishing activities and their drivers following MPA establishment. Our data represents 6 years of information before the implementation of an MPA network and 8 years after implementation. Different types of boats responded in different ways to the closures, ranging from behaviors by commercial dive boats that support the hypothesis of fishing-the-line, to behaviors by urchin, sport fishing, and recreational boats that support the theory of ideal free distribution. Additionally, we found that recreational activities targeted areas that are sheltered from large waves and located near their home ports, while fishing activities also avoid high wave areas but are not constrained by the distance to their home ports. Our work is the first empirical study to analyze the response of both commercial and recreational boats to closure. Our results will inform MSP in better accounting for effort redistribution by ocean users in response to the implementation of MPAs and other closures.

THE NEED TO FIND CORAL REFUGES IN A CHANGING CLIMATE (Abstract ID: 29481)

Reef corals are suffering from thermal stress in a rapidly changing climate, and in places reefs are failing to keep up with sea-level rise. This research focuses on modeling the distribution of a representative suite of reef-coral species to highlight locations where

corals could potentially survive into the year 2100 under climate change. Species-specific responses for this suite of reef- building corals were modeled using both Bayesian mixed effects and generalized linear models on light and temperature parameters, and using a range of mechanistic constraints. Turbidity was also incorporated into model runs, since moderate levels of turbidity has been shown to lower stress by shading the corals from extremely high light. These models were further modified to determine reef community response to projected climate change if coral species are capable of adapting to a 1oC increase in thermal stress. Twelve clear-water climate-change refuges were identified in the Pacific and Indian Ocean. Turbid refuges aligned with the location of clear-water refuges in the southern hemisphere, but were also identified in the northern hemisphere outside of the clear-water refuges. Modeling the capability to adapt to a 1oC increase in thermal stress decreased the predicted loss into the year 2100, although massive Porites spp., were predicted to increase slightly. Our latest models incorporate genetic connectivity to predict distributions into the future.

ENVIRONMENTAL FACTORS SHAPE SPACE USE OF CORAL REEF FISH (Abstract ID: 28488 | Poster ID: 518)

Variation in the abiotic environment can shape animal movement because it mediates resource acquisition, reproduction, and competition. For instance temperature governs fish metabolism, while water motion can structure fish community composition, distributions, and foraging ability. Despite the importance of fish space use on key ecosystem processes, the effect of the environment on fish mobility and its implications for reef functioning has not been examined. For 16 months we monitored the movements of 251 acoustically tagged fishes from 39 species within two oceanic reefs in the central Red Sea and quantified their response to changes in water temperature, tides, current, wind speed, and lunar and solar ephemerides. Environmental variables influenced both daily cumulative and maximum distance in a large majority of the fish, but with no detectable pattern across species or trait groups like feeding guild or shoaling behavior. However, we found a number of predictable effects on fish movement in general. An analysis of the network formed between fish and its coral reef habitat revealed that fish visited a larger area of the reef during periods of high tidal amplitude and a smaller area during strong currents. In addition, the overlap of fish spatial niche decreased at high temperatures even though the overall distance moved was not significantly affected, presumably due to a concentration on reef areas of higher productivity. Our results help understand how the role that fish play on reef resilience might be shaped by a changing environment.

CORAL INTERIOR CARBONATE CHEMISTRY MEASURED WITH PH AND CARBONATE MICROELECTRODES SUGGESTS THAT THE CHEMISTRY OF THE CALCIFYING FLUID AFFECTS RESILIENCE TO OA (Abstract ID: 28076)

Reliably predicting how coral calcification may respond to ocean acidification (OA) depends on our understanding of coral calcification mechanisms and inorganic carbon processing. To better understand these processes, we used pH and carbonate microelectrodes to profile through coral tissue and into the calcifying fluid in three species of coral (Acropora millepora, Orbicella faveolata, Turbinaria reniformis). These first combined measurements of pH and carbonate in corals constrain the inorganic carbon system allowing inference of CO2, total dissolved inorganic carbon (DIC), and alkalinity concentrations. We observed sharp increases in carbonate and pH from the gastric cavity to the calcifying fluid, confirming the existence of a proton pumping mechanism. We also show that corals can achieve a high aragonite saturation state by maintaining high pH while at the same time keeping DIC low. Such a mechanism may require less proton-pumping and energy for upregulating pH compared to the high DIC scenario and thus allow corals to be more resistant to ocean acidification. These results also suggest that differences in calcifying fluid chemistry among coral species may in part explain differences in susceptibility to ocean acidification.

LIVELIHOOD VULNERABILITY OF COASTAL COMMUNITIES TO CHANGES IN MARINE RESOURCE USE: CASE STUDY OF FIJI AND SOLOMON ISLANDS (Abstract ID: 28683)

Fisheries support the livelihoods of over half a billion people globally. The Pacific Islands are surrounded by the sea, therefore most coastal communities traditionally are highly dependent on marine resources as their main source of animal protein and livelihood. Their dependence on marine resources makes them highly vulnerable to any change in the status of these resources. In this study we examined livelihood vulnerability of coastal communities in Solomon Islands and Fiji to changes in marine resource availability over time. Household surveys, key informant interviews and focus groups were conducted in ten communities in Fiji and nine in the Solomon Islands. Livelihood vulnerability was measured as a function of exposure to changes in marine resource availability as a result of overharvesting and other anthropogenic pressures; sensitivity factors related to dependency on and access to these resources; and adaptive capacity in terms of physical, natural, financial, human and social capital. We find that livelihood vulnerability of households is highly contextual. Remote communities lacking physical and financial capital displayed low vulnerability, and the most exposed community may not necessarily be the most sensitive. However, households that are directly dependent on marine resources are highly sensitive to any decrease and are extremely vulnerable if they have low adaptive capacity. Therefore contextual management approaches that consider the different sources of vulnerability and potential strengths are a necessity in community-based marine resource management.

A COMPARATIVE NETWORKANALYSIS OF A MARGINAL REEF FROM THE EASTERN PACIFIC PRIOR AND AFTER 20 YEARS OF PROTECTION (Abstract ID: 29761 | Poster ID: 524)

Cabo Pulmo is the northern most coral reef in the eastern Pacific and it was declared as a marine protected area in 1995. It has become an icon of an effective no-fishing area thanks to the support of the local community. Under the hypothesis that after 20 years of effective protection the ecosystem should be more 'mature' sensu Odum, we built two balanced mass trophic models using Ecopath, one with field data gathered in 1998 and other with 2013 data, to compute biomass flow (Total system throughput. T), Production/Biomass (P/B), Ascendency, (A), Overhead (O), development capacity (C) and other ecosystem attibutes. Both models have the same 48 functional groups selected based on their functional role in the ecosystem. Present P/B = 28.507, Total system throughput is 43,343.5 t/km$^2$/year, A = 38,896.0 flowbits, O = 63,281.1 flowbits and C = 116,889.9 flowbits. Even when there has been a notably increase of biomass of the higher trophic level groups and, as expected, current P/B < 1, total system throughput has only increased 1%, Ascendency 4%, Overhead 7%, C 5% and O/C, a measure of system resistance (redundancy), 1%, in comparison with prior to protection condition. This would suggest that either protection not necessarily leads to maturity or it may take longer than expected.

QUANTIFYING THE CONTRIBUTION OF SEA URCHINS TO THE BIOEROSION OF HAWAIIAN CORAL REEFS (Abstract ID: 29777)

Bioerosional processes from urchins can contribute significantly to the destruction of reef geomorphology, shifting the balance between erosion and accretion necessary for the persistence of coral reefs. We estimate the relative contribution of sea urchins to benthic erosional processes inside and adjacent to a long-term no-take MPA in the Hawaiian Islands, hypothesizing that bioerosional contributions would be dominated by sea urchins outside of the reserve, where urchin predators are targeted by fisheries. At 50 sites inside and adjacent to the 'Āhihi Kīna'u Natural Area Reserve, divers observed the size frequency of urchins using standard visual survey methods. Empirically-derived relationships

between bioerosional rate and body size were then used to estimate the total bioerosional contribution for urchins based on their size-specific densities at each site. Urchin communities were dominated by the rock-boring urchin Echinometra mathaei and the red slate pencil urchin Heterocentrotus mamillatus with lower densities of five other urchin species. A better understanding of the bioerosional contribution of urchins provides vital information for the understanding of thresholds in the accretion-erosion dynamics of coral reefs.

APPLICATION OF SATELLITE SST-BASED CORAL DISEASE OUTBREAK PREDICTIONS FOR HAWAII (Abstract ID: 28853)

Remote sensing of sea surface temperature (SST) has become increasingly valuable for identifying threats to coral reefs in recent years. Here, we compare field observations with satellite-based predictions of disease prevalence for the three most common coral diseases in Hawaii: Montipora white syndrome, Porites growth anomalies and Porites tissue loss syndrome, with data collected from 18 Hawaiian Islands and atolls between 2004 and 2015. Our predictive boosted regression tree models were created using ~4km SST data and site level measurements (e.g., host density), and predicted disease risk up to 6 months prior to an expected outbreak event. Our results suggest winter pre-conditioning and host density are key drivers of disease susceptibility. However, the relative influence of seasonal thermal metrics varied with the specific disease. Coral disease outbreaks often occur subsequent to bleaching events, although the underlying relationship explaining this pattern remains unclear. In light of the recent mass coral bleaching in Hawaii, it will be useful to closely monitor coral health in the upcoming year. Experimental coral disease outbreak tools are currently available through NOAA Coral Reef Watch; the models here can improve interpretations of the near real-time products for these Hawaiian diseases. This enhances management capacity to prepare for and respond to emerging coral diseases and can be modified for other diseases and regions around the world. Additional remotely sensed parameters, such as ocean color metrics, could enhance such models in the near future.

REEF FISH SURVEY TECHNIQUES: ASSESSING THE POTENTIAL FOR STANDARDIZING METHODOLOGIES (Abstract ID: 29872 | Poster ID: 270)

Dramatic changes in reef fish populations have been documented globally and, in response, the research community has initiated efforts to assess and monitor reef fish assemblages. A variety of visual census techniques are employed, however results are often incomparable due to differential performance of methods. Although comparability of data may promote improved assessment and management of nearshore fisheries, to date no standardized and agreed-upon survey method has emerged. This study aims to describe the use of methods across the research community and to test potential factors linked with selection of method. An online survey was distributed to researchers from academic, government, and non-government organizations internationally. Although many methods were identified, 89% of survey-based projects employed one of only three methods – belt transect, stationary point count, and some variation of the timed swim method. The selection of survey methods was found to be independent of the research design (assessment goal) and region of study, but related to the researcher's home institution. While some researchers expressed willingness to modify their current survey protocols to more standardized protocols (76%), their willingness decreased when methodologies were tied to long-term datasets of ongoing projects of 5 or more years. Willingness to modify current methodologies was also less common among academic researchers than resource managers. By understanding both the current application of methods and the reported motivations for method selection, we hope to focus discussions towards increasing the comparability of quantitative reef fish survey data.

NIGHTTIME DISSOLVED OXYGEN SPIKES ACROSS CORAL REEF ENVIRONMENTS: BIOLOGICAL OR NOT? (Abstract ID: 28946)

Light driven photolysis of water is believed to provide all the elementary oxygen found in nature. The evolution of photosynthesis, the only known biological photolytic process, profoundly shaped the face of this planet. This has led to the assumption that photosynthesis is the only significant source of ecological primary production, and the main input to consider when calculating a total ecosystem oxygen budget. However, during our attempts to calculate just such a budget, a prevalent, globally observed spike in dissolved oxygen concentration occurring at night altered our assumptions regarding primary production. These spikes have been observed across a multitude of tropical environments over many years, as evidenced by our own research and an exhaustive literature survey of studies involving high resolution, overnight dissolved oxygen measurements. Calculating a complete and accurate oxygen budget will need to include the contribution of these nighttime dissolved oxygen concentration spikes where ever they occur, regardless of whether they are biotic or abiotic in origin. Using a combination of field and experimental measurements, we show that: 1) this phenomenon can be isolated in vitro using benthic samples collected from a coral reef, 2) it is strongly associated with crustose coralline algae, and 3) it cannot be explained by a purely abiotic process. This leads to the prediction of a biological source for these nighttime dissolved oxygen spikes, and suggests that a process other than canonical photosynthesis may be involved.

PILOTING A WATERSHED-SCALE MODEL FOR COLLABORATIVELY ADDRESSING LBSP STRESSORS ON CORAL REEFS IN WEST MAUI, HAWAII, USA (Abstract ID: 28492)

In response to the complexity of stressors contributing to the decline of live coral in West Maui, Hawaii, USA and the need to go beyond managing ocean pressures to addressing land based pollutants, a collaborative partnership cutting across jurisdictions and interests called the West Maui Ridge to Reef Initiative (R2R) was formed in 2012. The network of partnerships in the R2R including those enabled through US Coral Reef Task Force and State priority watershed designations have been central to early successes and shared lessons learned in the region. The R2R is led by federal and state agencies that provide funding and oversight for watershed management planning and implementation in West Maui, as well as technical and research support. However, without the support from the community, landowners, and other local stakeholders, the buy-in is missing for implementation of proposed mitigation strategies. As a result, a local working group representing targeted land and ocean interests was formed to provide practical insights that facilitate the transition from watershed planning to implementation. A loosely defined Hui (team) of non-profits, researchers and consultants carry out recommended strategies on a project by project basis. Lessons learned to date follow themes universally relevant to watershed managers, such as the importance of sufficient scientific information, the barrier maintenance presents where capacity is limited, the importance of an institutional support structure and the degree of community and local government engagement needed to remain relevant.

ACROPORA CERVICORNIS SEXUAL CORAL REPRODUCTION TO COMPLEMENT THE RESTORATION PROGRAM IN NURSERIES IN THE DOMINICAN REPUBLIC (Abstract ID: 28395)

In recent decades there has been a reported decline in the abundance of corals worldwide. As part of a strategy to reduce the degradation of reefs and contribute to the recovery of diminished coral populations, nurseries and areas of transplanted coral fragments have been established in different parts of the world. In the Caribbean Acropora cervicornis loss has resulted in a reduced ability to successfully reproduce both sexually and asexually. In the Dominican Republic there are coral gardening programs of restoration, growth and transplant of A. cervicornis. The sexual reproductive maturity of this species in coral nurseries has been evaluate in order to supplement the program. Histological sections of fertile polyps confirmed the maturity of the gonads prior to spawning. Collection of gametes and assisted reproduction was conducted as well as the observation and documentation of the stages of embryonic development, larval development, larval settlement and metamorphosis into primary polyps. Currently, tests are underway for the incorporation of symbionts. It was documented that in nurseries the largest fragments had the highest percentage of spawning, presenting a lower rate of growth, while fragments that did not spawn showed a higher rate of growth. It is important to combine restoration techniques not only to restore degraded areas but also to ensure the genetic diversity of the species.

LEGACIES OF THE PAST FEED MISMATCHES BETWEEN REGULATIONS AND CORAL REEF FISHERIES (Abstract ID: 30142)

Fisheries regulations should evolve in response to improved science and the changing dynamics of the fisheries in question. However, the legacy of past regulations may still manifest themselves when they are no longer appropriate. This may be particularly evident in small-scale fisheries in developing island nations where resources and capacity to respond are limited. As a case study, we investigated the fisheries legislation of the Turks and Caicos Islands in order to identify any mismatches with the fisheries they are designed to regulate, and to assess the obstacles preventing these mismatches from being rectified. Numerous mismatches were evident, particularly for the most economically important fishery, spiny lobster (Panulirus argus). Some long-standing regulations have become culturally engrained, and are enshrined along with an outdated or incorrect understanding of the species' ecology. Confronting these mismatches would be met with heavy resistance, and could also jeopardise the credibility of the management authority.

CHANGES IN THE ULTRASTRUCTURE OF THE CORAL *POCILLOPORA DAMICORNIS* EXPOSED BY HIGH TEMPERATURE, ULTRAVIOLET AND FAR-RED RAYS (Abstract ID: 28600 | Poster ID: 427)

Light and temperature are known stressors causing the collapse of coral-algal symbioses. However, it has been poorly understood how these stressors induce coral degradation in an early stage. Here we investigated ultrastructural changes in coral tissues and symbiotic zooxanthellae under high temperature (HT), ultraviolet (UV) and far-red (FR) rays. Coral was collected from Tosa Bay, Japan and small fragments were maintained in glass dishes with sterilized seawater at ambient room condition. Regenerating corals were placed on 32C water bath, while other exposed to UV-A (4.5 w/m2) and FR (2.0 w/m2) rays. After 15min–48h treatments, samples were fixed and embedded in resin. Thin sections were observed with TEM. In control, coral tissue was generally intact that consists of epidermis and gastrodermis interconnected by acellular matrix mesoglea. Zooxanthellae were enclosed by two membrane-like structures in the cytoplasm of gastrodermis. There were few autophagosomes and lysosomes in the coral tissues. After 6h exposure to FR and UV-A, dark granules appeared along with vacuolization of gastrodermal cells. Prolonged light treatments brought brought about fragmentation and destruction of cytoplasmic contents. This eventually led the collapse of gastrodermis then release of gastrodermal cells containing zooxanthellae in the gastric cavity. Zooxanthellae were remarkably affected where thylakoids and cortical membranes partially rupture. Autophagosome densities gradually increase. Treatment with HT also induced gastrodermal degrdadation, zooxanthellae disruptions and autophagic structure.

MANGROVE HABITATS SELECT CORAL POPULATIONS TOLERANT OF PH AND TEMPERATURE CONDITIONS PREDICTED FOR REEFS UNDER CLIMATE CHANGE (Abstract ID: 28099)

Corals can persist in environments that are considered extreme and approach the edge of conditions where corals normally thrive. Within tropical reef systems, mangrove habitats routinely experience reduced pH and elevated temperature that effectively parallel (or exceed) climate conditions predicted over the next 100 years. Corals persisting among mangroves are thus potentially "future proofed" but to date have been largely unstudied. Exactly how corals are able to survive under these extremes is unknown. We present data from two reef-adjacent mangrove systems from the Indian (Seychelles) and Pacific (New Caledonia) Oceans. As expected, coral diversity and abundance is lower among the mangroves than on the neighbouring reef. However, several species observed in the mangroves are those that comprise the main neighbouring coral reef framework. Novel "pH-performance assays" for key coral species demonstrated that mangrove populations appear to thrive by diel downregulation of metabolic processes during the most extreme pH-temperatures, whereas reef populations attempt metabolic regulation that incurs a cost to their overall fitness. We also identify how high organic content, paralleled with increased respiratory metabolism, suggests that heterotrophic plasticity is important in facilitating coral acclimatisation to combined hot-acidic waters. Together these data reveal key physiological traits potentially required for corals to survive climate change. We also highlight present day coral populations that could become central to future reef restoration programs.

CAN ANYONE BE A SCIENTIST? EXPLORING THE ROLE OF CITIZEN SCIENCE IN CORAL REEF RESEARCH (Abstract ID: 29893)

Individuals lacking scientific training have made important contributions in many disciplines historically, but the role and value of public participation in modern professional research is controversial within the scientific community. Beneficially, citizen scientists provide a source of labor, a variety of skills, and capital, for example, paying to spend their vacations participating in environmental and ecological research. This link between the public and research serves as a bridge between science and education, creating a more environmentally informed populace. Additionally, citizen science is becoming a major supplement to undergraduate degree programs, providing opportunity for students to acquire applied field experience. At the same time, the contributions of non-scientists are questioned and more easily dismissed by the scientific community on the basis that the data they collect may not be accurate. Through a survey of participants, organizers, and scientists, this study evaluates and compares the role of both public and student-oriented citizen science in coral reef research, with a case study focused on the Central Caribbean Marine Institute on Little Cayman Island, at which the lead author participated in an ongoing National Science Foundation Research Experience for Undergraduates program. We examine stakeholder perceptions, interest, engagement, quality of experience, and outcomes, with the goal of identifying challenges and opportunities that, if addressed, could optimize the use and effectiveness of citizen science programming, and resulting outreach.

ACOUSTIC DIVERSITY AND BEHAVIOR OF CORAL REEF FISH AGGREGATIONS FROM SONAR SURVEYS (Abstract ID: 29625)

Coral reef ecosystems are among the most diverse and productive in our oceans. Over 4000 species of teleost fishes are associated with coral reefs, raising challenges to monitor the abundance and the distribution of reef fish in order to develop an effective conservation policy and to evaluate the effect of management actions. Fisheries acoustics is one of the tools that is widely used in fishery assessments, but remote species identification is challenging in diverse reef systems with limited studies on acoustic characteristics of reef species. The work proposed here is an attempt at improving the marine ecosystems acoustics for the study of coral reef fish communities. We review long-term marine ecosystem acoustic surveys in the US Caribbean and evaluate metrics that describe behavioral patterns and species-specific acoustic characteristics of coral reef species. Based on these metrics, schools and aggregations were clustered into 5 distinct groups. The use of underwater video surveys from a Remote Operating Vehicle (ROV) conducted in the proximity of the acoustic observations allowed us to associate the clusters with broad categories of species groups such as large predators, including fishery important species to small forage fishes. The distribution of the clustered aggregations was then paired with habitat–related metrics derived from multibeam surveys in order to evaluate the association of coral reef species with habitat complexity that could further improve species classification during acoustic surveys and develop predictive models of species distribution. Challenges and possible applications of the approaches used in this work are presented and discussed.

THE RESPONSES OF CALCIFIED GREEN ALGAE (*HALIMEDA* SPP.) TO CLIMATE CHANGE STRESSORS (Abstract ID: 29495)

Ocean acidification (OA) stands to influence the physiological functioning of a variety of marine calcifiers. While many of these responses have been documented for reef invertebrates, we know relatively little about the responses of other taxonomic groups, primarily calcified green algae. Furthermore, in addition to elevated $CO_2$, the interactive effects of alternate environmental parameters (e.g. temperature) are just now being investigated, which can add complexity to previously documented responses. We present a series of mesocosm experiments that describe both the singular and combined effects of OA and thermal stress on several species of calcified green algae. Multiple experiments with *Halimeda incrassata*, *Halimeda simulans* and *Halimeda opuntia* were conducted in independent tanks which replicated a variety of $pCO_2$ (400-1400 ppm) and temperature treatments (28-31°C). Measured responses included calcification (alkalinity anomaly and buoyant weight), photosynthetic output (oxygen evolution), and mineral $CaCO_3$ content (gravimetric acidification). Data show that while calcification generally declined with OA for multiple species, elevated temperature had an opposing effect, serving to increase both calcification and photosynthetic production. Thus, in certain

cases, elevated temperature (+3°C) may mitigate OA effects. Subsequent experiments with *H. opuntia*further reveal linear increases in net calcification with temperature, thereby highlighting the importance of other environmental parameters on OA responses. http://www.sms.si.edu

WATERSHED RUNOFF AND SEDIMENT RESUSPENSION: FACTORS AFFECTING TURBIDITY AND SEDIMENTATION IN BAYS WITH CORAL REEFS, ST. JOHN, USVI (Abstract ID: 29153 | Poster ID: 438)

Land-based erosion and terrigenous sedimentation is a major coral reef stressor in the USVI. On St. John, land development has increased sediment yields and marine terrigenous sedimentation by up to an order of magnitude above background. Once deposited, resuspension of benthic sediment may further increase turbidity and deposition (T-D). However, isolating the relative contributions of runoff vs. resuspension using conventional sediment trap monitoring has proven challenging. Here we describe the spatial variability of marine sediment dynamics in response to runoff vs. resuspension events in St. John and compare monthly vs. high-resolution monitoring approaches. Nephelometers (10-min. res.) were deployed beside sediment traps (~monthly res.) at three reef and four shoreline sites next to ephemeral stream outfalls equipped with water level sensors (10-min. res.) and peak crest gauges (~2-week res.). Monthly mean sediment trap accumulation rates and nephelometer data were strongly correlated. Runoff events resulted in high-magnitude (up to 900/17,000 times background) but short-lived (hours) spikes in T-D. Resuspension-induced spikes in T-D were lower in magnitude but longer (days-weeks), particularly at sites with finer-grained benthic sediments, and were associated with increased wave height during low tides. While the relative contribution of runoff vs. resuspension to T-D was spatially variable, both processes produced responses that greatly exceeded water quality standards and coral stress thresholds for short timeframes (hours to days).

CLIMATE VARIABILITY AND THE RESILIENCE OF LOW DIVERSITY CORAL COMMUNITIES TO BLEACHING IN THE GILBERT ISLANDS, KIRIBATI (Abstract ID: 28273 | Poster ID: 207)

Ocean warming due to climate change threatens to cause frequent coral bleaching and degrade coral reefs across the Pacific. Recent research has suggested that past temperature experience, including exposure to variable temperatures and/or frequent heat stress, confer greater resilience to climate change. The central equatorial Pacific, where the El Niño / Southern Oscillation, drives year-to-year shifts in current strength, current direction and consequently ocean temperatures, is an ideal natural laboratory for evaluating the influence of past sea surface temperatures (SST) on the susceptibility of individual corals and coral communities to heat stress. This presentation describes changes in the coral community over the past decade, including multiple El Nino-driven heat stress events, in the little-studied Gilbert Islands of Kiribati. Changes in benthic cover, coral size distribution as well as the bleaching index (for the 2009-2010 El Niño) are contrasted between a matrix of sites exposed to different levels of SST variability and human disturbance across four atolls. Spatial analysis shows that patterns in coral bleaching are best correlated with light and the coefficient of variation of past sea surface temperatures, rather the magnitude of heat stress during the El Niño event (e.g. degree heating weeks). The long-term data indicates that reefs subject to the combination of high human disturbance and high temperature variability are the most resilient to heat stress, due to the presence, and continued expansion, of the "weedy" species Porites rus.

FREQUENCY OF MAJOR STRESS EVENTS ON THE GREAT BARRIER REEF: LONG-TERM TRENDS IN CALCIFICATION AND COMMUNITY COMPOSITION AS INDICATORS OF REEF RECOVERY (Abstract ID: 29843)

Defining, measuring and monitoring coral reef health is fundamental to understanding the future of coral reefs in a changing ocean. Long-term trends in reef health improve our understanding of how dynamic reef processes alter the composition and productivity of reef ecosystems in order to identify resilient reef habitats for management. In this study we combine two key indicators of coral reef health, annual trends in colony calcification rates and benthic composition and cover, with environmental factors to document and assess the frequency of major disturbances and their impacts across decadal and century time-scales. Calcification rates for the Great Barrier Reef suffered an 11% decline between the late 20th and early 21st century, following two major widespread bleaching events in 1998 and 2002. Calcification records from a subset of these coral colonies, collected a decade later, indicate that calcification rates recovered from these thermal stress events within 3-4 years, returning to baseline calcification rates. These skeletal growth records provide a long-term assessment of how individual coral colonies respond to stress events, enabling us to quantify rates of recovery. In this presentation we will compare trends in coral calcification with shifts in community composition to understand and define the frequency and severity of major disturbances and assess recovery trends on reefs along the Great Barrier Reef.

SEASONAL VARIATIONS IN STABLE ISOTOPIC VALUES OF PARTICULATE ORGANIC MATTER FROM LUHUITOU FRINGING REEFS, SOUTH CHINA (Abstract ID: 27837 | Poster ID: 305)

Coral reefs have suffered remarkable declines of both coral cover and coral species worldwide. Nutrient over-enrichment is considered to be one of the causes of coral decline. Luhuitou fringing reefs, south of Sanya city, is a famous tourism spot and much influenced by anthropogenic activities. This study reviews current nutrient status of fringing reefs in South China and evaluates primary nutrient sources using stable isotopic method. Results show that δ13C and δ15N values of particular organic matter (POM) are statistically significant with seasons. In dry seasons (spring and winter), there are more terrestrials and anthropogenic-derived nutrients; and in wet seasons (summer and autumn), there are more marine derived nutrients. The overall δ13C values suggest marine and terrestrial-derived nutrient sources. Organic carbon is a mixture of marine phytoplankton, marine benthic algae and terrestrial-derived plants. The δ15N values suggest terrestrial-derived sewage and upwelling-dominated nitrogen sources. In the presence of natural upwelling and coastal currents, coastal coral reef areas are more vulnerable to the increasing anthropogenic nutrient inputs. These results provide some understanding of the declining coral reef ecosystem and the importance of conservation areas and coastal coral reef resource management.

HITCHHIKING IN THE SEA: EVIDENCE OF VECTORS TRANSPORTING THE INVASIVE CORAL SPECIES TUBASTRAEA COCCINEA AND T. TAGUSENSIS IN THE SOUTHWESTERN ATLANTIC OCEAN (Abstract ID: 29676)

Human activities are responsible for an unprecedented connectivity in the marine environment. The opportunistic and highly competitive invasive species Tubastraea coccinea and T. tagusensis were first recorded in Brazil in 1980 on oil platforms and have spread over 3,000km, including oil platforms and monobouys. This study presents the first data on the genetic diversity and population structure of both species from rocky shores, oil platforms and a monobuoy along the Brazilian coast using 11-12 microsatellite loci. A high number of clones were found for both species, particularly in the coastal populations. The occurrence of repeated MLG and small values of genotypic richness observed at coastal populations indicates that these are most clonal, originated mainly from asexual reproduction. Despite the small number of individuals, in both species the vectors had the highest allelic diversity and expected heterozigosity compared to rocky shores, which is the expected for source populations. A lack of population structure was detected for T. tagusensis, which might be explained by introductions from the same native population. Conversely, five genetic clusters were recovered for T. coccinea, which might be associated with the occurrence of multiples introductions. These findings are expected, as T. coccinea is cosmopolitan while T. tagusensis has a more restrict distribution. Results show that the coast, oil platforms and monobouys share alleles, indicating that the latter two have relevant roles in the spreading of both invasive species along the Brazilian coast.

PHYSIOLOGICAL STRATEGIES TO ACCLIMATISE TO HIGH SEAWATER TEMPERATURE STRESS WHEN HOSTING DIFFERENT SYMBIODINIUM (Abstract ID: 29165)

One mechanism to survive bleaching events is for the host to shuffle to a more thermally tolerant Symbiodinium clade D. Studies have shown that corals shuffle back to Symbiodinium clade C (thermally sensitive) months after heat stress disappears suggesting that there is a tradeoff for corals. But the interactive physiology and fitness benefits of hosting clade D are poorly understood. The South of Taiwan provides a perfect scenario to study the influence of high SST. At the nuclear power plant outlet (OL) in Kenting, there is a constant hot water effluent with an average SST during summer of 2.0–3.0°C higher

than at other sites. In this research with the use of reciprocal transplantation experiments (RTE) the physiological processes of*Leptoria phrygia*, coral that associates with clade D at the OL and clade C in Wanlitong, a site that is not influenced by hot water stress, are being monitored during 18 months. Growth rate, chlorophyll a fluorescence, algae density, protein, and lipids are being measured and compared with *Porites lutea*, a specialist species that associates with the stress-tolerant Symbiodinium clade C15 to understand the different physiological strategies corals have. Preliminary results indicate that only those corals transplanted from Wanlitong to OL that were able to shuffle to clade D survived the hot water stress during the summer. And those corals transplanted from OL to Wanlitong are performing better than the control group. This study will help determine how corals will acclimatise to high SST under future climate change scenarios.

## BACTERIAL VIRULENCE GENE EXPRESSION UNDER HIGH CONCENTRATIONS OF DOC PROVIDES INSIGHT INTO THE PATHOGENIC SWITCH IN OPPORTUNISTIC MICROBES (Abstract ID: 28679)

Algal cover in tropical coral reefs has increased worldwide leading to the alteration of the biogeochemical cycling and microbial metabolism, by the release of DOC-rich exudates. Algal exudates support the growth of virulent bacterioplankton populations, which consequently affect reef health deterioration and disease emergence. However, these same bacterial populations are also associated with healthy reefs, where they fulfill key functions to support the ecosystem. To date there has been no compelling evidence correlating environmental conditions triggering virulence in these opportunists. To shed light on this matter, we evaluated microbial gene expression of the most dominant microbial populations under elevated concentrations of dissolved neutral monosaccharides (DNM) naturally present in algal exudates. Through metagenomic sequencing, we successfully assembled 3 near-complete (>95%) and 20 population genomes (>50%) representing from 14.2 to 30.6% of the community. Bacterial mRNA reads were isolated, sequenced, and mapped to the recovered genomes to determine differential gene expression. The differential gene expression analysis showed a high number of genes involved in pathogenesis during the DNM enrichments, including genes encoding cholera-like toxins and proteins involved in hydrogen sulfide synthesis. Our findings suggest that elevated concentrations of DNM act as a driver of expression of virulence genes in coral reef ecosystems and provide a mechanistic explanation for a functional switch of opportunistic to pathogenic bacteria.

## ASSESSING MITIGATION EFFORTS TO REDUCE SEDIMENT RUNOFF ON CORAL REEFS IN ST. JOHN, USVI USING CORAL GEOCHEMICAL PROXIES (Abstract ID: 28376)

Coral reefs have declined dramatically in the US Virgin Islands (USVI) over the past several decades. Sedimentation is a major stress to USVI coral reefs. Previous work found increased terrigenous sedimentation below developed watersheds in St. John. Erosion control measures recently put in place appear to be at least partially effective. To determine whether mitigated sediment runoff has reached pre-development levels, we are reconstructing historical proxy-based sedimentation records using geochemical signatures in coral cores. We will compare changes in proxy-based sedimentation records over time as well as between Coral Bay (a developed watershed) and Lameshur Bay (a relatively undeveloped watershed), allowing for comparison of how land use change has increased sedimentation in a recently developed watershed. Long-term records of sedimentation onto reefs in St. John based on metal/Ca records from Siderastrea siderea coral cores will be presented, in addition to results from a replication study from multiple short coral core-tops collected adjacent to one another. Cores were also collected adjacent to sediment traps that have recorded seasonal changes in sedimentation over multiple years, thus allowing the possibility of ground-truthing the proxy-based records to actual sediment runoff quantities. Understanding the efficacy of various erosion control methods is vital to controlling anthropogenic inputs in other watersheds. The records constructed here will provide feedback for watershed management strategies employed on St. John and other similar high islands.

## INTEGRATING WATERSHED AND HYDRODYNAMIC MODELS TO QUANTIFY LAND-DERIVED SEDIMENTATION ON REEFS (Abstract ID: 29256)

Land-based sediment transported by rivers and plumes is a major cause of coral reef destruction. However, there are very few integrated quantitative studies that can be used to track sediment transport between land and sea realms. To address this gap, quantitative watershed and hydrodynamic models were linked to describe the sediment exposure of coral reefs in El Nido, Philippines. We used the Soil and Water Assessment Tool to identify critical watersheds that had high sediment yield. We then inputted the sediment load data to Delft3D Flow model to estimate dispersal and deposition of suspended sediments by river plumes. We calibrated and validated the models using low cost water level and light sensors to ensure accuracy of estimated discharge and suspended sediment concentration. We then estimated the exposure of coral reefs to sedimentation by using different scenarios of land use, precipitation, winds and ocean variability. We found that high discharge plume boundaries covered areas in the North of the inner Bacuit Bay, wherein some reefs and islands are used for tourism. This sediment is predominantly Coron-Malalag clay and sourced from a subbasin which is 47% shrubland, 30% forest and 23% mangrove. Hydrologic retention time in the North embayment is relatively long, causing extended periods of turbid water episodes. This study highlights the utility of quantitative models to describe the effects of land-based activities on reefs, and the importance of integrated studies in order to manage sedimentation and land-sea interactions more effectively.

## DEFINING SUCCESS IN ACTIVE CARIBBEAN ACROPORID POPULATION REPLENISHMENT EFFORTS: RESULTS FROM OVER NINE YEARS OF WORK IN SOUTHERN BELIZE (Abstract ID: 27909)

Coral restoration efforts are becoming more accepted as an active management tool but still lack a realistic sense of scale, and quantifiable, comparable, success indicators. Specific active replenishment goals are to restore lost ecosystem services like shoreline protection, fisheries enhancement, biodiversity preservation, and provisioning of aesthetic and economic services for the tourism industry. Continuity is key to ecosystem service values, which requires that the restored coral community be (1) self-sustaining and self-propagating, and (2) resilient against persistent insults. Genetic diversity must be addressed regardless of propagation methods. How much genetic diversity is needed? What amount of coral coverage, and where, is needed to trigger natural regenerative processes at larger scales? Presented here are data from over nine years of acroporid restoration efforts at Laughing Bird Caye National Park, Belize, where over 26,000 nursery-grown acroporid fragments have been out-planted. Data were acquired on host and algal clade diversity, growth rates and survival, bleaching history, reproductive indicators, methods for measuring live coral cover over time, methods to assess changes in fish biomass on out-planted sites, and mechanisms to include local community members in the work. We suggest realizable goals and success indicators, offer guidance for expanding restoration efforts to new sites, and recognize Marine Protected Areas and stakeholder involvement as key to coral restoration.

## GROWTH AND DEMOGRAPHY OF THE MEDITERRANEAN ENDEMIC SOLITARY CORAL *BALANOPHYLLIA EUROPAEA* LIVING ALONG A NATURAL $PCO_2$ GRADIENT (Abstract ID: 28605)

Increasing research effort on marine calcifying organisms is important and urgent, given the projected $CO_2$-driven ocean acidification for the coming century. Here we assess the

growth and population dynamics of the Mediterranean endemic zooxanthellate solitary coral *B. europaea* at three sites along a natural $pCO_2$ gradient of the volcanic vents off Panarea Island (Italy), in the Mediterranean Sea. *B. europaea* was the only scleractinian found along the gradient and its abundance decreased with increasing $pCO_2$. The age-length relationships, obtained for each site by sclerochronology through computerized tomography, resulted homogeneous and then data were pooled to obtain a general age-length relationship. Skeletal linear extension rate and bulk skeletal density were measured and net calcification rate was calculated for each sample at each site. While linear extension rate did not vary with $pCO_2$, bulk skeletal density and net calcification rate decreased with increasing $pCO_2$. The population age structure was obtained by analyzing photoquadrats and several observed and theoretical demographic parameters were derived (age structure stability, instantaneous rate of mortality, average age, % of immature individuals, age at maximum biomass, average age of biomass) and compared among sites. Populations showed a deficiency of young individuals with increasing $pCO_2$. The species seems sensitive to ocean acidification even if the photosynthetic efficiency of its symbionts increases with $pCO_2$, suggesting an even higher sensitivity for shallow water non-zooxanthellate scleractinians.

A 3000 YEAR RECORD OF ABUNDANCE AND DYNAMICS OF THE KEYSTONE URCHIN DIADEMA ANTILLARUM FROM ANALYSIS OF SUBFOSSIL SPINES FROM REEF SEDIMENT CORES (Abstract ID: 30055 | Poster ID: 5)

The long-spined sea urchin Diadema antillarum has been described as a keystone grazer in Caribbean coral reef ecosystems. In the 1980s an unknown pathogen resulted in a mass die-off that caused a near extinction of this population across the Caribbean, catalyzing an explosion in macroalgal cover that led to a region-wide decline in coral abundance. Because of Diadema's importance as the last abundant reef herbivore following the overfishing of herbivorous fishes and its failure to recover following the mass dieoff, it is important to understand its baseline abundance and prospects for future recovery. However, little is known of the natural dynamics of this species due to the lack of a historical baseline. We reconstructed a 3000 year record of Diadema abundance by isolating and weighing spines preserved in reef matrix cores collected from three reefs in Bocas del Toro, Panama. We found that Diadema was a consistently rare component of the urchin community at the midslope zone (6-8m), comprising only 3% of total urchin spine weight on average. Diadema abundance was closely linked to reef accretion rates, indicating its strong reliance on coral-dominated habitat. Other than declines associated with declines in reef accretion, we did not find any evidence of previous mass dieoffs. We also found no evidence of an increase in Diadema abundance over the historical period due to prey release from overfishing. These results reveal that Diadema's failure to recover following the dieoff may be related to the degradation of coral habitat in subsequent decades.

ENVIRONMENTAL DAMAGE TO CORAL REEFS IN THE SOUTH CHINA SEA AND INTERNATIONAL ARBITRATION UNDER THE UNITED NATIONS CONVENTION ON THE LAW OF THE SEA (Abstract ID: 29776)

Recent island building activities and unrestrained exploitation on the reefs of the South China Sea raise questions regarding national obligations under international treaties. An historic test of these obligations under the United Nations Convention on the Law of the Sea (UNCLOS) was heard before the UN Permanent Court of Arbitration at the International Court of Justice in the Hague in November, 2015. Evidence was presented to document the extensive coral reef damage from dredging for island building in the South China Sea. Scientific evidence indicates that this damage to coral reefs is likely to influence reef productivity throughout the region, including in adjacent exclusive economic zones. Additional evidence of unrestrained exploitation targeting giant clams, corals and reef fishes was presented that are indicative of poor fisheries management and causing additional threats to endangered species. The Permanent Court of Arbitration accepted to hear the case under UNCLOS and environmental lawyers argued that these actions contravene UNCLOS treaty obligations. Arguments were also made that actions violating the UN Code of Conduct for Responsible Fisheries support the case according to obligations under UNCLOS. A decision on this arbitration, expected in the first half of 2016, will have far-reaching policy implications for environmental actions in disputed waters.

A SPATIAL MANAGEMENT TOOL FOR SEAGRASSES IN THE GREAT BARRIER REEF WORLD HERITAGE AREA (Abstract ID: 27805)

The Great Barrier Reef (GBR) World Heritage Area includes one of the world's largest seagrass ecosystems (35 000 km2) with approximately 20% of the world's seagrass species. Key to understanding and managing this important ecosystem is reliable data on seagrass distribution, abundance and species composition, and how this changes through time. A range of mapping and monitoring programs since the 1980s have documented GBR seagrasses. These include GBR-wide coastal and seabed seagrass mapping through the 1980s and 1990s and a biodiversity mapping project in 2004; reef-top meadow mapping adjacent to shipping lanes as part of an oil spill response atlas in the remote northern GBR (2011-2014); and small-scale but long-term (>15 years) monitoring programs at coastal ports (e.g. Cairns and Gladstone). Until recently managers could not access the full range of seagrass spatial data in a format that included a range of scales, site and meadow information, nor could they interrogate the reliability of the dataset. We found, evaluated and incorporated over 300 seagrass spatial data sets collected from the GBR spanning 30 years into two publicly available GIS layers. We include information on seagrass presence/absence, percent cover, biomass, species present, dominant species, meadow area and survey date. This management tool allows seagrass information to be categorized depending on management questions regarding development, zoning, and planning, and is available for resource managers to model connectivity, better understand seagrass change, identify regions where seagrass information is deficient, and identify key seagrass areas for dugong and turtles.

COMPETITIVE STRATEGIES OF THE CORALLIMORPH *RHODACTIS HOWESII*: ALLELOPATHIC EFFECTS ON CORAL MICROBIOMES AT PALMYRA ATOLL (Abstract ID: 29866)

Phase shifts from coral to algal dominance have become increasingly common on coral reefs around the globe, often in association with anthropogenic activities. However, alternative states can include other benthic organisms such as soft corals, sea anemones, sponges, or corallimorpharians, and are often associated with large-scale physical disturbances. Here, we focus on the invasion of *Rhodactis howesii* , a corallimorpharian on the coral reefs of Palmyra Atoll. Despite the apparent competitive dominance and demonstrated invasive potential of the corallimorph, little is known about the mechanisms involved in its spread across around the atoll. We used a laboratory experiment involving the exposure of the reef building coral *Acropora yongei* to corallimorph crude extract to investigate potential allelopathic effects of the extract on the coral microbiome. Exposure to the extract resulted in significant tissue loss and a decrease in photosynthetic efficiency of the corals. Samples were taken from degraded and healthy *Acropora* tissue for metagenomic analysis to look at shifts in the microbial communities present. This study represents an important initial step in determining what provides *Rhodactis howesii* with its competitive abilities and will help further our understanding of the invasion occurring at Palmyra Atoll.

EFFECTS OF BLEACHING ON CORAL REPRODUCTION (Abstract ID: 28887)

Bleaching profoundly impacts coral reproduction often for years after an event. However detailed reproductive characteristics of coral post-bleaching have not been broadly described, especially as it relates to cryopreservation. Therefore, we measured a number of reproductive characteristics in coral in Kaneohe Bay in Hawaii in two species, Fungia scutaria and Montipora capitata during the bleaching period of 2014 and 2015. We examined and compared comprehensively with historical data: 1) spawning periods; 2) egg morphometry; 3) sperm concentration; 4) fresh and cryopreserved sperm motility exposed to differing concentrations of dimethyl sulfoxide; 5) time of first cleavage; 6) larval survival with fresh and cryopreserved sperm; 7) infection success; and 8) settlement success. Virtually all parameters of reproduction were reduced due to warming and bleaching stress. Because of this, we were interested in how cryo-stress might affect fertilization success and the time of first cleavage. In stressed fresh eggs and sperm, the addition of dimethyl sulfoxide altered the time of first cleavage. Moreover, once sperm was cryopreserved, this resulted in a steep decline in post-thaw viability and prevented any substantive further use in reproduction for conservation benefit. Worldwide as bleaching events become more frequent, the ability to bank and conserve coral ex situ will become significantly reduced. Thus, it is imperative that while genetic diversity is still high in these populations that intensive efforts are made to bank coral species during non-bleaching periods.

IDENTIFYING SOURCES OF RESILIENCE IN CORAL COMMUNITIES USING A SPATIAL AGENT-BASED MODEL (Abstract ID: 28449)

Identifying attributes of coral reefs that confer resilience in the face of multiple stressors is a pressing challenge, but one that is logistically difficult to meet. By facilitating simultaneous manipulation of processes and attributes that would otherwise be too numerous or unwieldy to explore experimentally, agent-based models (ABMs) provide one valuable approach. Here we describe a spatially explicit, 2-dimensional ABM designed to elucidate if and how functional diversity (FD) within coral reef communities moderates resilience in response to multiple stressors. Each grid cell of the ABM covers 1 cm2 of a reef benthic community, and can represent part of a coral colony, a patch of algae, or a portion of barren ground. Agents can change their state through time in response to the following processes: spatial competition, erosion, grazing, and larval settlement, the latter moderating connectivity. Initial FD of communities varies among iterations, is derived from trait information gleaned from the literature, and is quantified in terms of the volume and dispersion that it exhibits in multi-dimensional trait space. Cyclones and bleaching events are imposed in the simulation, and the response of communities is measured in terms of resistance, recovery and capacity to retain identity of the community. We believe that this bottom up modelling approach can contribute to our understanding of the theoretical relationship between resilience, FD, and connectivity in coral reef ecosystems, and can also inform ongoing research and management efforts.

BACTERIAL COMMUNITY PROFILING OF CORAL SPECIES ACROSS A BLEACHING EVENT (Abstract ID: 28791)

The functional importance of microbial communities associated with eukaryotes is increasingly recognized in many fields. The reef-building coral holobiont is notably diverse with microbes occupying roles everywhere from intimate endosymbionts to transients associated with external mucus layers. While the complexity is great and the full architecture of associations is not known, microbial communities are highly dependent on geographic location, host species, and environmental conditions. Recently, microbial communities have been suggested as playing an important role in coral bleaching. Recognizing the likely importance of the microbial dimension to understanding and predicting the response and resilience of corals to thermal stress, we surveyed Acropora hyacinthus, A. gemmifera, Porites cylindrica, and Pocillopora damicornis before, during, and after a significant natural bleaching event in 2015 in American Samoa. Although prior to the bleaching event samples had not been collected with microbial profiling in mind, we developed methodology to extract microbial DNA from our archived samples. We used 16S rDNA amplicons coupled with multiplex barcoding and paired-end 300bp sequencing on the Illumina MiSeq platform to survey hundreds of individual samples per species cost-effectively. Increased sample size and the ability to use archived samples in microbial surveys significantly adds to experimental power in the search for microbial correlates of coral heat resilience. We discuss the results of our particular survey as well as general considerations for undertaking similar metagenomic work.

PERIODICALLY-HARVESTED CLOSURES EMERGE AS OPTIMAL MANAGEMENT STRATEGIES WHEN FISH BEHAVIOR IS CONSIDERED (Abstract ID: 29225)

Periodically-harvested closures (PHCs) are a form of community-based fisheries management often implemented within customary fishing grounds throughout the Pacific. Communities, and their co-management partners that advocate the use of PHCs, have broad objectives of fishery sustainability and conservation. However, PHCs are designed more specifically to increase harvest efficiency, and for occasional exploitation of protected stocks to support local social events. Despite their prevalence, the effectiveness of PHCs for simultaneously achieving these objectives remains uncertain. To assess PHC fishery outcomes, we developed a bioeconomic fisheries model that included fish behavior, and quantified how PHC open-closed schedule affects harvest efficiency (catch-per-unit-effort), biomass conservation and sustainable fishery yield. We also compared PHC effects with the effects of non-spatial and no-take marine reserve harvest regulations – forms of conventional management often heralded as optimal in well-managed and over-fished systems, respectively. Optimal PHC design was sensitive to overharvesting; regardless PHCs were more effective at achieving the multiple objectives than either conventional method. Key to the results is the fishers' ability to reduce fish wariness and increase catchability in PHCs targeting finfish using strategic harvest schedules. These findings challenge the dogma that PHCs are simply a cultural legacy to be accommodated by contemporary fisheries science, and instead place PHCs center stage as a potentially optimal fisheries management strategies.

EFFECT OF MULTIPLE AND SYNERGISTIC STRESSES ON CORALS AT MICRO/NANO SCALE (Abstract ID: 28613)

Global environmental changes are recently occurring faster than any other time. The resulting combinations of natural and anthropogenic disturbances are strongly affecting coral reef communities. Coral damage can be caused both by abiotic factors (temperature, nutrients inputs, etc) and biotic factors (overgrowth of algae, diseases). These factors acting mostly in synergy had resulted in world-wide coral reef deterioration. Coral bleaching is the most impacting process that is affecting coral survival under elevated sea surface temperature and high irradiance scenario. Bleaching is well known to occur around the world; however its mechanism is not well understood. This is due to the high complexity of the "coral holobiont" (coral in symbiosis with its zooxanthellae and a microbial community that is maintain a delicate balance to keep the coral healthy. A novel point of view of bleaching mechanism using micro/nano size scales will be presented: 1) Study of pigments during thermal induced bleaching revealed that bleaching is a detoxification strategy to avoid oxidative stress; 2) Synergistic action of thermal stress with pathogenic bacteria exacerbates bleaching process and 3) Synergistic effect of thermal stress in a nitrate enriched environment can impede the recovery of corals after a bleaching event, turning the corals to be more susceptible to other environmental or anthropogenic stressors. This scientific approach to study the effects of multiple stresses at micro/nano scales revealed the importance of organisms' adaptations within certain thresholds

CHARACTERIZING THE GROUPER FISHERIES AND STOCKS IN SELECTED MUNICIPALITIES OF THE PHILIPPINES (Abstract ID: 29051)

Groupers are found all over the Philippines but are prone to population decline and extirpation due to high fishing pressure and lack of effective fisheries regulations throughout the country. This study provides an overview on grouper fisheries and standing stock in at least ten municipalities in the Philippines. Data from fisheries assessments using focus group discussions and semi-structured interviews and from underwater fish visual census were used in the analyses. Results show that municipalities with intense and unregulated grouper fisheries (i.e. Anda, Bolinao, Lian, Governor Generoso, Bais, Cabugao and Santiago) have low grouper densities (0.25-3 ind/500m2.), low biomass (6.82-137 g/500m2), and an assemblage dominated by few, small-sized and least-valued species only. In contrast, municipalities with functional and effective fisheries management interventions (e.g. gear restrictions, marine protected areas) that attenuate the effects of fishing, such as in Taytay and Sablayan, have higher densities (4-6 ind/500m2) and biomass (223-486 g/500m2), and with large or highly valued species still present in their coral reefs. In the case of Samal Island, high grouper density (5.56 ind/500m2) yields a relatively low biomass (78 g/500m2) due to the fact that most of the observed fishes were juveniles, suggesting that adults might be overfished. This study provides a list of areas that need prompt action to remediate further stock collapse and identifies critical grouper species that should be prioritized for conservation.

RESOURCE COMPETITION AND PREDATION RISK DIFFERENTIALLY AFFECT PARROTFISH FORAGING BEHAVIORS (Abstract ID: 28442)

Parrotfishes interact with coral reefs in many important ways. They consume algae that compete with coral for space on the benthos and facilitate coral settlement by scraping bare spaces on the reef. It has been demonstrated that the spatial patterning of herbivore foraging may be an important determinant in the trajectory of coral reef benthic state. In

order to evaluate the relative importance of food resource abundance, competition, and predation risk on structuring parrotfish foraging behavior, we conducted a comparative study at two islands that are subject to drastically different management regimes. One of the islands (Palmyra Atoll) is pristine and unfished with high biomass of herbivores and predators while at the other (Mo'orea, French Polynesia) both trophic groups are fished. Our results indicate that both predation risk and competition for resources play a role in structuring foraging behaviors in Bullethead parrotfish (*Chlorurus sordidus* ), but they act of different aspects of foraging. Bite rates were affected primarily by direct interference competition and chronic level of predation risk, measured by predator abundance. However, predator abundance had no effect on space use which was related to levels of exploitative competition from other herbivores in the community, particularly large-bodied parrotfishes. Because herbivore and piscivore populations are sometimes independently managed on coral reefs, it is important to understand how interactions among these trophic groups affect a suite of behaviors related to herbivory.

A TEST OF TROPHIC CASCADE THEORY: FISH AND BENTHIC ASSEMBLAGES ACROSS A PREDATOR DENSITY GRADIENT (Abstract ID: 27990)

Removal of predators is often theorized to alter community structure through trophic cascades. However, evidence is often circumstantial on coral reefs because fishing pressure frequently co-varies with other anthropogenic effects. Australia's Great Barrier Reef (GBR) has experienced fishing-induced declines of apex predators and mesopredators, but fishers do not target herbivorous fishes and pollution is minimal on the outer GBR; thus, the GBR provides an ideal system to investigate trophic cascade theory. Here, I quantify fish and benthic assemblages across a fishing-induced predator density gradient on the GBR, including apex predators and mesopredators to herbivorous fishes and benthic assemblages, to test for evidence of trophic cascades. Using a structural equation model, I found no cascading effects from apex predators to lower trophic levels: a loss of apex predators did not lead to higher levels of mesopredators, and this did not suppress mobile herbivores and drive algal proliferation. Likewise, I found no effects of mesopredators on lower trophic levels: a decline of mesopredators was not associated with higher abundances of algae-farming damselfishes and algae-dominated reefs. These findings indicate that top-down forces on coral reefs are weak, and densities of most community members are regulated by indirect factors that vary through space, such as regional effects, stochastic disturbances, trophic versatility, and system openness. We conclude that predator-mediated trophic cascades are probably the exception rather than the rule in this complex ecosystem.

DECLINE IN ABUNDANCE AND HEALTH STATE OF AN ATLANTIC SUBTROPICAL GORGONIAN POPULATION (Abstract ID: 29560)

Losses in coral cover have been widely reported for the Caribbean. In contrast, much less is known about the health state of the Brazilian reef fauna, which was declared as a priority for Atlantic biodiversity conservation due to its high degree of endemism. In the present study we assessed the general health state of *Phyllogorgia dilatata* assemblages at the subtropical reefs of Arraial do Cabo (southeastern Brazil), where observations suggest that the abundance of this endemic gorgonian species has declined. We found that about 49% of the sampled colonies were dead, and 73% of the living colonies were affected by tissue loss. Tissue loss initially manifested as multifocal holes in the planar colonial coenenchyme and peripheral tissue retraction leaving denuded skeletal axes. In combination with other recent studies, our results raise the awareness for an increasingly threatened Southwestern Atlantic reef coral fauna.

IMPACT OF OCEAN WARMING ON CENTURY-SCALE GROWTH TRENDS OF INSHORE AND OFFSHORE CORALS THROUGOUT THE WESTERN CARIBBEAN SEA (Abstract ID: 29535)

Anthropogenic elevation of atmospheric carbon dioxide continues to cause global ocean temperatures to increase. Although this rise in ocean temperature has generally reduced rates of coral growth worldwide, considerable variability in corals' growth response to thermal stress exists across the reefscape. Previous studies suggest that corals exposed to historically greater baseline diurnal and seasonal fluctuations in temperature are better able to cope with future anthropogenic thermal stress. We investigated the relationship between historical sea surface temperatures and annual skeletal growth parameters (skeletal density, skeletal extension, calcification rate) of *Siderastrea siderea* and*Pseudodiploria strigosa*–two abundant, widespread, and long-lived massive scleractinian corals–across three different reef systems spanning 2000-km of the western Caribbean Sea. Over 240 coral cores were extracted from paired inshore-offshore localities of the Florida Keys Reef Tract, Belize Barrier Reef System, and Panama's Bocas Del Toro Reef Complex and then scanned for density using computer tomography. Our results indicate considerable variability in coral growth response to warming both between and within the three reef systems, with a colony's specific growth response to recent anthropogenic warming being closely linked to its baseline environmental history. Results provide one of the most comprehensive overviews of coral growth response to past ocean warming and offer insights into how corals are likely to respond to predicted future changes in ocean temperature.

DYNAMICS OF CARBONATE PRODUCTION OF HALIMEDA ON SHALLOW CORAL REEFS (Abstract ID: 28428)

The calcifying alga Halimeda contributes significantly to the production of carbonate sediments. Carbonate production by Halimeda is driven by primary productivity, calcification and herbivory, yet the relative importance of these processes is unclear. Understanding Halimeda dynamics is critical to make plausible predictions about their contribution to reef carbonate budgets. For example, Halimeda is often flourishing within the complex structure of branching acroporids which offer protection from herbivory but how coral habitats affect Halimeda carbonate production is unknown. This is important because these corals are highly susceptible to climate change. To answer this question we developed an individual-based model of Halimeda population dynamics by incorporating rates of recruitment, segment growth, herbivory and other sources of mortality. The model was parameterized with seasonal demographic rates estimated using fish-exclusion cages in Heron Island, Australia, and successfully predicted the observed biomass of Halimeda both inside and outside Acropora habitats. Carbonate production peaked in summer with Halimeda productivity being enhanced by temperature. Because carbonate production was higher inside Acropora habitats in summer, high temperature in the future may increase Halimeda production of carbonate sediments. However, this outcome may be altered by future losses of Acropora habitats due to thermal stress. As fish herbivores may also be affected by a loss of structural complexity, predicting the future of Halimeda carbonate dynamics is uncertain.

HISTORIC STEPS TAKEN BY CUBA AND THE U.S. TO COLLABORATE ON MARINE PROTECTED AREAS (Abstract ID: 28184)

On Nov 18, 2015, the U.S. signed a memorandum of understanding (MOU) with Cuba's Ministry of Science, Technology and Environment to cooperate on the conservation and management of Marine Protected Areas – one of the first official bilateral agreements following the recent renewal of diplomatic relations between the U.S. and Cuba. The MOU is the basis for a working relationship between NOAA's Office of National Marine Sanctuaries and Cuba's National Center for Protected Areas (CNAP) and includes sister sanctuary relationships between Flower Garden Banks and Florida Keys National Marine Sanctuaries and Guanahacabibes National Park and Banco de San Antonio at the western

tip of Cuba. The National Park Service is also part of the MOU and links Dry Tortugas and Biscayne National Parks in the sister relationships. This achievement follows years of work by many individuals and organizations to bring together marine scientists, resource users and managers in both countries to develop joint conservation strategies for the marine ecosystem of the region. The goal of this collaboration is to understand, enhance, and protect the connections between the coral reefs of Cuba and the U.S. and address shared conservation challenges in the marine protected areas of the two countries. The signing of the MOU lays the foundation to build important cooperative programs to support marine science, management, and education efforts in both countries.

BIOECONOMIC EVALUATION OF MARINE RESERVE SIZE: PROTECTING RESTORED CORAL REEFS WHILE MAXIMIZING FISHERY VALUE (Abstract ID: 28457 | Poster ID: 266)

The cost of coral propagation and restoration coupled with limited funding make cost-effective measures to protect restored reefs and maximize program ROI critical. Marine reserves can be effective in protecting reefs and enhancing fishery value, however, determining optimal reserve size to accomplish both objectives is challenging. A framework for evaluating the costs and direct economic value of marine reserves protecting restored reefs can inform decisions related to marine resource policy and management. This study will develop a conceptual model for determining the optimal size (maximizing the present value of net fishery revenues) of no-take marine reserves protecting local coral reef restoration efforts and inform a broader examination of the Total Economic Value and ROI of active reef restoration in the Caribbean. The present value of the fishery will be evaluated for reserves of varying size, subject to outplanted coral population dynamics and diffusion of fish from the reserve to fishing grounds. Demographic data from outplanted corals will be used to generate preliminary empirical estimates of fish population levels, harvest and fishery value. The results of this study may inform efforts to determine the optimal size of reserves for the protection of restored coral reefs as well improve the understanding of the economic value of active reef restoration. Whether, and under what conditions, a clear "business" case can be made for reserves to protect restored reefs will be useful for a variety of audiences and may aid in prioritization of management actions.

MPA PERFORMANCE UNDER PRESSURE: CAN THEY YIELD DISTURBANCE REFUGES AND ENHANCE RECOVERY? (Abstract ID: 28972)

No-take marine reserves are key tools for biodiversity conservation, yet their role in enhancing resistance and recovery from disturbance remains equivocal. Coral reefs of the Keppel Islands, Great Barrier Reef (GBR), have been heavily impacted by climatic disturbances (coral bleaching, floods and a cyclone) over the past decade. We monitored fish and coral communities throughout this period, on no-take reserve and fished reefs. We found high coral mortality from bleaching in 2006 and the major floods in 2011 and 2013. The highest levels of live hard coral cover were recorded in 2004 (65%) and in 2009 (61%); 2013 was the lowest ebb in reef condition (heavy losses of corals and fishes). In 2015, several reefs provided key refuges for coral (predominantly Acropora spp.), with 50%+ cover. The abundance of the primary fishery target species on the GBR, coral trout (Plectropomus spp.) is highly dynamic and correlated with the cover of live hard coral cover, habitat structural complexity and prey abundance. Reserve reefs have supported higher abundances of larger coral trout than reefs that are open to fishing throughout the survey period, except when reef condition was at its worst in 2013. The loss of corals, structure and prey eroded the benefits of the no-take zones, but the rate of recovery between 2013 and 2015 was significantly greater in reserves than on fished reefs. While coral refuges are independent of protection, reserves that resist disturbance can provide important refuges that may enhance recovery of community structure, productivity and fishery target species.

WEST MAUI COMMUNITY-BASED STREAM RESTORATION: SOLUTIONS TO PREVENT SEDIMENT FROM REACHING THE NEARSHORE ENVIRONMENT (Abstract ID: 29163 | Poster ID: 439)

Sediment from stream inputs represents a major source of land-based pollution that is negatively affecting coral reefs around the world. Successful solutions to this problem will include community ownership and buy-in, sustainable stewardship, and incorporation of cultural values and practices. In West Maui, recent studies conducted of perennial streams found that approximately 40% and 55% of the banks of Ka'Opala and Papua streams respectively consist of actively eroding fine-grained sediment. During rain events, this sediment becomes suspended, and is transferred to the nearshore environment via stream channels. This creates plumes of turbid water along the coastline, which negatively impact coastal water quality and coral reefs. Modern adaptation and implementation of traditional Hawaiian land management practices will help to solve this problem. The Coral Reef Alliance is leading a knowledge sharing group consisting of local and regional experts and restoration practitioners who will together identify solutions that integrate traditional Hawaiian practices such as lo'i kalo (wetland taro cultivation) into a modern management system. In this talk, we will present the preliminary findings of the knowledge sharing group with the goal of informing similar efforts underway in other geographies.

ATTENUATION OF WHITE BAND DISEASE TRANSMISSION IN*ACROPORA CERVICORNIS* BY A QUORUM SENSING INHIBITOR (Abstract ID: 28059)

Among the greatest threats to global coral reef health are coral epizootics, which are increasing in frequency and severity. In particular, white band disease (WBD) has devastated Caribbean acroporid populations since its initial outbreak in 1979. However, despite its widespread and devastating effects, the etiology of WBD remains largely uncharacterized. Here we examine the role of quorum sensing (QS) within bacterial communities associated with WBD-infected *A. cervicornis*. QS refers to the phenomenon in which bacterial gene expression is regulated in response to changes in population density. This is accomplished through the secretion and detection of signaling molecules called autoinducers. Microbial communities isolated from WBD-infected *A. cervicornis* were exposed to QS inhibitor (an autoinducer antagonist) and then dosed onto healthy test corals. WBD-associated bacteria supplemented with QS inhibitor lost the ability to transmit disease whereas all *A. cervicornis* exposed to uninhibited (i.e. control) WBD bacterial communities became infected within two days. In order to determine the species influenced by the addition of QS inhibitor, bacterial samples were taken from each test coral at three time points: (T0) pre-dosing (T1) post-dosing at 12 hours and (T2) post-dosing at 24 hours (after WBD symptoms appeared in control corals). Microbial 16S V3-V4 rRNA metagenomic sequencing and multivariate analyses were then used to identify shifts in the bacterial communities between QS-inhibited and uninhibited WBD-associated bacterial communities.

SEXUAL AND ASEXUAL RECRUITMENT OF POCILLOPORID CORALS ON AN EQUATORIAL EASTERN PACIFIC REEF FLAT (Abstract ID: 28943 | Poster ID: 201)

Coral recruitment, the addition of new colonies to a population, can result from either sexual reproduction via larval settlement or through asexual reproduction via fragmentation. We studied the patterns of temporal variation in the number of recruits of sexual and asexual origin in a community of species of Pocillopora on a reef flat at Gorgona Island, Colombia. To estimate rates of recruitment and mortality, we periodically followed recruits during ten months between November 2012 and September 2013 on ten permanent belt transects (10 x 2 m). Recruitment peaks were observed in June 2013 for both sexually and asexually-produced recruits, with 0.08 ± 0.07 and 0.76 ± 0.48 colonies m-2 mo-1, respectively. However, recruitment was spatially variable and temporal variation was significant only for the rate of asexual recruitment. Mortality of recruits increased significantly towards the end of the study, but temporal variation in mortality was significant only for sexually-derived recruits. The balance between recruitment and mortality of juveniles indicates that in this community Pocilloporids can maintain themselves through either sexual or asexual recruitment. However, 91.3% of total recruitment was asexually-produced supporting the notion that pocilloporid reefs in the eastern Pacific are maintained mainly by asexual reproduction and are, therefore, more vulnerable to global change than reefs elsewhere.

LABORATORY TEMPERATURE SELECTION IN SYMBIODINIUM CAN ENHANCE CORAL THERMAL RESILIENCE (Abstract ID: 28516)

Temperature increases of only 1 °C above summer maxima can cause coral bleaching. This breakdown in the endosymbiosis between coral and their Symbiodinium can cause considerable coral mortality. As coral bleaching tolerance is dependent on their symbionts, the human-assisted acceleration of evolutionary processes in Symbiodinium has been proposed as a strategy to enhance coral thermal resilience. We report an adaptive response in cultured Symbiodinium after only ~150 generations of thermal selection at 31 °C, a 4°C increase from the control temperature; the 31°C selected Symbiodinium outperformed the wild-type at 31°C, with higher growth rates, photosynthetic performance and lower extracellular reactive oxygen species production. At ambient temperature the performance of the selected-type was similar to that of the wild-type across most traits, indicating limited costs of thermal selection. Coral recruits of three Acropora species were subsequently inoculated at 27°C with both the selected and wild-type symbionts. Once symbiosis had established, a proportion of each was moved into 31°C. We observed species-specific differences in performance under elevated temperature. At 31°C, recruits harbouring the selected-type symbionts bleached slower than those infected with the wild-type cells, had greater photosynthetic capacities and exhibited similar growth to recruits harbouring selected and wild type symbionts at 27°C. Inoculation of corals with laboratory selected Symbiodinium may provide a highly valuable approach to enhance coral fitness in our warming oceans.

LARVAL PERFORMANCE OF A CARIBBEAN BROODING CORAL UNDER HEAT STRESS DEPENDS ON THE THERMAL CONDITIONS EXPERIENCED BY THEIR ANCESTORS (Abstract ID: 30009)

Global warming causes increased physiological stress to corals worldwide, yet many coral populations survive well above their optimal temperature range. Recent studies have identified key physiological pathways that allow these corals to cope with heat stress. It is however not fully understood how these traits emerge in a population: through short-term acclimatization, or long-term local adaptation? We investigated how heat tolerance traits in a Favia fragum population are passed on from parental colonies to their offspring. This species grows at the warm-water outflow of a desalination plant on Curaçao, where temperature greatly fluctuates daily and frequently exceeds 31°C. In an ex-situ reciprocal transplant experiment, we compared survival, settlement, and photosynthetic efficiency of larvae brooded by colonies from the warm outflow site to that of larvae from a nearby ambient reef. When exposed to heat stress for 5 days, larvae from the warm site survived 40% better and settled 5 times more than those from the ambient site. The latter suffered a 15% reduction of maximum quantum yield compared to larvae from the warm site. We conclude that parents that grow in warmer habitats transmitted key heat resistance traits to their offspring. Preliminary population structure analysis supports adaptation as the primary mechanism for heat tolerance. We hypothesize that in 60-years operation of the desalination plant, the rapid generation time of F. fragum caused natural selection over several generations that allowed these corals to acquire heritable traits for heat tolerance.

CONTRASTING ABUNDANCE OF JUVENILE CORALS AT TWO NATIONAL PARKS IN THE ANDAMAN SEA (Abstract ID: 29363 | Poster ID: 664)

Understanding the patterns and relationship of coral larval supply and juveniles are crucial in enhancing reef biodiversity, recovery and resilience in response to disturbances. The objective of this study is to compare diversity and abundance of juvenile coral colonies on natural substrates and recovery trends in Mu Ko Surin and Mu Ko Phi Phi in the Andaman Sea. Results showed that highest density of coral recruits was found at Ao Suthep (Mu Ko Surin) while lowest density was at Ao Loh Samah (Mu Ko Phi Phi). Among study sites, Ao Suthep had the most diverse coral (at the genus level) while Ao Loh Samah had the least. Generally, *Fungia* was the dominant coral recruit at Mu Ko Surin while *Porites* was the dominant juvenile coral at Mu Ko Phi Phi. Species composition of coral recruits was significantly different between Mu Ko Surin and Mu Ko Phi Phi. Coral recruits and percentages of live coral cover were positively correlate ($r=0.25$, $p<0.01$) in all sites. This suggests that coral recovery following the bleaching events at Mu Ko Phi Phi would require a longer period of time.

VARIATION IN GENOTYPIC DIVERSITY OF THE THREATENED PILLAR CORAL, DENDROGYRA CYLINDRUS, AND ITS ALGAL SYMBIONT IN FLORIDA, CURACAO, AND THE US VIRGIN ISLANDS (Abstract ID: 28939 | Poster ID: 186)

The threatened pillar coral, Dendrogyra cylindrus, is the only species in its genus, and thus its extinction would mean the extinction of a genus. Comprehensive surveys of Caribbean reefs over the past 30 years failed to find any pillar coral recruits, mobilizing efforts for active management of this unique species. Prior to nursery rearing and outplanting of fragments, the population genetics of the host and its specific symbiotic algal species (Symbiodinium 'dendrogyrum') must be evaluated. Eleven microsatellite markers were developed de novo for D. cylindrus and nine existing microsatellites markers were applied to S. 'dendrogyrum'. Coral colonies from sites along the Florida Reef Tract, Curacao, and the US Virgin Islands were genotyped using these markers. Results indicate that D. cylindrus is highly clonal in Florida, with dense patches containing just one host genotype. Host populations in Curacao, however, appear to be more diverse and were highly differentiated from Florida populations. The genotypic diversity of S. 'dendrogyrum' is lower than its host, with identical clones often occupying multiple reefs. While D. cylindrus is known as a gonochoric broadcast spawner, observations revealed that pillars of identical genotype released gametes of the opposite sex, indicating that D. cylindrus might be a hermaphrodite capable of geitonogamy. The low genotypic diversity of host and symbiont and apparent strong host population differentiation in D. cylindrus make it imperative that diverse genotypes are incorporated into local restoration efforts throughout the Caribbean.

THE NEED FOR AN EX-SITU CORAL RESTORATION NURSERY IN HAWAII (Abstract ID: 28210)

Hawaii has both large commercial harbors and military ports. The reefs proximate to these harbors have a higher chance of incurring damage due to large vessel groundings, spills, dredging activities, and harbor modifications. In addition, there are many small recreational boat harbors around the Main Hawaiian Islands where associated damage from small boat groundings and anchor damage is common. Given the extremely low natural recovery rates for coral in Hawaii, there is a strong need to mitigate for these damages. The Hawaii Division of Aquatic Resources has established the first ex-situ Coral Nursery in Hawaii, with the broad goal of addressing the mitigation challenges accompanying modern harbor-associated anthropogenic impacts. The DAR Coral Nursery represents an opportunity to test a variety of concepts toward innovative coral reef restoration and mitigation, including preservation of rare and threatened coral species in a coral "ark", asexual planulation for mitigation, and a fast-growth protocol for reaching size refuge targets.

ASSISTED EVOLUTION VIA HYBRIDIZATION: A NEW APPROACH IN CORAL REEF CONSERVATION (Abstract ID: 28272)

The world's coral reefs are facing unprecedented changes in temperature and carbonate chemistry. This rate of change can surpass the ability of many organisms to acclimatize or adapt to survive. Here we assess the value of assisted evolution via hybridization as one possible way of accelerating evolutionary processes to assist corals to survive current climate change. Hybridization may create novel recombinant genotypes, providing

a wider array of variation for natural selection to act upon compared to purebred organisms alone. Colonies of four *Acropora* species were collected in the Central Great Barrier Reef and were experimentally crossed in Dec 2015. Fertilization rates were high (>90%) in purebred and hybrid crosses of both directions in *Acropora tenuis* x *Acropora loripes*, as well as *Acropora florida* x*Acropora sarmentosa*. Rates of embryonic development were assessed for each cross at 3, 9, 15, 21, 33, 45, 57, 69, and 93 hours after fertilization. Rates of*Symbiodinium* uptake, growth, survival and photosynthetic performance under ambient condition (27.5°C, 415ppm) and mid-century condition (28.5 °C, 685ppm, RCP8.5) in purebreds and hybrids of the two crosses will be discussed. This project will assess whether interspecific hybridization can be used as a novel approach for enhancing coral reef restoration initiatives in a changing climate.

ENHANCING HERBIVORE ASSEMBLAGES BARRICADE FURTHER DEGRADATION OF LINGERING CORAL REEFS IN GULF OF KACHCHH, INDIA (Abstract ID: 29245 | Poster ID: 302)

Despite being at the northern most margins of coral reef distribution in the Indian Ocean, experiencing arid climate, transgressed sea level due to the past tectonic up-liftment, high sedimentation, semi-diurnal tidal fluctuation, coral exploitation and industrialization, Gulf of Kachchh still preserves some most temperature tolerant and wide adapted residual coral population. These degraded and poor resilient reefs are also affront with the indiscriminate macro algae growth and exploitation of herbivore fishes at their juvenile stage. Herbivores play a critical role in coral reef resilience by limiting the establishment and growth of algal communities that impede coral recruitment. Present study quantified the status and seasonal variation of herbivors assemblage on the natural reefs and artificial coral restoration structures in 3 spatially distinct sites along the Gulf. Density of Trochus spp. observed high during post monsoon on both natural reefs and artificial structures (5.04±0.69/m2and 5.38±0.76/m2 respectively). Sea urchin density was found very low throughout the study period (maximum of 0.77±0.09/m2 during post monsoon). Although density and abundance of herbivore grazers and detrivores fishes were found assembled conspicuously in and around the artificial coral restoration structures, it is inadequate for the whole reefs. Managing exploitation and restoration of herbivory are also an urgent priority to improve the resilience and recovery of the Gulf. Strategies for improving the herbivores of the reefs are discussed.

GENETIC VARIATION IN POPULATIONS OF A TROPICAL MYSID, MYSIDIUM GRACILE (Abstract ID: 30093 | Poster ID: 31)

The swarm-forming mysid Mysidium gracile aggregates near coral reefs and are important components of reef ecosystems. Occupying an intermediate level of marine food webs, they transfer energy and nutrients from planktonic species to reef fishes. However little is known about the genetic composition of swarms, connectivity of populations, and thus overall regional levels of genetic diversity. Here we assessed genetic variation within and among swarms occurring near seven Caribbean islands. The COI gene was amplified and sequenced for 121 mysids representing 17 swarms. Haplotype diversity was determined using DnaSP5.0. Twenty-four haplotypes were detected with a haplotype diversity of 0.93, thus indicating a high level of haplotypic variation. Bayesian phylogenetic reconstruction showed 7 distinct clades. Mysids from San Salvador (Bahamas), Frederiksted (USVI), Culebra (Puerto Rico), St. Thomas (USVI) each formed unique, well-supported clades as did a subset of individuals from St. John (USVI). An additional clade was composed of individuals from Guanica (Puerto Rico), Bigelow Guana (BVI) and some individuals from St. John (USVI). The final clade included individuals from St. John (USVI) and White Bay Reef Guana (BVI). Overall, these results show that there is substantial genetic variation among mysid populations and that some genotypes are shared across the region. This variation may become important as reef conditions changes in response to changes in climate.

UNDER PRESSURE – HOW SEED BANKS PROVIDE A FUNCTIONAL CLUE INTO DEEPWATER SEAGRASS SUCCESS (Abstract ID: 28881 | Poster ID: 514)

As a functional group seagrasses are ubiquitous throughout the Great Barrier Reef World Heritage Area (GBRWHA), from offshore coral reefs to inshore estuaries and embayments. Mounting concern for acute and chronic anthropogenic pressures on seagrasses have steered efforts to develop indicators of light attenuation stress. Developing a "one-size-fits-all" model for the 15 species found in the GBRWHA is ineffective without accounting for functional differences in their life history traits. We investigated the growth attributes and adaptation of deepwater (>10m) seagrass communities with a goal to improve coastal management strategies impacting this functional group. We explored what role density and stratification of a seed bank plays in meadow resilience, and how the optical challenges of growing at depth may affect seed germination in these ephemeral meadows. Sediment cores were collected over three years from three *Halophila* spp. meadows within the GBRWHA. Seed densities varied over time and with depth (≤ 10cm) but followed similar trends among meadows. Collections of mature fruits afforded fresh seeds to establish the first successful seed viability test known for this genus. Fresh seeds were also used to examine the role spectrally-refined light at depth has on germination success. While strategically *Halophila* spp. are known to rely on seeds, having a more intimate understanding of the functionality of their seed banks and how they respond to environmental cues, bridges a science gap for effectively mitigating light-driven loss of tropical deepwater seagrasses.

CAN FISH HELP CORALS DURING BLEACHING EVENTS? (Abstract ID: 28520 | Poster ID: 345)

Global environmental change is likely to have profound influence on how marine symbioses operate, thus impacting nutrient cycling, ecosystem function, and evolutionary processes. On coral reefs, fish living within the branches of coral colonies can promote coral growth and it has been hypothesized that the enhanced water flow and nutrients provided by fish could ameliorate coral bleaching. The aim of this study was to evaluate the influence of small schooling damselfish on the health of their host corals during and after a thermal bleaching event. Using a controlled laboratory experiment this study demonstrates that corals inhabited by fish have higher photosynthetic efficiency in both control and heated treatments and that elevated temperatures caused higher mortality and a larger decline in photosynthetic efficiency in corals that did not have fish present. Thus, our experiment provides the first experimental evidence that fish living within coral colonies can affect coral susceptibility to thermal bleaching. Understanding how interactions between species, such as fish-coral mutualisms, can moderate the effects of changing environmental conditions is critically important for understanding the effects of climate change on reef organisms and coral reef management.

IMPROVING CORAL PROPAGATIONS IN THE HATCHERY THROUGH FEEDING AND LIGHT CONTROLS BEFORE TRANPLANTATION TO NATURAL REEFS (Abstract ID: 30075)

Mass culture of corals using sexual propagation technique was successfully developed in Thailand. The fertilization rates of gametes ranged between 92-97%. After fertilization in the hatchery, the juvenile corals were then reared in a land-based rearing system for at least 2 years before they were transplanted back to natural reefs. The survival rate of juvenile corals after transplantation into the reefs was more than 50%. At present, 5 year-old post-settlement colonies were detected to be reproductively mature and subsequently spawned every year since 2013. However, since juvenile corals propagated from sexual reproduction needed to be raised in the hatchery for at least 2 years before transplantation, the maintenance cost were high; more than 100 USD per 1 juvenile colony. Thus, feeding and light control experiments were conducted to determine whether adding those factors could enhance higher growth rates of juvenile corals in the hatchery. The results showed that when juvenile corals were fed by Artemia salina nauplii, and additional lights were added in the hatchery, the growth rates of juvenile corals increased significantly, twice as high as those without feeding and additional light. Therefore, feeding juvenile corals with supplementary food such as Artemia salina nauplii and additional light controls can be options for enhancing growth of juvenile corals in the captivity before transplanted to natural reefs. Detailed results will be showed and discussed.

FROM CORAL TO "SPONGE REEFS"? EXCAVATING SPONGES AS INDICATORS OF CHANGE (Abstract ID: 28067)

Coral reef communities in the Caribbean and Florida have changed dramatically during the past three decades, shifting ecological phases or states. Although sponges provide habitats on reefs, destructive excavating sponges such as Cliona delitrix also compete and take over space from declining corals. To evaluate how much excavating sponges can take over coral reefs affected by climate change, we developed a Markov chain model based on field data obtained over a period of 10 years from 100 coral colonies in a high latitude coral reef in Florida, USA. The model takes a multi-taxa approach in which corals, sponges, and algae are included. Analysis of the ten-year data set showed an increase of C. delitrix in 2002 that was accentuated after the 2005 heat-stress related coral mass mortality event. Projections of the mean model and sensitivity analysis suggested that for the continuous survival of this coral reef, coral recruitment has to increase. When disturbance was added, macroalgae became the dominant final state on reefs in most projections. However, in case of consecutive, moderate coral mortality events, the excavating sponges could reach higher cover. Under a climate change scenario (i.e. heat stress), both corals and excavating sponges declined, although sponges at a slower rate. Success or decline of excavating sponges depended on the intensity of heat stress and coral mortality events that provided the sponge with substratum.

A NOVEL FEMALE-SPECIFIC AND SEXUAL REPRODUCTION-ASSOCIATED DMRT GENE DISCOVERED IN THE STONY CORAL, EUPHYLLIA ANCORA (CNIDARIA, ANTHOZOA) (Abstract ID: 27920)

Transcription factors encoded by the Dmrt gene family regulate multiple aspects of animal reproduction. Most the studies investigating the Dmrt gene family were conducted in model organisms from bilateral species, with a particular emphasis on their role in male sex determination. It is still unclear whether the Dmrt genes found in basal metazoans such as cnidarians, share similar characteristics with their orthologs in other metazoans. In this study, seven full Dmrt gene transcript sequences for a gonochoric coral, Euphyllia ancora, were obtained through transcriptome data mining, RT-PCR/RACE, and sequencing. These EaDmrts were subjected to quantitative assays measuring temportal and tissue-specific expression. The results demonstrate a unique gene expression pattern for EaDmrtE, which is enriched in female germ cells during the spawning season. Based on the phylogenetic analyses performed across the homologous Dmrt genes in metazoans, we found that the female-specific EaDmrtE is not related to Acropora coral DM1 nor vertebrates Dmrt1, which are involved in sexual reproduction, especially in sex determination (vertebrate Dmrt1). Additionally, high levels of EaDmrtE transcripts detected in the unfertilized mature eggs are retained in newly formed zygotes, but decrease during embryonic development. We suggest that the newly discovered gene might play a role in oogenesis and early embryogenesis as a maternal factor in corals. Therefore, the sexual reproduction-associated Dmrt gene(s) should have arisen in cnidarians and might have evolved multiple times in metazoans.

ATTEMPTED GENETIC TRANSFORMATION OF *SYMBIODINIUM MICROADRIATICUM* USING VARIOUS TRANSFORMATION TECHNIQUES (Abstract ID: 28553 | Poster ID: 119)

The endosymbiotic interaction of *Symbiodinium* spp. with various marine invertebrates represents the basis of the entire shallow-water coral ecosystem. The specificity of this interaction can vary greatly depending on the specific *Symbiodinium* sub-species, invertebrate species and environmental conditions in question. One of the key advances that would greatly aid the elucidation of the molecular details of this interaction would be the establishment of a tractable genetic transformation system in a*Symbiodinium* species. A silicon carbide whiskers-based transformation technique was reported for *Symbiodinium microadriaticum* 18 years ago, and we have attempted to use this protocol for transformation of *Symbiodinium microadriaticum* strain CCMP 2467. In addition, we have attempted to use standard algal transformation techniques such as biolistics and electroporation as well as non-standard techniques such as FuGENE transfection. To date, we have been unable to introduce antibiotic resistance or GFP fluorescence under the control of the previously published p35S promoter or endogenous *Symbiodinium* promoters as genetic markers into our *Symbiodinium* cells. Whilst we have not attempted to test these techniques on other *Symbiodinium* strains, we propose that a new, radical transformation method may be required to introduce extracellular DNA in*Symbiodinium*.

DNA-BARCODING REVEALS NICHE DIFFERENTIATION AMONG DIFFERENT GALAXAURACEAE SPECIES (RHODOPHYTA) IN THE DONGSHA ATOLL NATIONAL PARK, TAIWAN (Abstract ID: 27947)

Dongsha Atoll National Park is located in the most northern part of South China Sea and consists of three parts, namely the inner lagoon area, the reef rim area, and the outer reef area. Therefore, Dongsha Atoll National Park comprises various marine habitats, for example, the lagoon, seagrass bed, coral reef and sandy ground. The water is much calmer in the inner lagoon area that is sheltered by the reef rim area, but much more disturbed by waves in the outer reef area. Therefore, Dongsha Atoll National Park is a perfect area to examine how different types of habitats shape the distribution of marine organisms. To tackle this issue, we focus on common tropical / subtropical seaweeds, Galaxauraceae, and applied DNA-barcoding (rbcL gene) to assess the effects of various habitats on their distribution in the Dongsha Atoll National Park. From ten different sampling sites in the inner lagoon area and the outer reef area, we found four genera and nine galaxauraceous species in the Dongsha Atoll National Park. Overall, Dichotomaria marginata, D. obtusata and Galaxaura divaricata occurred more abundantly in calmer water area, whereas D. elegans, G. rugosa and Tricleocarpa occurred more frequently in wave-exposed area. These results allowed us to discuss how different types of habitats affect the distribution of seaweeds. Based on our research, we proposed that Galaxauraceae can be developed as a bioindicator to classify clam and wave-exposed habitats in tropical / subtropical coastal marine ecosystem.

PARTNERING WITH PRIVATE TOURISM AND HOTEL DEVELOPMENT SECTORS TO INITIATE CORAL REEF RESTORATION IN CHINA (Abstract ID: 28257)

The Sanya region of Hainan Island, China, is an important tropical destination for the domestic tourism market, which relies heavily on coral reef-related coastal activities. The coral community in the Sanya region has suffered a dramatic decline due to increasing threats, including coastal development, eutrophication, overfishing, destructive fishing and coral mining, along with overloaded, irresponsible diving activities. The Nature Conservancy (TNC) China Program has recently started the first coral reef restoration project in Sunny Bay and Baifu Bay of Sanya, under a partnership with the private hotel developer, the Sanya Sunnybay Development Co., Ltd., the owner of the site's management rights. On-site evaluations identified high stress levels and recruitment failure, which confirmed the necessity for active interventions in order to increase reef resilience and to provide time to address the threats. TNC is closely engaged with the partner and planning to introduce coral gardening, algal and predator removal, marine education to the project site, and to explore fisheries interactions with local community. This project has generated a growing interest among local stakeholders that rely on reef-related tourism. TNC aims to demonstrate a model for partnership between the conservation community and the private sector, and to initiate a business alliance for conservation. This alliance is viewed as essential opportunities for engaging the local and provincial governments in long-term regional strategies to address fundamental issues such as water quality.

DIGITIZING THE CORAL REEF: SURVEYING THE BIODIVERSITY OF CORAL REEF BENTHOS USING UNDERWATER HYPERSPECTRAL IMAGING (Abstract ID: 29178)

Coral reefs are characterized by a high degree of spatial complexity and biodiversity. Rapid large-scale surveys at a fine spatial resolution and automation of substrate recognition will help to quantify the spatial structure of the reef's biodiversity. This is a pre-requisite to assess changes, both natural and anthropogenic, in the ecological status of

coral reefs. We describe a novel method to survey and map the biodiversity of coral reef benthos using a diver-operable hyperspectral imager called hyperdiver. The hyperdiver survey technique captures spectral and visual images, topography, water chemistry and light field data from survey transects. The technique combines the information derived from high-resolution spectra and imagery to feed a machine learning analysis, which can be used to create classified reef maps down to the taxonomic level of genera. Comparison of machine classification against expert analysis of taxa shows very good congruence. Consequently, the hyperdiver technique allows us to rapidly visualize the biodiversity of the reef benthos from the centimeter scale upwards, along with profiling the bedform rugosity and light climate. We used hyperdiver to survey unique Pacific reefs near natural CO2 vents and reefs nearby unaffected by elevated CO2 levels. The survey covered several kilometers, and the data was used to create classified reef maps with 1-2 cm spatial resolution. We visualized and analyzed the strong effects of ocean acidification on the composition and rugosity of the benthic assemblage from the centimeter to reef scales.

SIMULATING THE DYNAMIC TRANSITION FROM REGIONAL DESIGNS TO LOCAL ACTIONS (Abstract ID: 28670)

Regional-scale conservation planning is important to allow emergent system properties such as complementarity, connectivity of areas, and accounting for vital large-scale processes. Such scale of planning, however, results in a mismatch of scales between that of planning and implementing the plans, which occurs at local scales. Despite considerable acknowledgement of this issue in the literature, explicit strategies to facilitate this transition of scales are obscure and yet to be quantified. Using the computer language, 'R', we coded a framework to simulate dynamically transitioning from prioritised regional designs to implementing local actions, defined by management units, in the protracted application of conservation actions. We tested how the frequency of updating the regional design with local information on currently achieved objectives during the transition, influenced the extent of change in spatial configuration between the initial proposed design and the final implemented actions, measured with Cohen's Kappa statistic. Increased frequency of updating the regional design decreased the spatial similarity between the initial design and final actions. However, increasing the frequency of updates also increased the spatial and cost efficiency of implemented reserves compared to simulations with less frequent updates. Our findings refute current perceptions that the implemented network needs to be as spatially similar as possible to the best-proposed design, and that frequent revision of regional designs during the transition to implementation decreases efficiency.

SHARKS AND RAYS OF THE SOLOMON ISLANDS: STATUS, THREATS AND A KNOWLEDGE REVIEW (Abstract ID: 27885)

The Solomon Islands lie within a global centre of coral reef biodiversity, and are a focal point for coral reef and fisheries research in Melanesia. However, little is known about the status and diversity of sharks and rays in the Solomon Islands. Nevertheless, sharks and rays are under increasing threat in the Indo-Pacific, and the limited data available suggests that they are taken in the Solomon Islands as target and bycatch in large scale commercial fisheries, artisanal and subsistence fisheries. Recognising these issues, in 2013 the Solomon Islands government stated its intent to develop a*National Plan of Action* for conserving shark resources. However, crucial baseline data about species status and biodiversity are needed to support these efforts. This project collated and analysed available information to assemble an account of the biodiversity, status, and current management of Solomon Islands' sharks and rays. Given the paucity of data available, a wide range of information sources were explored including published and grey literature, management documents, ethno-biological information and museum records, as well as opportunistic information from private individuals such as historical photographs. This information was compiled into an annotated species checklist, providing the first systematic review of Solomon Islands elasmobranchs, and includes global range extensions for species such as sawfish. This work also demonstrates the benefits of a broad scale, interdisciplinary approach when synthesising information about data poor regions and topics. https://research.jcu.edu.au/portfolio/andrew.chin

A COMPUTATIONAL MODEL OF THE IMPACT OF UNI AND BI DIRECTIONAL FLOW ON COLONY SYMMETRY OF BRANCHING SCLERACTINIAN CORALS (Abstract ID: 30132)

Many branching scleractinian corals tend to develop symmetrical growth forms. A long-standing question is whether radial symmetrical colonies have emerged due to the environment condition such as water movement or genetic blueprint. To address this issue, we used a computational approach to study whether bi-directional current causing the radial symmetrical morphology of representative branching corals. Using advection-diffusion equations we linked an earlier developed coral growth model to simulated, but varying bi-directional flow environments. We investigated the relative importance of flow to the corresponding symmetry of the simulated morphologies by changing Peclet number. We compared the simulated results with in situ collected and CT-scanned colonies of the genus Madracis and the species Pocillopora verrucosa. The comparisons were based on 10 distinct morphometric traits comprising local morphometric traits, i.e. relevant to the local geometric property of the colony, and symmetry-oriented traits, that involve the measurement of how internal branches change relatively to the direction of the incoming flow. Our analysis shows a separation between symmetrical coral assemblies versus asymmetrical ones with some of the simulated corals under bi-directional flow environments overlapped with those of real colonies suggesting the symmetry of a branching colony can be explained by the influence of flow.

EFFECTS OF TEMPERATURE AND SALINITY ON THE OXYGEN CONSUMPTION RATES AND BEHAVIORS OF THE NUDIBRANCH, JORUNNA FUNEBRIS (KELAART, 1858) (Abstract ID: 29634 | Poster ID: 43)

Temperature and salinity are primary environmental factors that influence metabolic rates of reef invertebrates. Changes of temperature and salinity can alter respiration rates and some behaviors of animals such as changes of movement and excretion. In this study, we investigated the effects of temperature and salinity levels on the oxygen consumption rates and behaviors of the nudibranch, Jorunna funebris (Kelaart, 1858). The results showed that the changes of both temperatures and salinity levels affected the oxygen consumption rates of the nudibranchs in all size classes. The results also showed that rates of oxygen consumptions of nudibranch increased with the increase or decrease of temperature and salinity levels. In addition, the temperature and salinity stresses caused nudibranchs inactive or more active than usual. More mucous secretion and increase of respiration rates were also observed.

EFFECT OF MONSOON ON THE ASSOCIATION BETWEEN REEF FISH RECRUIT AND BENTHIC STRUCTURAL COMPONENTS (Abstract ID: 29043 | Poster ID: 243)

While it is recognized that reef fish recruitment is strongly influenced by benthic structural features, the strength of this relationship at different monsoonal periods have yet to be investigated. The study aims to fill this data gap and investigate if there is variation in the strength of pomacentrid recruit association with specific benthic structural characteristics across monsoon seasons in an established protected area in Mabini, Batangas, Philippines. In the study, we quantified the strength of association between pomacentrid recruit abundance with rugosity, vertical relief, loose abiotics and live coral cover. The surveys were conducted monthly during peak recruitment periods on four permanent 50m transects. Currently, data collection for inter-monsoonal (April to June) and southwest monsoonal seasons (July to October) has been completed. Survey for the northeast monsoonal period will be conducted from January to March 2016. Initial results showed that reef fish recruit and benthic structural characteristics association was strongest in the southwest monsoon. Significantly, during this period, more recruits were found associated with live coral cover and substrates with notable vertical relief. We hypothesize that recruits aggregate on these benthic features not only to minimize mortality due to predation but to also seek refuge against high energy waves brought about by strong winds during southwest monsoon. This study has important implications in management specifically in modeling the impacts of live coral and overall structural loss on reef fish recruitment.

DRONES THAT SEE THROUGH WAVES - FLUID LENSING AS A NEW TECHNOLOGY IN OCEAN REMOTE SENSING (Abstract ID: 30146)

The use of small, unmanned aerial vehicles (UAVs, commonly known as drones) and experimental NASA-developed Fluid Lensing technology is presented as a novel means to image underwater marine ecosystems from above the ocean's surface, producing cm-scale imagery in three dimensions over tens of square kilometers. Fluid Lensing uses water-transmitting wavelengths to passively image underwater objects by exploiting time-varying optical lensing events caused by refractive distortions from traveling surface

waves. Preliminary high-resolution datasets present the first cm-scale image of a reef acquired from above the ocean surface without wave distortion and show clear distinction of coral, fish and invertebrate species at depths of up to 3 m. State-of-the-art machine learning algorithms were used to map coral morphologies and calculate percent cover with up to 5% accuracy vs. 25-50% error using current remote sensing technologies. Fluid Lensing thus improves upon existing state-of-the-art remote sensing technologies captured at meter-scale resolution by up to two orders of magnitude. These preliminary findings show Fluid Lensing and multirotor electric drones offer a unique and cost-effective solution for large-scale surveys of shallow marine biospheres.

THE ROLE OF OPTICAL SPECTROSCOPY DATABASE SYSTEMS FOR MARINE CONSERVATION EFFORTS – WORKING TOWARDS INTERNATIONAL CAPACITY BUILDING (Abstract ID: 29943)

Optical spectroscopy data collected for marine system research can assist conservation efforts by offering valuable reference data crucial to sensor calibration, field validation campaigns, or as research data alone. While a wealth of spectroscopy data exists, often access is limited because data are stored locally and subject to the often disjointed lifecycle of research projects. Yet such data has the potential to benefit the wider marine system community as well as to contribute to international spectral libraries to fill existing gaps in collections. The crux of developing more holistic user-based data services is to meld efforts into sustainable research data capability. Capability building requires an evolution of the data services provided across the international sector which accommodates advancing practice. Distinct challenges are faced at this juncture, which ultimately depend on financial and user investment, but includes issues beyond user demands for system enhancements, including: community building, ethical clearance of data sharing, process development, project administration and liaison with the global community to promote international standards. Only if these elements are addressed, can infrastructure initiatives be embraced to build true international collaboration capability. This paper will present a brief summary of the Australian experience to serve as a catalyst of discussion regarding the sustainability of spectroscopy research data services and raise the challenges and issues that arise in the sustainable delivery of research infrastructure.

OOCYTES EXPRESS AN ENDOGENOUS RED FLUORESCENT PROTEIN IN A STONY CORAL, *EUPHYLLIA ANCORA*: A POTENTIAL INVOLVEMENT IN CORAL OOGENESIS. (Abstract ID: 28041)

Sexual reproduction of corals is an important means of facilitating the generation of new coral reefs. To date, however, the molecular and cellular mechanisms underlying coral sexual reproduction remain largely unknown. We performed a differential screen to identify genes related to oogenesis in the stony coral *Euphyllia ancora*. We identified a clone encoding a novel *red fluorescent protein* cDNA of *E. ancora* (named *EaRFP*). Microscopic observation and quantitative RT-PCR revealed that EaRFP is almost exclusively expressed in the ovary of the adult coral. The combination of the ovarian-cell separation method and the RT-PCR analysis revealed that the oocytes, but not the ovarian somatic cells, are the cells expressing EaRFP. Immunohistochemical analysis revealed that the expression of EaRFP starts in the early stage of the oocyte and continues until the maturation period. Furthermore, recombinant EaRFP was shown to possess an $H_2O_2$degradation activity. These results raise the possibility that EaRFP plays a role in protecting the oocytes from oxidative stress from the early to late stages of oogenesis. The present study provides not only the first evidence for the potential involvement of FPs in coral oogenesis but also an insight into a cellular strategy underlying coral sexual reproduction.

IMPACT OF EXOTIC SPECIES (BANTARIELLA BOCKI) ON GORGONIAN AND BLACK CORAL AT JEJU ISLAND IN KOREA (Abstract ID: 29148 | Poster ID: 219)

In 2015, bryozoan, Bantariella bocki was observed to be increasing rapidly on the Seogwipo coast of Jeju Island. It was observed that the colonies of coral (Gorgonian and Black Coral) were entirely covered with B. bocki. Attached B. bocki had a significant impact on the survival rate of coral. This invasion may be contributing to a decrease in black coral and endemic gorgonian coral at shallower depths. In particular, the same phenomenon of rampant B. bocki was observed in 2005. We conducted a study to find the cause of this sudden increase in B. bocki. We investigated the influence of the environment such as seawater temperature, turbidity, and changes in topography. Secondly, to investigate the quantitative change in invasion rates, 60 colonies grouped according to invasion rate ranges of 0~30%, 30~60, 60~100% were individually tagged at the beginning of this study. We also measured the mortality and recovery rate of coral. Increase in B. bocki showed a correlation with seawater temperatures. The invasion rate of corals showed a maximum effect at 20~30m, and small colonies showed higher rates of death.

DOES NUTRITIONAL ECOLOGY DRIVE THE EVOLUTION OF LIFE HISTORIES IN HERBIVOROUS REEF FISHES? (Abstract ID: 27904)

Reef fish have distinct life history signatures with differences driven by variable longevities, sexual ontogeny and somatic growth. We commence analysis of the processes responsible for life history diversification by focussing on herbivorous reef fishes comprising 5 major clades (pomacentrids, scarine labrids, acanthurids, siganids and kyphosids). There is strong phylogenetic structure associated with herbivory. Reef herbivores access a range of autrotrophic resources with processes associated with digestion and assimilation being highly clade-specific. Those with short life spans, high growth and episodes of rapid somatic and reproductive outputs harvest autotrophic resources rich in protein. Conversely those species with extended life spans and low rates of somatic growth obtain energy and nutrients via carbohydrates through fermentative digestion. We evaluate how nutritional ecology influences life history signatures. Our hypothesis is that the dominant herbivores on coral reefs, parrotfishes, have food processing modes that allow harvesting of protein rich microbial biomass which underwrites their protogynous life history. Conversely acanthurids maintain a life history with modest annual somatic growth and reproductive outputs maintained by processing of carbohydrates. Temporal patterns of diversification in each clade are distinct; parrotfish diversified in the Pleistocene while surgeonfishes have an Eocene history. We identify the recent diversification of parrotfishes as a unique trophic event with profound consequences for reef ecosystems.

RESERVE NETWORK DESIGN TO DELIVER REAL-WORLD CONSERVATION AND FISHERIES BENEFITS (Abstract ID: 28823)

Recognising the need to preserve nature for its sustainable use, the science of reserve design has become more pragmatic. An ideal network of marine reserves ought to promote the persistence of metapopulations while benefiting fisheries by replenishing nearby areas through adult and larval spillover. So far reserve network design has focused on optimising local persistence through the use of rules of thumb for the entire network (e.g. minimum reserve size based on average dispersal distances) or static measures that characterize each site (e.g. self-retention). Several studies have considered closed loops of replacement that could allow the persistence of the network as a whole, but these have focused on assessing the value of particular network configurations, not on choosing an optimal design overall. Here we design a network of reserves to accomplish conservation and fisheries objectives using a spatially realistic seascape, and the linkages among nearby populations in terms of adult and larval connectivity. Our reserve network design considers seascape management units and uses dynamic population models to identify optimal reserve network configurations that allow the persistence of the metapopulation while maximising fisheries yield. To our knowledge, the study represents the first example of a reserve network that has been designed for fisheries benefits while considering network persistence. The resulting network design will be implemented in Honduras.

IUU FISHING HAMPERED NO-TAKE MARINE RESERVE PERFORMANCE: A CASE STUDY FROM SIMCA, SABAH, MALAYSIA. (Abstract ID: 29042 | Poster ID: 673)

The benefits of no-take marine reserves are related to the efficacy of protection, where good protection stems from the combination of compliance and effective enforcement. This paper reports the occurrence of illegal, unreported, and unregulated (IUU) fishing within Sugud Islands Marine Conservation Area from 2006 to 2014. The illegal fishing activities were highly organized, occurred during odd hours of the day, and conducted at boundary between Malaysia and Philippine water. Fishing methodology categorized into dynamite fishing, sodium cyanide, bottom gillnet, trawling and hook and line. The intensity of dynamite fishing reached average to 30 blasts detected a day from August 2014 to September 2015. Fishing with sodium cyanide and hook and line targeting on Leopard Coralgrouper (Plectropomus leopardus) and Humphead wrasses (Cheilinus undulates) for the live reef food fish trade (LRFFT). Two illegal fishing targeting on Leopard Coralgrouper confronted from August 2013 to September 2014. Fish census conducted on the density of Leopard Coralgrouper before and after two fishing incidents showed that the fish population abundance was reduced to 5.33 ± 2.39 (N =12) fish per census, from 29.42 ± 13.24 (N = 24) fish per census and after the two incidents. Fishing on spawning aggregation has reduced large reproductive Leopard Coralgroupers of up to 80%. This paper shows that illegal fishing continues posting threat to MPA in Malaysia. Illegal activity hampered the overall effectiveness of a no-take marine reserve for the recovery of fish biomass and density.

PROTEOMICS OF SYMBIOTIC FUNCTION, DYSFUNCTION AND RECOVERY IN REEF-BUILDING CORALS (Abstract ID: 28065 | Poster ID: 16)

Because we are in the midst of alarming losses of coral reefs owing to mounting levels of environmental stress, a much fuller understanding is required of how coral symbiosis is regulated if we are to predict the impact of environmental change on the future resilience of tropical coral reef ecosystems. The photosynthetic bleaching response of Acropora formosa, Stylophora pistillata and Pocillopora damicornis collected from the Great Barrier Reef were previously compared under empirical conditions of environmental stress (Beltran et al., 2012). Briefly, after 48 h of stress (high light/low temperature, high light/high temperature, and low light/high temperature), A. formosa was found to be a thermally-sensitive species under both light conditions, S. pistillata was thermally-tolerant but light-sensitive, while P. damicornis was least sensitive to bleaching and showed attributes of light and thermal tolerance. Protein samples were collected at T=0, T=24h and T=48h during each treatment for quantitative high-throughput proteomic analyses of the intact coral holobiome. Such data provides a vital backdrop to examine the effects of heat and light on coral bleaching and the reacquisition of algal partners in post-stressed corals, which will be discussed in context with our experimental photophysical observations.

BRIGHT SPOTS AMONG THE WORLD'S CORAL REEFS (Abstract ID: 27887)

Ongoing declines among the world's coral reefs require novel approaches to sustain these ecosystems. A presently untapped approach is systematically identifying and learning from outliers- places where ecosystems are substantially better (bright spots) or worse (dark spots) than expected, given the environmental and socioeconomic conditions they are exposed to. We compile data from 2,500 reefs and develop a Bayesian model to generate expectations of how sreef fish biomass is related to 18 socioeconomic drivers and environmental conditions. We then identify 15 bright and 35 dark spots, defined as sites that had biomass levels two standard deviations from expectations. Bright spots were not simply comprised of remote areas with low fishing pressure- they include localities where human populations and use of ecosystems resources is high, potentially providing novel insights into how communities have successfully confronted strong drivers of change. We surveyed experts about conditions at these sites to reveal that bright spots were characterised by strong sociocultural institutions such as customary tenure, high levels of local engagement in management, high dependence on marine resources, and beneficial environmental conditions such as deep-water refuges. Alternatively, dark spots were characterised by intensive capture and storage technology and a recent history of environmental shocks. Our results suggest that investments in strengthening fisheries governance could facilitate innovative conservation actions that help communities defy expectations of global reef degradation

CORAL-SYMBIODINIUM INTERACTIONS ACROSS A GRADIENT OF LOCAL STRESSORS ON KIRITIMATI ATOLL (Abstract ID: 29057)

The resilience of coral reef ecosystems is shaped by a variety of dynamic coral-symbiont interactions. Corals host a variety of single-celled algae (Symbiodinium) clades and types, some of which are better suited to sustained environmental stress than others. Some clades, such as clade D, provide increased thermal tolerance in stressed coral colonies, although not without certain functional drawbacks. Determining the mechanisms behind changes in coral-Symbiodinium interactions is essential to understanding the ability of the coral symbiome to adapt to climate change and other anthropogenic stressors. For this study, we evaluated the dynamics of Symbiodinium communities within coral colonies across a gradient of human disturbance (i.e. coastal nutrient input and fishing pressure) on Kiritimati atoll (Christmas Island). We collected coral tissue samples for three coral species (P. lobata, M. foliosa, and P. eydouxi) and analyzed them using MiSeq ITS2 amplicon sequencing with a clustering approach and Minimum Entropy Decomposition. We found coral species-specific patterns in symbiont genetic diversity that persisted across the human disturbance gradient, and site-specific distribution of "sub-optimal" symbiont types. By describing the relationship between local stressors and coral symbiont genetic diversity, these results assist in elucidating interactions between human disturbance, coral-symbiont interactions, and broad-scale reef ecosystem resilience.

IMPROVING THERMAL STRESS REPRESENTATION ON OCEANOGRAPHICALLY DIVERSE PACIFIC REEFS USING A COMBINATION OF IN SITU AND SATELLITE DATA (Abstract ID: 28871)

Coral reef managers increasingly use satellite products to monitor thermal stress on reefs due to the ease of accessibility and near real-time updating of these data. Despite improvements in spatial resolution to satellite sea surface temperature (SST) data, there is still variation in how well these data correspond to temperatures on coral reefs. Here, we use a dataset of 62 temperature loggers deployed across the Pacific from 2005 to 2012 to investigate how SST data represent in situ temperatures (IST) at a range of depths and oceanographic regimes. At many sites, SST data agree well with IST, with low (≈ 0.3°C) mean differences that are consistent year-round. However, at some locations, particularly deeper reefs at higher latitudes or in upwelling regions, SST can over-estimate IST by, on average, 1°C or more and with substantial seasonal variability. We apply the Coral Reef Watch Degree Heating Week (DHW) metric to IST to quantify in situ accumulated thermal stress, comparing this with corresponding DHW values from SST data. We calculated the in situ version of DHW for each site after adjusting the SST-derived Maximum of the Monthly Means (MMM) climatology by the average difference between the SST and IST datasets. This improved the correlation between satellite and in situ DHW values on reefs where temperatures were much lower than their overlying SST. This highlights the potential for the development of new techniques using both satellite and in situ data to better estimate thermal stress across a broad range of reef environment characteristics, including depth.

SUCCESSFUL CONTROL OF CROWN-OF-THORN STARFISH IN AMERICAN SAMOA (Abstract ID: 29088)

Population outbreaks of the coral-eating crown-of-thorn starfish (Acanthaster planci) are a significant threat to coral reefs. Control of large-scale outbreaks has had limited success despite over 100 attempts to control outbreaks populations (Rivera Posada et al., 2013). However, efforts continue to control outbreaks due to the importance of coral reefs to local communities and dive tourism. This study reports on successful efforts to control a small outbreak of A. planci in the National Park of American Samoa using methods refined over a 4 year period. Outbreaks of A. planci were detected using a simple but effective surface towboard technique, which allowed 50km of coastline to be surveyed in 3-4 days. Eradication efforts were targeted to areas with high A. planci densities. Subdermal injection of either sodium bisulfate or oxbile was used as a poison agent. Oxbile proved to be more efficient since only a single injection was needed to kill

the individual, while sodium bisulfate required the animal to be removed from the reef to administer 10-15 injections. These methods resulted in the elimination of over 25,000 individuals over a 34 month period, saving an estimated 285,000 m2 of coral reef from A. planci predation. Coral cover in park waters between 10 and 20m depth showed no significant change during this period, and densities of A. planci has been reduced to below outbreak levels. This study demonstrates a refinement of techniques that eventually proved to be very effective in controlling A. planci outbreaks in limited areas during small population outbreaks.

A MULTI-DISCIPLINARY APPROACH TO UNDERSTANDING HISTORICAL CHANGES IN CORAL COMMUNITIES (Abstract ID: 28627)

Long-term data with high-precision chronology are essential to elucidate past ecological changes on coral reefs beyond the period of modern-day monitoring programs in order to appropriately assess the current status of reefs. In 2012 we revisited two inshore reefs within the central Great Barrier Reef, where a series of historical photographs document a loss of hard coral cover between c.1890-1994 AD. Here we use an integrated approach that includes anecdotal historical evidence (photographs), elevation and ecological surveys, as well as high-precision U-Th dating specifically tailored for determining the age of extremely young corals, to provide a robust, objective characterisation of ecological transition. The timing of mortality for most of the dead in situ corals sampled from the historical photograph locations was found to coincide with major flood events in 1990-1991 at Bramston Reef and 1970 and 2008 at Stone Island. Evidence of some recovery was found at Bramston Reef with living coral genera similar to what was described in c.1890 present in 2012. In contrast, very little sign of coral re-establishment was found at Stone Island suggesting delayed recovery. These results provide a valuable reference point for managers to continue monitoring the recovery (or lack thereof) of coral communities at these reefs. A similar approach can be applied to other reef locations where an accurate chronology for the timing of substantial declines in coral cover, shifts in species composition and associated drivers are required.

SUB-REGIONAL VARIABILITY IN THE CORAL BLEACHING RESPONSE AT NINGALOO REEF DURING THE 2010/11 LA NIÑA: PERTURBATIONS IN THE CORAL SR/CA PALEOTHERMOMETER (Abstract ID: 29221)

During the summer of 2010/11 a regional warming event driven by strong La Niña conditions caused coral bleaching of historically unprecedented severity along the western coast of Australia including the 300-km Ningaloo Reef Tract. However, highly contrasting degrees of coral bleaching severity were observed from two nearshore reefs located just 20km apart (~20% at Tantabiddi and ~90% at Bundegi); thus, suggesting that thermal stresses imposed at these two reefs varied considerably during this regional warming event. We measured records of Sr/Ca at monthly resolution over a period spanning ~17 years (1996-2013) from cores collected from massive Porites sp. corals at Tantabiddi and Bundegi to assess the response of this normally reliable paleothermometer proxy to acute periods of thermal stress. We found that there was a strong (~65%) temporary decline (~6 months) in the slope of the Sr/Ca-temperature correlation in the Bundegi coral beginning in the summer of 2010-11. In contrast, changes in the slope of the Sr/Ca-temperature correlation from the Tantabiddi were more muted; ranging from -20% to +7% of the slope for the entire 17-year record) and were more likely the result of sampling inconsistencies related to coral growth effects. The strong reduction in slope observed in the Bundegi record was observed to be similar to that expected to occur between day versus night-time calcification. We thus hypothesise that during periods of elevated thermal stress, enhanced Sr/Ca ratios reflect both a decline in photosynthesis and reduced activity of the Ca2+ATPase enzyme.

REEF FISHERIES MAY NOT ALWAYS BENEFIT FROM TRANSITION OF LOCAL FISHERS INTO TOURISM: A SIMULATION STUDY (Abstract ID: 30030)

Excessive fishing pressure has been identified as a key driver of degradation of coral reefs. As a logical response, tropical marine conservation initiatives often encourage the transition of fishers into (eco-)tourism. In addition to reducing fishing pressure, this strategy is also seen as a way to improve the social and financial situation of fishers, and creates local stewardship of natural resources. Using simulations of model systems with varying parameters, we demonstrate that while such initiatives may result in benefits to the fishers who made the transition to tourism, conservation gains depend heavily on the local context. Fishing pressure is unlikely to decline in systems where (1) catch per unit effort remains high, (2) tourist opportunities are limited or seasonal, (3) the fishing industry is shaped by external drivers, and/or (4) local fishers can be replaced by immigrant fishers. In addition, various realistic scenarios illustrate that conservation strategies based around developing alternative income opportunities for fishers can be counterproductive.

SEA STAR PREDATION THREATENS CORAL PERSISTENCE IN SMALL RESERVES (Abstract ID: 27847)

Habitat fragmentation and trophic downgrading of ecosystems worldwide has led to numerous instances of mesoconsumer overabundance that dramatically alter ecological interactions and processes. On Indo-Pacific coral reefs, population outbreaks of the crown-of-thorns sea star*Acanthaster planci* (COTS) are a primary cause of coral decline, and determining the ecological contexts that promote or hinder outbreaks is crucial to successful coral reef management. We explored the population and behavioral dynamics of COTS within a network of small, no-take marine protected areas (MPAs) in Fiji. Using a combination of observational and manipulative experiments, we found that COTS densities were 2.1-3.4 times greater within MPAs than in adjacent fished areas and that sea stars accumulated in MPAs via selective movement from fished areas into coral-rich MPAs. These findings are contrary to previous studies that suggest reduced fishing pressure, such as via the establishment of MPAs, may help regulate COTS outbreaks by fostering more intact food-webs that can exert top-down control on COTS populations. We propose that key reserve features including small size and marked differences in habitat quality (coral abundance) between protected and fished areas may lead to concentrated COTS feeding within reserves. These findings highlight the context-dependent nature of corallivory, as well as its implications for the conservation and management of small, relatively intact MPAs embedded within a background of degraded, coral-impoverished reefs.

ASSESSMENT OF THE FUNCTIONAL COMPLEMENTARITY AMONG GRAZING HAWAIIAN SURGEONFISH: A MULTI-PRONGED APPROACH (Abstract ID: 29862 | Poster ID: 584)

Herbivores on coral reefs are instrumental in mitigating the competitive interactions between reef-building corals and fleshy algae; however, not all herbivores provide the same ecological function. Grazers/ detritivores consume turf algae (and associated organic matter), which are the primary spatial competitors to corals in the Main Hawaiian Islands. This study highlights functional diversity among surgeonfishes through observations of foraging behavior, analysis of stomach contents, and analysis of stable isotopic signatures of muscle tissue (d13C and d15N) for three common species (*Acanthurus nigrofuscus*, *Acanthurus olivaceus*, and *Ctenochaetus strigosus*) on the leeward side of Maui. Similar foraging behavior was observed in *A. nigrofuscus* and *C. strigosus*, with both biting primarily on turf; *A. olivaceus* grazed primarily sand in addition to turf. Diet composition based on stomach contents was different among species, and variation in composition was influenced by site. Measured d15N values indicate similar trophic position in the three species; however, d13C values varied among species at different sites, indicating consumption of different algal resources. Collectively, these data suggest that surgeonfish grazers exhibit significant within-guild functional diversity with respect to impact on the turf community; however, the differences and degree of divergence revealed depend on the methods used.

DEVELOPING TRANSGENIC TOOLS TO STUDY CNIDARIAN-SYMBIODINIUM SYMBIOSIS IN A SEA-ANEMONE MODEL SYSTEM (Abstract ID: 29156 | Poster ID: 24)

Transcriptomic studies in cnidarians have identified many intriguing gene-expression correlations with the establishment and breakdown of symbiosis. Nonetheless, the molecular bases of these processes remain poorly understood, in part because of the lack of a tractable genetic system to functionally test candidate genes and pathways. The small anemone Aiptasia is symbiotic with Symbiodinium and has many experimental advantages over corals, including a high – but as yet unrealized – potential for the needed genetic studies. As a first step in developing transgenic methodologies, we are attempting to express fluorescent proteins from both capped-mRNA and Aiptasia-promoter expression constructs. If successful, these technologies should allow both expression of tagged proteins for localization studies and the overexpression of candidate genes to analyze gain-of-function phenotypes. To introduce the constructs, we are using both various electroporation protocols with adults and larvae and microinjection of zygotes. In parallel, we are developing tools to knock down and knock out genes using morpholinos and CRISPR-Cas9 for analysis of loss-of-function phenotypes. If both gain-of-function and loss-of-function methods can be established, Aiptasia should become a uniquely powerful genetic model system for the study of cnidarian-Symbiodinium symbiosis.

COMPARISONS OF PHOTOSYNTHETIC FUNCTION OF SYMBIODINIUM GROWN IN CULTURE AND IN HOSPITE (Abstract ID: 29622 | Poster ID: 129)

Symbiodinium provides the cnidarians with the great majority of its fixed carbon, while the animal may allocate nutrients to the alga and offer the alga a safe haven. We are examining the photosynthetic activities of various Symbiodinium isolates, specifically probing differences in the ways in which these algae perform photosynthesis in the free-living relative to the endosymbiotic lifestyle? Photosynthetic electron transport is composed of linear and cyclic electron flow. In linear electron flow, electrons are extracted from water by the oxygen evolving complex of photosystem II (PSII) and then are transferred sequentially to the plastoquinone pool, the cytochrome b6f complex, plastocyanine, photosystem I (PSI) ferredoxin and ultimately to NADP+ to yield reducing equivalents. In cyclic electron flow, electrons are cycled around PSI to establish a proton gradient that can be used for the generation of ATP. Using both fluorescence and spectroscopic assays, we have measured the extent of both electron flows in Symbiodinium both in culture and in hospite. In our initial studies we have observed that PSI is more oxidized when the alga is associated with its animal host than when grown in culture under the same light conditions. These results suggest that the animal represents a strong sink for the reductant (fixed carbon) generated by the alga, as expected. The link between this damage under stress conditions, overall photosynthetic activity and the loss of the alga from the animal host, is being explored in detail in a collaboration of the Pringle-Grossman laboratories.

IMPACT OF THE LIONFISH (PTEROIS VOLITANS) IN THE REEF FISHES ASSOCIATIONS IN TWO CARIBBEAN MARINE PROTECTED AREAS (CUBA AND MEXICO). (Abstract ID: 28409 | Poster ID: 633)

The effectives MPAs are an essential tool for the management and conservation of fishes communities. However, these MPAs may be exposed to the invasion of alien species as Pterois volitans. Such is the case of the Guanahacabibes National Park, Cuba and Reefs of Xcalak National Park, Mexico. In both areas visual census (line transect censuses and stationary) were performed to assess the structure and composition of fish assemblages and their conservation status, and its relation with the distribution and abundance of lionfish. The number of individuals of all species observed and the size were estimated from 2010 to 2015.In Guanahacabibes the values of density, height and biomass increased significantly from 2010 to 2013, probably due to the lack of management actions with the lionfish and the favorable conditions in the area (food and shelter). Xcalak values of density, biomass and size were very low, due to the protected area management with the species. The MPA authority perform catches of this species all year through temporary employment programs. In Guanahacabibes 411 individuals of lionfish were captured for the analysis of stomach content. We identified in the diet of lionfish, 10 orders, 19 families and 35 species. Fishes was the best represented group and the families with the highest incidence were Gobiidae, Pomacentridae, Mullidae, Labridae and Scaridae. In Xcalak 128 stomachs were analyzed, reporting 3 orders, 7 families and 10 species. The families with the highest incidence in the diet were Gobiidae, Labridae, Pomacanthidae, Balistidae and Monacanthidae.

WARMING AND ACDIFICATIONALTER SKELETAL MORPHOLOGY OF THE REEF-BUILDING CORAL *SIDERASTREA SIDEREA* (Abstract ID: 28336)

Increasing ocean temperatures and decreasing seawater pH threaten coral reefs worldwide. Controlled laboratory experiments were conducted to investigate and quantify the effects of temperature (25, 28, 32°C) and CO2-induced ocean acidification (PCO2 = 324, 477, 604, 2553 µatm) on the skeletal morphology of the resilient Caribbean reef-building coral *Siderastrea siderea*over a 95-day interval. Post-treatment *S. siderea* corallites were imaged via stereomicroscopy to evaluate effects of warming and acidification on corallite height and infilling. Reduced (25°C) and elevated (32°C) temperatures both resulted in increased corallite height but decreased corallite infilling relative to the control. In contrast, corals reared under the lowest (324 µatm) and highest PCO2 treatments (2553 µatm) exhibited both decreased corallite height and decreased corallite infilling relative to the control. Interestingly, warming (32°C) and acidification (604 µatm PCO2) projected for the end of the century both resulted in increased corallite height and reduced corallite infilling relative to the control. Our results suggest that corals exposed to increased warming or acidification will modify the skeletal morphology of *S. siderea* by the end of the 21st century, which may exacerbate observed declines in coral health across Caribbean reef systems.

MULTI-METHOD APPROACH TO MONITORING A REEF-ASSOCIATED WHALE SHARK AGGREGATION IN THE RED SEA (Abstract ID: 29267)

The whale shark (*Rhincodon typus*) is known to aggregate seasonally in specific sites within its circumglobal range. Among these is Shib Habil, an inshore reef off the western coast of Saudi Arabia where whale sharks are known to gather each spring. In 2010 an array of 32 acoustic receivers was installed on and around Shib Habil. From 2009-2015, 59 satellite and 91 acoustic tags were deployed on sharks in the Red Sea, including 33 animals that were fitted with both. Satellite telemetry demonstrated strong population-scale site fidelity to the southern Red Sea. Based on the acoustics, the aggregation season was defined as February through May; these months account for over 90% of whale shark detections in the area. Levels of activity were compared between receiver stations and the most active receivers also account for over 90% of whale shark detections. Approximately 40% of acoustically tagged sharks were detected again the following year. Satellite data shows that 12 of these phylopatric sharks migrated hundreds of kilometers away from Shib Habil between aggregation seasons. Establishing this baseline serves as a point of comparison as conditions change through time. For instance, we anticipate being able to show whether a recent bleaching event at Shib Habil correlates to a change in the aggregation during the coming season.

A MULTI-PLATFORM APPROACH TO MAP THE U.S. CORAL REEF TASK FORCE FAGA'ALU BAY WATERSHED PARTNERSHIP INITIATIVE PRIORITY STUDY AREA, TUTUILA, AMERICAN SAMOA (Abstract ID: 28256 | Poster ID: 445)

The coral reef in Faga'alu Bay, Tutuila, American Samoa, has suffered numerous natural and anthropogenic stresses. Areas once dominated by live coral are now mostly a rubble surface covered with turf or macroalgae. In 2012, as part of the U.S. Coral Reef Task Force Watershed Partnership Initiative, Faga'alu Bay was designated as a priority area on which to focus research and restoration to help improve the health and viability of the coral reef ecosystem. To support these ridge-to-reef efforts, the U.S. Geological Survey mapped nearly 1 $km^2$ of seafloor to depths of about 60 m using a combination of WorldView-2 satellite imagery, IKONOS satellite-derived pseudobathymetry, and

underwater video and photographs. The resulting benthic habitat map uses a 100 $m^2$ minimum mapping unit (MMU), which is more applicable to ecological studies and management than previous maps of the area. Unconsolidated sediment (predominantly sand) constitutes slightly greater than 50% of the seafloor in the mapped area; reef and other hardbottom potentially available for coral recruitment constitute nearly 50% of the mapped area. Of this potentially available hardbottom, only slightly greater than 37% is colonized with at least 10% live coral, which is fairly evenly distributed between the reef flat, fore reef, and offshore bank/shelf. This benthic habitat map documents current baseline conditions and will assist with future monitoring and management.

EVERY POPULATION MATTERS: HOTSPOTS OF GENOME-WIDE GENETIC DIVERSITY IN HAWAIIAN 'OPIHI (*CELLANA EXARATA*) (Abstract ID: 29760)

Populations with low genetic diversity can be particularly vulnerable to environmental and anthropogenic stressors due to the loss of advantageous mutations. Population genetic theory predicts that genetic diversity will scale with population size. In this study, we use genome-wide surveys of genetic variation in 'opihi (*Cellana exarata*) from the Hawaiian islands (HI) to test for a relationship between genetic diversity and population size. Historical 'opihi population sizes (pre-human colonization) are predicted to have ranged from ~1E6 to 1E8 and have been reduced by up to four orders of magnitude by harvesting. Contrary to expectations, nucleotide diversity exhibited a strong negative relationship with historical census population size but was unaffected by harvesting. These results indicate that 'opihi populations within the main HI are not in equilibrium and have experienced a major bottleneck in pre-human times, followed by a net population expansion. Two alternative explanations are (1) either 'opihi was extirpated from the main HI and they were recolonized from populations in the Northwestern HI or (2) demographic history, migration and mutation rates have led to a predictable non-equilibrium relationship between diversity and population size. Overall, these results suggest that the 'opihi in the Northwestern HI harbor a stockpile of genomic diversity, despite relatively small population sizes. Depending on the locus, however, every island harbors a genetic diversity hotspot, and management plans should focus on maintaining genetic diversity range-wide.

LARVAL BIOLOGY OF THE CARIBBEAN OCTOCORAL ANTILLOGORGIA AMERICANA AND ITS IMPLICATIONS FOR DISPERSAL (Abstract ID: 30018)

Interest in the extent of larval dispersal and population connectivity of coral reef taxa has increased exponentially. While new methodological approaches have greatly improved our understanding of larval dispersal, the role of larval biology in controlling dispersal remains largely unknown. We characterized spawning, larval development, swimming behavior, longevity, survivorship and settlement of the Caribbean octocoral Antillogorgia americana in the Florida Keys. Colonies of A. americana split-spawned over two major events two weeks apart, 5 and 20 d after the full moon of November 2014. Fertilized eggs developed into motile planulae over 2-3 days. Despite the fairly rapid onset of competency to settle (4 d), the great majority of larvae delayed settlement for an extended period of time, with 50 and 95% of the original cohort settling/dropping onto the substrate by 36 and 58 d, respectively. Egg buoyancy and larval swimming behavior changed with age. Eggs were positively buoyant with a mean rising velocity of 0.17 cm/s. There was a significant decrease in vertical velocities during embryogenesis, but following the onset of larval swimming behavior velocities gradually increased. Larval mortality in the laboratory was extremely low (10% over 58 d). Behavioral data such as these are critical to modeling larval dispersal, and these efforts are currently underway. The pattern of a long delay in settlement, allied with negative geotactic swimming behavior should lead to a high dispersal potential, which may explain the broad distribution of A. americana in the Caribbean.

EARLY SYMBIONT ACQUISITION WITHIN ACROPORA PALMATA AND ORBICELLA FAVEOLATA RECRUITS (Abstract ID: 29009)

The symbiotic relationship between dinoflagellate algae of the genus Symbiodinium and corals forms the base of the tropical reef ecosystem. Yet, despite their importance to the host, the majority of these symbionts are horizontally transmitted. We followed symbiont uptake in Orbicella faveolata and Acropora palmata recruits in the lab and field in the Florida Keys. Lab assays demonstrated that prior infection does not limit the ability of the O. faveolata recruits to acquire additional symbionts; however, the ability of asymbiotic O. faveolata recruits to acquire symbionts decreased after 4 months. Thus early exposure to Symbiodinium may benefit lab reared recruits (e.g., enhance growth) without limiting their ability to transition to natural Symbiodinium associations upon outplant. O. faveolata and A. palmata recruits, exposed to environmental symbionts in the lab and field, acquired a range of symbiont types, with those within Clade D dominating in samples collected over the course of 16 months. Interestingly, during a recent bleaching event, A. palmata yearlings did not visibly bleach. As with other coral species that initially acquire a range of symbiont types, these species may transition to the dominant symbionts found within these hosts in the Florida Keys (S. fitti and Symbiodinium within the B1 lineage for A. palmata and O. faveolata, respectively), but the presence of Symbiodinium within Clade D may provide resilience to recruits and its continual dominance would represent a potential mechanism to improve survival in response to local thermal warming events.

THE ROLE OF BASIN-SCALE CLIMATE VARIABILITY IN THE DECLINE OF CARIBBEAN CORALS (Abstract ID: 29874)

Anthropogenic climate change is principle threat to coral reef survival. However, the effects of the projected decrease in nutrient export and net primary production (PP) resulting from enhanced stratification of the upper oceans, has received little attention. We generated century long growth histories from three dominant Atlantic coral genera using skeletal cores collected from live colonies across the Caribbean and Bermuda, and from fossils preserved in Last Interglacial reefs. We find that growth of modern corals has been in steep decline since the mid-70's. However these changes are cyclical rather than secular as coral growth exhibits coherent, large-amplitude decadal-scale changes through the 20th century. Similar patterns are evident during the Last Interglacial, suggesting that Atlantic corals respond strongly to basin-scale changes internal to the climate system. A comparison of our records with output from the MOM4 physical model shows that coral growth tracks changes in mixed layer depth (MLD). We further investigated the link to MLD using the nitrogen isotope ratio ($\mathbf{d}15N$) of skeletal bound organic (SBO) material. Interpreting our results within the framework of a coral-symbiont N recycling model suggests that coral heterotrophic feeding increases under MLD-fueled productivity, enhancing skeletal growth. The strong sensitivity of coral growth to past changes in productivity implies that the projected 21st century decline in net PP could potentially rival and will certainly exacerbate the effects of warming and OA on coral reef ecosystems.

HATCHERY PRODUCTION OF TRIPNEUSTES GRATILLA FOR BIOCONTROL OF INVASIVE SEAWEEDS IN CORAL REEF RESTORATION (Abstract ID: 29722 | Poster ID: 476)

The native collector sea urchin Tripneustes gratilla is raised as a biocontrol to mitigate the effects of invasive seaweeds on indigenous corals in Kaneohe Bay, Hawaii. Animals are hatchery reared rather than transplanted from wild stocks so as not to cause an imbalance in other parts of the Island of Oahu. Tripneustes gratilla is being successfully raised in the hatchery at the Anuenue Fisheries Research Center in Honolulu. Wild broodstock are collected and spawned on a monthly basis. First feed is administered three days after fertilization. Larvae are grown in round tanks with mild aeration. They are fed a microalgae diet at an initial density of 30,000 cells per milliliter. Feeding density is adjusted as needed. Larvae are maintained in UV treated seawater, pre-filtered to one micron at a temperature range of 25C to 26C. Water is changed daily and tank changes are performed as needed to maintain hygiene. Competency in a majority of larvae is usually observed at 23 days post-fertilization. Competent larvae are moved to settlement tanks for metamorphosis. Settlement tanks are prepared with natural biofilms. Post-larval urchins are allowed to remain in settlement tanks and graze on biofilms for eight to twelve weeks. At 5mm to 7mm juvenile urchins are switched to a diet of cultured macroalgae. Within three to five weeks of feeding on macroalgae, urchins more than double in size and are ready for outplanting in Kaneohe Bay.

TRACKING THE SIGNALING CARGO OF EXTRACELLULAR SYMBIONTS INTO HOST TISSUES (Abstract ID: 28617)

Animal-microbe symbioses are fundamental to animal physiology but how and where bacteria interact with their host, remain largely elusive. The mutualistic association between the Hawaiian bobtail squid, *Euprymna scolopes* and its luminous bacterium *Vibrio fischeri* is a powerful model to investigate signaling between the host and its microbial symbiont. In this system, bacteria are acquired *via* horizontal transmission within hours of hatching and colonize the light organ as an extracellular partnership. Here, we combined TEM and NanoSIMS imaging to visualize $^{15}$N-labeled bacterial products within the tissue of newly-hatched squids. The nuclei of epithelial cells in the light organ were highly enriched in 15N with hotspots localized in the nucleolus as early as 2 h following inoculation. Closer examination revealed labeling was concentrated in the euchromatin regions of the nucleus, where DNA is often under active transcription. Taken together, our results show that *V. fischeri*-derived molecules target the host nucleus. We also exposed squid to $^{15}$N-labeled outer membrane vesicles (OMVs) extracted from *V. fisheri* as they are known to play a key role in signaling between symbiotic partners. Interestingly, $^{15}$N-enrichment patterns were similar to squid inoculated with intact bacteria. We are now exploring the species-specificity of these labeling patterns using other bacterial species. The unique link between spatial and functional information provided by the NanoSIMS technology has the potential to open a new frontier for the study of communication between host and symbiont.

VARIATION IN BIODIVERSITY OF CRYPTIC REEF FISHES ALONG A RED SEA ENVIRONMENTAL GRADIENT (Abstract ID: 28628)

Small cryptic reef fishes are one of the most underestimated communities in coral reef studies due to their small size, biases in sampling, and cryptic nature. This is particularly true in the Red Sea, where previous surveys to comprehensibly document fish assemblages have been limited to visually conspicuous species. We conducted standardized collections of small and cryptic fishes to formally identify fish communities and compared results along a gradient of oceanographic and ecological environments. To help resolve taxonomic difficulties, genetic techniques were used in addition to morphological characteristics to identify and catalog individuals. Approximately 200 OTUs (operational taxonomic unit) from 35 families were collected, identified, and vouchered. Abundance and diversity increased from the clear oligotrophic reefs in the north to the shallow turbid reefs in the south. Community composition differed among regions, largely driven by relative abundances damselfish and gobies. Only 40% of the OTUs could be confidently assigned to species. The diversity of this understudied group plays a potentially important role in the ecology of reef fish assemblages, particular in the transfer of energy between trophic groups, but our current understanding of this role is limited by the lack of taxonomic clarity. This study has established a valuable collection of vouchered specimens with the potential to uncover new species and confirm new records in the Red Sea. Overall, further work in this area will help to place the Red Sea in a wider biogeographic context.

FRESH GROUNDWATER IMPACTS ON INORGANIC CARBON DYNAMICS IN COASTAL HAWAI'I (Abstract ID: 29995 | Poster ID: 380)

The shoreward margin of coral reefs contain many habitat types within a short distance, are affected by freshwater inputs, and can be heavily impacted by humans interactions. The aragonite saturation, a factor influencing how easily organisms can produce calcium carbonate, in this region depend on the salinity and the concentration of total inorganic carbon (TCO2) in groundwater. To determine the impact of freshwater on TCO2 dynamics between the shore and reef, total alkalinity and pH were measured in the morning along transects at six sites around Hawai'i Island. The pH of fresh groundwater differed among the sites, between 6.8-8.2 at the shoreline and increasing to 8.2 at the reef. At all sites, aragonite saturation was lower than open ocean conditions, and on average lower than most coral reefs worldwide. The magnitude of aragonite saturation decrease depended on watershed characteristics (geology, land use, precipitation) that controlled the groundwater pH and TCO2. To determine how TCO2 in fresh groundwater discharge varies across Hawai'i, USGS measurements of pH and alkalinity from coastal wells were used to calculate TCO2 of each aquifer unit. The well data and estimates from the nearshore data were significantly correlated. Statewide, only a few locations, including the Waianae coast of Oahu, have higher TCO2 than seawater, potentially buffering the impact of ocean acidification. Concerted effort to collect samples statewide and analyzed with a consistent method is needed to identify priority sites for monitoring the effects of ocean acidification.

REGAL PHYLOGEOGRAPHY: RANGE-WIDE SURVEY OF THE MARINE ANGELFISH PYGOPLITES DIACANTHUS REVEALS EVOLUTIONARY PARTITIONS (Abstract ID: 29229)

The Regal Angelfish (Pygoplites diacanthus; family Pomacanthidae) occupies reefs from the Red Sea to the central Pacific, with distinct color morphs in the Indian Ocean to Red Sea and Pacific Ocean. To assess population differentiation and evaluate the possibility of cryptic evolutionary partitions in this monotypic genus, we surveyed mtDNA cytochrome b and two nuclear introns (S7 and RAG2) in 547 individuals from 15 locations. Phylogeographic analyses revealed four mtDNA lineages (d = 0.006 – 0.015) corresponding to the Pacific Ocean, the Red Sea, and two admixed lineages in the Indian Ocean, consistent with known biogeographical barriers. Both S7 and RAG2 showed strong population-level differentiation between the Red Sea, Indian Ocean, and Pacific Ocean. The only consistent population structure within these three regions was at the Society Islands, where surrounding oceanographic conditions may reinforce isolation. Coalescence analyses indicate a Pacific expansion (1.71 Ma) that gave rise to a Red Sea lineage (1.44 Ma) followed by a radiation of two lineages that currently occupy the Indian Ocean (0.93 – 0.72 Ma). Persistence of a Red Sea lineage through Pleistocene glacial cycles indicates a long-term refuge in this region. The affiliation of Pacific and Red Sea populations, apparent in cytochrome b and S7 invokes the possibility that the Indian Ocean was recolonized from the Red Sea, possibly more than once. Assessing genetic architecture in this widespread monotypic genus reveals cryptic evolutionary diversity that merits subspecific recognition.

DISPERSION OF SEAGRASS PROPAGULES AND CONNECTIVITY AMONG MEADOWS IN THE GREAT BARRIER REEF WORLD HERITAGE AREA, QUEENSLAND, AUSTRALIA. (Abstract ID: 27828)

Severe tropical storms and floods in north- eastern Australia between 2007 and 2012 damaged or destroyed seagrass meadows along hundreds of kilometres of coastline. The subsequent deaths of turtles and dugong have led to the very status of our iconic Great Barrier Reef World Heritage Area being questioned. We examined how meadow loss at this scale may re-establish from the dispersion of propagules floating in the water. We conducted a study based around Townsville and Abbot Point in North Queensland using a 2 dimensional numeric model developed for studying water movement. We released virtual propagules in the model between August and November 2011 with actual wind and current data. Model results suggest connectivity between offshore meadows and inshore meadows is likely to be low, limiting their ability to provide a reservoir of propagules. Time of year, location of release and the location of the propagule (surface or sub-surface) influenced movement. Over an 8 week model duration most propagules remained between 30 and 60 kilometres of their release point but distances up to 950 kilometres were possible. Most movement was to the north –west. An initial analysis identified where propagules from many source meadows accumulate and re-establishment would be more likely and where meadows were not well connected to other meadows. We report on the value of this exercise and management implications.

EL NINO IMPACT ON CORAL REEFS OF THE CENTRAL PACIFIC –USE OF SENTINEL 2, A TEST IN THE MARQUESAS (Abstract ID: 30162 | Poster ID: 344)

Last December, a powerful El Niño Southern Oscillation combined with waxed ambient sea surface temperatures entailed significant anomalies across the equatorial Pacific Ocean which are likely to stress hard coral reefs, cascading in the symbiotic algae expulsion

(bleaching). Given the remoteness and spread of coral reefs, remote sensing has increasingly been advocated for monitoring the dynamics of these ecosystems. A decade ago, the Landsat-7 satellite allowed the typology and bathymetry to be rendered as a world atlas by leveraging a 30-m spatial resolution. However, both this spatial resolution and the spectral dimensions remain too coarse to understand the benthic heterogeneity process occurring at the coral colonies scale and time series analysis was not conducted. The Sentinel-2 sensor has the potential to improve monitoring of the coral reefs ecology thanks to the increased spatial resolution and number of wavebands, and the European Space Agency has tasked ARGANS Ltd with support of the Italian CNR and un. of Tartu to develop the EO data processors, un. of Queensland being involved in their validation. Meanwhile, given the very likely thermal stress event, monitoring of the 2015-2016 coral bleaching in the central equatorial Pacific has started, i.e. surveys of the Northern Marquesas Archipelago (French Polynesia), South Kiribati and Norther Cook Islands. Field spectra and photoquadrats of shallow coral reef habitats in the Marquise isles enabled to "calibrate" the Sentinel-2 data alongside Landsat, as well as the very high spatial resolution Pléiades1.

EVOLUTIONARY ADAPTATION POTENTIAL: FROM NOVEL SCIENCE TO PRACTICAL APPLICATION (Abstract ID: 29799)

Earth's ecosystems—and their ability to provide services and benefits—are changing at an alarming rate due to a combination of local stressors and global climate change. Perhaps the most pressing question in conservation and management is: how can we design our actions to help species survive and continue to provide the services upon which humans rely? We believe that the answer lies in designing management actions to encourage billions of evolutionary match/mismatch tests, allowing nature to draw from diverse portfolios to pick winning combinations of genes and species that will persist into the future. However, there is little in the way of a comprehensive scientific theory that describes how population size, demographic connectivity, and diversity (e.g., genomic, phenotypic, species) affect evolutionary adaptation potential, defined as the probability of finding successful evolutionary combinations and propagating those across environmental mosaics. Similarly, there is limited guidance available for managers and conservation professionals about actions they could take to promote adaptation via natural selection. In this talk, we will synthesize ideas presented in this session and discuss how this information can help to design conservation and management actions that will promote coral adaptation via natural selection.

A PHYLOGENOMIC BACKBONE FOR SCLERACTINIA BASED GENOME AND TRANSCRIPTOME DATA. (Abstract ID: 29590)

Stony corals (Order Scleractinia) have been studied for decades because of their fundamental role in reef building and their excellent fossil record extending back to the Triassic. Nevertheless, our understanding of scleractinian evolution and taxonomy has changed profoundly with the recent advent of molecular phylogenetics. However, most phylogenetic studies to date are still based on only a handful of mostly mitochondrial loci and tend to focus on individual coral genera and families with very few studies addressing deeper nodes. A robustly supported phylogeny of the deepest nodes is therefore still missing. Here, we present the first Scleractinia phylogeny based on genomic data. Our dataset is comprised of newly sequenced RNA-Seq data for deep and shallow water Scleractinia and published genome and RNA-Seq data from other stony-coral and outgroup lineages. At present, our phylogenetic analyses include 27 samples that span 10 scleractinian families and additional sequencing is currently underway to further extend our taxonomic range. Phylogenomic matrices so far contain between 73 and more than 2500 exclusively Metazoan orthogroups that are shared by 50-90% of all samples. Our results provide a well-resolved, robust, phylogenomic backbone for Scleractinia, addressing long-standing questions about the monophyly of the so-called complex and robust clades as well as resolving the position of particular groups such as the family Pocilloporidae.

CORAL REGULATION OF THE CALCIFYING FLUID IS AFFECTED BY SEAWATER DISSOLVED INORGANIC CARBON CONCENTRATION (Abstract ID: 28014)

In the context of ocean acidification, it is important to understand how modifications of the carbonate chemistry affect the mechanisms of calcification in corals, and how such effects at the cellular level are translated to the organismal level. To better understand the calcification mechanism of corals it is critical to determine the extent to which both biological and environmental factors influence the chemistry of the calcifying fluid (CF), where the skeleton forms. To distinguish the effects of varying seawater dissolved inorganic carbon concentration [DIC] from varying seawater pH, we manipulated seawater [DIC] while maintaining seawater pH constant and measured the responses of photosynthesis, calcification, and pH in the CF ($pH_{CF}$). Photosynthesis and calcification in the light and dark increased as a function of [DIC]. $pH_{CF}$ measured by confocal microscopy also increased with [DIC]. A second phase of experiments will be run to determine the effects of seawater [DIC] manipulations on the [DIC] in the CF using geochemical tools; the preliminary results will be reported during this presentation. This study shows that in addition to seawater pH, [DIC] can also modify chemical conditions in the CF, which in turn modulate the calcification rate of organisms. Understanding the key mechanisms controlling coral calcification is critical to making further progress in determining the response of coral reefs to OA.

A FRAMEWORK TO ASSESS RIDGE TO REEF ECOSYSTEM HEALTH IN AMERICAN SAMOA (Abstract ID: 29509)

A coupled approach to assessing ecosystem health and functioning of coral reefs is important in prioritizing and protecting resources that millions of people are dependent upon for livelihood, cultural, and aesthetic uses. In American Samoa, the proximity of development and growing human population to watershed stream discharge areas predisposes reef communities to be adversely affected by non-point sources of pollution. This project aims to develop an ecosystem health index using water quality and coral reef monitoring protocols that can be used to assess the current status of streams and coral reefs, pinpoint specific sources of degradation, and provide spatially-explicit threat models highlighting areas where these stressors occur. Main tasks to be accomplished under this grant include: development of a framework to assess ecosystem health, training workshops on field monitoring and analyses methods, field surveys of coral reef and watershed sites in Tutuila, compilation and analyses of survey results for assessment of ecosystem health at the watershed level, and building local capacity in monitoring, analyzing, and disseminating results. The final products of this project will include: a comprehensive ridge to reef framework and baseline data that can be used to predict significant drivers of threat to ecosystem health at the watershed scale and a training toolkit using the ecosystem health monitoring criteria. The identification of the most important causes of reef impairment can help make informed decisions using innovative tools and comprehensive datasets that can enable systematic prioritization for protection of valuable coral reef resources in American Samoa.

KEY PREDICTORS OF EXTINCTION RISK IN SEA BREAMS AND PORGIES (FAMILY: SPARIDAE) (Abstract ID: 27787)

Identification, understanding and prediction of the factors that drive species to heightened risk of extinction are important goals for conservation, especially since few areas on the planet remain unaffected by human activities. Global extinction risk assessments of an entire family of marine fishes (Family: Sparidae), using the International Union for Conservation of Nature Red List process, showed that 8.6% (13 species) of sparids were threatened. All have increased vulnerability to population declines from intense fishing pressure and habitat destruction. A further 7.9% were classified as Near Threatened. The majority of the sparids (69.5%) were assessed as Least Concern, while the remaining 21 species (13.9%) were listed as Data Deficient. In addition to presenting the first global assessment of sparid extinction risk, a Random Forest model was used to identify correlates of extinction risk in the Sparidae using 33 biological and threat variables. The model correctly classified up to 90% of Red List category placements and showed complex interactions between intrinsic and extrinsic predictors. Larger body size was the most important predictor of risk. Additional predictors included generation length, longevity, rocky reef habitat, recreational fishing, climate change, harvesting, area of occupancy, and lower depth limit. This analysis is the first time a predictive model of extinction risk has been applied to marine fishes and presents an opportunity to identify and mitigate threats affecting similar groups of highly valued and ecologically important marine fishes.

RELATIVE RESILIENCE POTENTIAL AND CLIMATE VULNERABILITY OF CORAL REEFS ALONG THE WEST COAST OF HAWAI'I ISLAND (Abstract ID: 28558)

NOAA coordinates activities and expertise in the West Hawai'i Focus Area on the NW side of Hawai'i Island to address objectives on coral health, climate change and community capacity. To support and help guide these efforts, we have assessed the ecological resilience potential of 40 sites in this area by examining indicators of resilience processes (e.g. herbivore biomass and coral recruitment), and how spatial variation in anthropogenic stress and projected future climate stress influences exposure and resilience. We found: 1) exposure to anthropogenic and projected climate stress is higher in the northern part of the survey area than in the south, and 2) resilience potential varies greatly across the survey area. The assessment results are used to identify and tailor management strategies to improve resilience at low resilience sites and maintain resilience at high resilience sites. We have an expansive engagement plan to socialize and disseminate the project results in a strategic way to key stakeholders, including local community members. These communication and capacity building efforts are critical to increase support for and compliance with any management strategies implemented in the near future. This multi-disciplinary project uniquely combines recent advances in resilience science and application with climate modeling and social science. This powerful case study describes how scientists, managers and local community members can work together to examine and then reduce the climate vulnerability of coral reefs in Hawai'i.

THE EFFECTS OF JAPANESE STYLE MPAS AND ACANTHASTER PLANCI ON CORAL COVER IN ISHIGAKI JAPAN (Abstract ID: 30081 | Poster ID: 451)

Marine Park Zones (MPZs) have been set up by the Japanese Ministry of Environment around the small island of Ishigaki in the Ryukyu archipelago in the attempt to protect dwindling populations of coral in the area. This study attempts to determine whether or not the management scheme has been successful. A combination of field surveys and existing time series data analysis has shown that the coral reef community appears to grow and decline independently of the MPZ system. An outbreak of Acanthaster planci occurred in 2009 on the leeward side of the island and it disparately affected the coral cover of protected and non-protected sites with the protected sites losing 32.040% of their coral cover and non-protected sites losing only 1.243% of their coral cover from 2009 to 2010. On the windward side of the island where there was not an outbreak of A. placi the coral cover increased by 10.024% from 2009 to 2010. Through further analysis of the regulatory regimes the recommendation is made to impose stricter fishing regulations and more vigorous A. placi management with the goal of allowing the natural ecosystem time to rebound.

FORGING PARTNERSHIPS TO LAY A FOUNDATION FOR ENVIRONMENTAL SUCCESS (Abstract ID: 29626)

The marine environment and the incomes of coastal communities in the Eastern Caribbean (EC) have benefited from partnerships established at the national and regional level under the Eastern Caribbean Marine Managed Areas Network (ECMMAN) project. 5 regional and international organizations with varying mandates in collaboration with governmental and non-governmental organizations in 6 EC countries have unified as one implementing unit with the shared objective to create a network that more than doubles the area of effectively managed marine managed areas while providing for improved livelihood opportunities. In order to build an effective partnership, each organization brought complementary strengths that contributed to building an effective mechanism for project implementation. The organizations 7 collective core areas of strength are local knowledge and experience, environmental policy, scientific research, training and education,sustainable financing, and public awareness and outreach. Some lessons learned from this collaboration included the need to: establish ground rules from the start, establish clear and open channels of communication, clearly define roles and responsibilities, immediately resolve issues, respect each other's organizational norms, and think outside of the box for creative solutions to problems. These collaborative actions have resulted in a uniquely strong, effective, nimble partnership that benefits conservation and management of the marine and coastal resources across organizational missions and international boundaries.

NOT ALL CORALS DINE IN: VARIATION IN NICHE PARTITIONING BETWEEN CORALS AND THEIR *SYMBIODINIUM* INDICATES A RANGE OF SYMBIOSES (Abstract ID: 29304)

The symbiosis between corals and *Symbiodinium* has allowed coral reefs to achieve high levels of productivity and diversity in oligotrophic habitats. By sharing resources, corals and *Symbiodinium* access novel niche space. Some have argued that the coral-algal interaction ranges from mutualism to parasitism. Trophic niche theory predicts that mutualist symbionts would occupy the same niche space as their host (shared resources) whereas commensal symbionts would occupy a different niche (fewer shared resources). To test this hypothesis, we measured the $\delta^{13}C$ and $\delta^{15}N$ of separated coral tissue and symbiont cells from 6 coral genera commonly encountered in Hong Kong. Using Stable Isotope Bayesian Ellipses in R (SIBER) analysis, we compared the isotopic niche placement and area of each host and symbiont pair. Our results supported the hypothesis: in some genera (*Acropora* and *Goniopora*) the host and symbiont had nearly 100% overlap of their isotopic niches implying shared nutritional resources, while in others (*Platygyra* and *Favites*) there was no overlap. Finally, some genera (*Pavona* and *Porites*) have partial overlap suggesting a flexible symbiosis. These patterns were driven by nitrogen, not carbon. Indeed, the difference between the $\delta^{15}N$ values of host and symbiont was positively correlated with calyx volume, suggesting that smaller polyps evolved to support obligate symbioses while larger polyps enable corals to meet their nutritional requirements through alternative means.

DEVELOPING A CONCEPTUAL MODEL FOR CORAL REEF MONITORING IN THE MEXICAN MESOAMERICAN BARRIER REEF SYSTEM (Abstract ID: 29897 | Poster ID: 523)

The Mesoamerican Reef System (MRS) is the second longest barrier system in the world and provides a variety of ecosystem services to adjoining nations. Ecosystem services include e.g. shelter from tropical storms, reef fisheries, and a wealth of biodiversity, a prosperous tourism industry or the provision of building materials. Besides global stressors (e.g. global warming and climate change, pollution, and others) it experiences a range of local stressors (e.g. land-derived eutrophication and sedimentation), particularly at the Mexican coast. The absence of effective MRS monitoring systems has been a limitation for its conservation. Conceptual models are a key element of coral reef monitoring programs since they integrate current understanding of system dynamics, identify important processes, facilitate communication of complex interactions, and illustrate connections between indicators and ecological states or processes. Well-constructed conceptual models provide the scientific framework for monitoring programs and the justification for the choice of indicators. This poster contribution presents the design of a management-targeted conceptual model that can facilitate conservation of the MRS. It thereby uses an innovative approach to fill the knowledge gaps of linking both types of reef data: reef field assessments and remote sensed data. The proposed model not only links scales and spatial dynamics, but also highlights main local impacts. From this perspective, the conceptual model to monitor the MRS will support decision makers to implement strategies for improved management, and to identify and prioritize the more changing and affected components.

MITIGATING PRESSURES IN HIGH TRAFFICKED AREAS USING CUSTOM DESIGNED REEFS (Abstract ID: 27842 | Poster ID: 468)

Where diving and coral reef tourism are particularly intense, the ecosystems are often overexploited and seriously degraded. On the island of Koh Tao, in the Gulf of Thailand, we have been developing custom designed reefs as alternative centres for tourism focus and ecosystem rehabilitation. Koh Tao entertains upwards of half a million visitors per year on a 21 km2 island. Much of the degradation is attributable to excessive numbers of poorly managed divers and snorkelers and the consequences of their visitation. Zoning plans and user guidelines help but limited resources for policing and enforcement have lead to the need for reef restoration programs and the development of artificial reef. Research

has shown that these locations assist in mitigating pressure and providing ecological solutions to localised reef degradation. Further they enhance awareness of conservation issues across a broad spectrum of the stakeholders from visitors, to local residents and government officials. Research also highlights the ecological value artificial reefs can have on marginalised reef communities. The development of artificial reefs on Koh Tao has been enacted primarily without external funding support and provides a template for use in other locations where resources, especially financial, are limited but willingness is high.

ACTIVE REEF RESTORATION: IMPROVING THE OUTCOME FOR DEGRADED REEFS IN THAILAND (Abstract ID: 27783)

The threatened ecosystems of coral reefs are particularly vulnerable in those locations where anthropogenic pressures are acute. On the island of Koh Tao, in the Gulf of Thailand scuba diving and coral reef related tourism places ever increasing pressure on the fragile reefs that surround this 21km2 island. Conservation groups in collaboration with local businesses, universities, scientists, government officials and community groups implement a range of reef restoration tools and activities that aim to increase the resilience of the reefs around the island. Using coral and giant clam nurseries, artificial reefs and a suite of monitoring tools conservation has developed into a mainstay of the economic model of this scuba diving dependent location. Developing artificial reefs combined with active reef restoration has released pressure from vulnerable natural reefs. These artificial locations allow opportunities for novel and innovative reef restoration techniques while providing welcome respite for overexploited reef environments. We explore the potential for truly community based tourism and conservation groups to develop these multi faceted targeted artificial reefs to ecologically support the recovery of natural reefs in this heavily perturbed environment.

CHARACTERIZING BENTHIC INVERTEBRATE COMMUNITIES OF THE SOUTH TEXAS BANKS (Abstract ID: 28993 | Poster ID: 327)

The South Texas Banks (STBs) are a rare hard bottom feature of the Gulf of Mexico (GOM) colonized by a community of deep water corals whose multi-species, high-density assemblages provide structurally complex habitat and significant ecosystem services. The depth of the banks, a persistent nepheloid layer, and strong currents have hindered efforts to collect quantitative data on what inhabits the rocky outcrops and relic coralgal reefs. The STBs were under consideration as a candidate for Marine Protected Area (MPA) status in 2008, but there was not enough information available to support this conservation action. Using a remotely operated vehicle, video data from 5 banks were collected in order to characterize the benthic communities. Community structure analyses show significant differences in benthic community composition between the two southern and the three northern banks surveyed. Also, by correlating the benthic communities' data with terrain patterns from multibeam sonar images, a habitat suitability model was created to predict the probability of presence of important coral species. This work significantly reduces the cost, time and effort in characterizing the banks, which is key to ensuring that these habitats are protected. The ability to create habitat suitability maps and discern biodiversity of the South Texas Banks from multibeam SONAR images will aid future marine protection efforts in the Northwestern GOM.

INTEGRATING KNOWLEDGE FROM SHALLOW REEFS, THE MESOPHOTIC ZONE AND CHARISMATIC MEGAFAUNA IN THE CONSERVATION OF A WORLD HERITAGE AREA: NINGALOO OUTLOOK PROJECT (Abstract ID: 29149)

Ningaloo Reef Marine Park, declared a UNESCO World Heritage Area in 2011, has unique biodiversity values, abundant marine life and is the only fringing coral reef on the west coast of a continent in the world. Much remains unknown about the reef and its inhabitants, with most research focusing on single elements and missing interactions in this complex ecosystem. A strategic research partnership between BHP Billiton and CSIRO is gathering new knowledge on shallow and deep water habitats, and shark and turtle populations to better equip those responsible for the conservation and management of the marine park. This talk will present an overview of the key objectives of the three research themes, and findings to-date: i. Deep Reefs research documenting the extent and character of deep water habitats; ii. Shallow Reefs gathering knowledge to better understand the ecological processes that are important in the structuring of reef flat and reef slope communities; and iii. Tagging to provide fundamental information needed to understand the ecology of sharks and turtles. The program will also provide information on interdependencies among different parts of the reef as well as long-term trends in corals, fish and iconic megafauna. A key component of the partnership is the engagement of local community members who have become ambassadors of the project. PhD scholars are also embedded in each research theme to provide training for the next generation of scientists. An overview of the community engagement program including those established in local schools will be presented.

MACROECOLOGICAL PATTERNS OF SEA URCHINS SPECIES IN SHALLOW REEF ENVIRONMENTS (Abstract ID: 28724)

Sea urchins are known to greatly influence benthic communities, mainly by controlling algal cover, both in tropical and temperate reefs. Despite this importance, there is a knowledge gap concerning their macroecological patterns. The relative importance of sea urchins on the dynamics of benthic cover may vary locally and regionally due to functional redundancy and relative abundance of species. In order to assess diversity patterns of sea urchins in tropical and temperate reef systems, we analysed a compilation of open databases, published and unpublished data. Regular sea urchin species occurring above 100m were selected for the analysis, consisting of 175 species (15 families, 7 orders). Tropical reefs from the Central Indo-Pacific showed highest species richness, longitudinally decreasing towards the west. Species richness decreased from low to high latitudes, similarly to patterns found for reef fishes and mollusks. Provinces of the Central and Western Indo-Pacific showed the highest levels of endemism, and the least structured data in ordination analysis. Temnopleuridae was the most speciose family, but Cidaridae was the most widespread globally. The wide latitudinal range of Toxopneustidae and Diadematidae species – often associated with urchins' blooms and barren formations – may indicate potential higher resilience of these taxa on tropical reefs. Macroecological patterns of species richness associated to functional diversity may help to explain known spatio-temporal variabilities of sea urchins, and its potential effects on high versus low diversity regions.

CONTROLS OF CORALLINE ALGAL CALCIFICATION: ROLE OF INTERNAL PH IN INFLUENCING RESPONSES TO OCEAN ACIDIFICATION AND OTHER ENVRIONMENTAL VARIABLES (Abstract ID: 28055)

Coralline algae are important in forming/binding reefs and provide a settlement substrate for many valuable species (e.g. abalone, corals), but are susceptible to ocean acidification through declines in net calcification rates. However they exhibit large variation in their responses, some of which could be explained by their physiology. Integral in the response of coral net calcification to ocean acidification is the capacity to elevate the pH of the calcifying fluid (pHcf) at the site of calcification; it is unknown whether the same principle applies to coralline algae. We ask: 1) do coralline algae elevate pHcf at the site of calcification in the cell wall; 2) how are changes in net calcification rates of coralline algae under OA related to changes in seawater pHT and calcifying fluid pHcf, and 3) what role does latitude, species, and wave exposure play in influencing pHcf and how is this related to net calcification? We examined the responses of net calcification and pHcf to ocean acidification, and compared pHcf with net calcification rates from the field for different species from various latitudes across a range of wave exposures. We find the majority of coralline algal carbonates have high $\delta$11B values (25 to 34 ‰), implying high pHcf values (>8.5) if only the tetrahedral B(OH)41- is incorporated. However, coralline algae precipitate calcite, rather than aragonite like shallow water corals, meaning high $\delta$11B trigonal B(OH)3 may also be incorporated. We also discuss how coralline calcification rates relate to pHcf from the field and under elevated CO2.

A COMPARISON OF STAGHORN CORAL FECUNDITY AND SPAWNING OBSERVATIONS FOR WILD, OUTPLANT, AND NURSERY COLONIES (Abstract ID: 28806 | Poster ID: 490)

The staghorn coral (Acropora cervicornis), a foundation species on Greater Caribbean coral reefs, has experienced population declines to a level where natural population

recovery is uncertain. With a listing of Threatened under the US Endangered Species Act, A. cervicornis has been identified as a high priority species in need of active population restoration efforts. Nurseries have been identified as a productive restoration method by increasing colony abundance and by reducing the spatial gap between populations, increasing the likelihood of successful sexual reproduction. The survivorship of outplanted colonies has been well documented; however their sexual reproductive capacity is not fully understood. We are addressing this information gap by comparing histologically derived gamete abundance and colony fecundity data with in-situ spawning observations for A. cervicornis wild colonies, outplanted colonies, and nursery colonies offshore southeast Florida. During 2014 wild colonies were highly fecund and mass spawned, outplant colonies had low fecundity and were not observed to have spawned, while nursery colonies were fecund and partially spawned. During 2015 wild colonies were fecund and partially spawned, outplant colonies had low fecundity and were not observed to have spawned, while nursery colonies were fecund and partially spawned. Stress associated with higher than average water temperatures in 2014 and 2015, colony ages, and colony fragmentation and transplantation history likely contributed to differences between colony types.

BENTHIC DIVERSITY SPECIES IN TIDE POOLS FROM REEF PLATFORM ON THE MACEIÓ COAST, ALAGOAS STATE, BRAZIL. (Abstract ID: 29281 | Poster ID: 61)

The Brazilian northeastern coast has many coral and sandstone reefs, where the top reef platform remains exposed during low tides. This study analyzed the diversity and distribution of benthic species in tide pools on the Sereia sandstone reef, coast of Maceió, Alagoas, Brazil. During two low tide periods in November 2015, by visual recordings, on 12 tide pools were analyzed the sessile and sedentary organisms by coverage percentage, and when necessary some specimens were collected for taxonomic confirmation in the laboratory. All tide pools were measured length, width and depth to include in smaller and bigger size. The water abiotic aspects were obtained to each tide pool studied including temperature, pH and salinity. The software Past 2.17 was used to calculate the diversity data to richness, Shannon index and evenness. Linear regression was obtained with the same program. In this study, 27 taxa of macrobenthic organisms were recorded including: 4 Chlorophyta, Rhodophyta 2, 6 Phaeophyta, 3 Porifera, Cnidaria 8, 2 Mollusca and Echinodermata 2. The results for the linear regression showed that the depth had a significant relationship with richness ($r = 0.82$; $p < 0.005$) and Shannon index ($r = 0.82$; $p < 0.005$). The data obtained for the tide pools indicated the depth as the main factor that influenced positively the richness and diversity of species. This was probably because the depth inside the tide pools protects the macrobenthic species from the impacts and stress caused by exposure during the low tides and by the brake waves associated with the high hydrodynamics local.

VISUAL EVOLUTION: LESSONS LEARNED FROM 100 FISH GENOMES (Abstract ID: 29528)

Imagine living a thousand meters below sea level surrounded by darkness but for a few bioluminescent rays of light. Now imagine living in a clear mountainous lake three thousand meters above sea level where the plethora of light can cause blindness anytime. There are many examples of animals that have adapted their vision to cope with different light conditions, yet little is known about the molecular basis of these adaptations. Thanks to recent technological advances, it has now become feasible to study the evolution and function of vision, along with its underlying molecular machinery (opsins and the visual pathway genes), one-on-one, in nature. Here, we report the evolutionary history of opsin genes based on the comparison of 100+ genomes and 40 transcriptomes spanning the teleost fish phylogeny. We show that the evolutionary history of opsins is very dynamic, involving frequent duplications but also gene losses that correlate with the light environment of different species. In particular, several deep-sea fish lineages have evolved ingenious strategies to adapt to the extremes of their photic environments, including one case of multiple rhodopsin duplications, which may well be the first evidence for rhodopsin-based color vision in vertebrates. Understanding how fishes perceive their world and how this allows them to adapt to different environments is crucial for future management purposes, especially since many fish species are facing imminent danger due to anthropogenic activities.

THE OUR FLORIDA REEFS COASTAL USE SURVEY: AN ONLINE SURVEY TO SUPPORT STAKEHOLDER MANAGEMENT RECOMMENDATIONS FOR SOUTHEAST FLORIDA (Abstract ID: 30172 | Poster ID: 591)

Coral reefs are an important resource world-wide. Unfortunately, coral reef conditions are declining in many areas due to both global and local stressors. The objective of this study was to survey stakeholders in southeast Florida to better understand reef use in the region. Stakeholders spatially identified where and how often they conducted their activities. These data were compiled and analyzed in GIS to determine spatial use patterns. Both location and intensity of use were analyzed to determine which areas may be under greater stress from recreational activities. It was found that reef use was not evenly distributed in the region, but clustered around inlets and piers. Reef use differed between user groups (i.e. SCUBA divers, fishers) and demographics. It was also found that use in the Broward-Miami Coral Reef Ecosystem Region was spread out over a wider spatial scale than the use in the regions north and south. These data are important as they have the potential to inform the recommendations being made to improve coral reef management in southeast Florida. The study can provide a better understanding of human-environmental relationships and the trade-offs involved so that recommendations can better decrease user conflicts, maximize economic productivity, and preserve the environment.

CAUSES AND CONSEQUENCES OF THE 2014 MASS BLEACHING EVENT IN PAPAHANAUMOKUAKEA MARINE NATIONAL MONUMENT (Abstract ID: 29602)

2014 marked the third reported mass bleaching event in Papahānaumokuākea Marine National Monument (Northwestern Hawaiian Islands), which is one of the world's largest marine reserves. Warming began in the central islands in late August 2014 and extended to northern atolls by early September. Cumulative thermal stress from satellite-derived temperature data ranged from 7 degree C weeks at French Frigate Shoals to 15 degree C weeks at Lisianksi Island by October 30th. To assess the temporal patterns in bleaching and resulting mortality, we surveyed permanent sites at French Frigate Shoals (FFS), Lisianski Island (LIS), Pearl and Hermes Atoll (PHR), and Midway Atoll (MID) in September 2014 and August 2015. In 2014, the mean % of severely bleached corals was 8, 22, 37 and 45% at FFS, PHR, MID and LIS, respectively. Mean % of severely bleached corals increased moderately and significantly with sustained high temperatures, but varied among habitats with shallow forereefs surrounding LIS and backreefs at PHR and MID most affected. While Montipora spp. were most affected, this event was unlike previous events due to widespread bleaching across 22 species. In August 2015, we did not observe widespread bleaching or thermal stress. While corals in certain regions demonstrated recovery and minimal mortality, mean % coral cover at permanent sites decreased by 68% at LIS. 3D reconstruction techniques were also used to assess the impact of bleaching-induced mortality on habitat structure. Coral mortality directly correlated with reductions in both habitat complexity and volume.

UNDERSTANDING THE CONSEQUENCES OF LAND-BASED POLLUTANTS ON CORAL HEALTH IN SOUTH KOHALA, HAWAI'I (Abstract ID: 30045)

Increasing human populations in Hawaii's coastal regions combined with ineffective land use practices has resulted in deteriorated water quality and impaired reef health through-

out the state. Land-based pollution is of particular concern in Puakō, Hawai'i Island due to land use change, strong evidence of sewage pollution, and a 50% decline in coral cover during the last 40 years. In this study we: 1. identified 12 sites across regions of low to high terrestrial input and characterized spatial patterns in nutrients, fecal indicator bacteria, and coral health; 2. tested the correlation between coral health and environmental metrics using mixed modeling; and 3. prioritized reef areas that may benefit from corrective action. Nutrient concentrations and fecal indicator bacteria abundance were highly variable across the study region, but were elevated in shoreline areas and declined reefward, confirming the presence of land-based inputs. Coral health was also highly spatially variable with the most prevalent conditions being growth anomalies and algal overgrowth, each affecting 20% of colonies. Nutrient concentration was the strongest environmental predictor of coral health, with a higher prevalence and severity of growth anomalies in regions with elevated nitrate + nitrate concentrations. Our study highlights that nutrients that can be associated with sewage or other sources are linked with impaired coral health, and that coral health should be integrated into management plans as a tool for identifying impaired reefs and understanding how watershed inputs affect reef health.

SPATIAL AND TEMPORAL PATTERNS IN BIODIVERSITY: A LOOK AT CRYPTIC CORAL REEF COMMUNITIES ACROSS THE HAWAIIAN ARCHIPELAGO (Abstract ID: 29330)

Ecosystem function and resilience are fundamentally connected to patterns in community composition. The goals of this study were to document spatial and temporal patterns in reef biodiversity, to identify correlations between community composition and environmental variables, and to investigate trends in species co-occurrences. This work focused on communities of semi-cryptic fishes and invertebrates closely-associated with Pocillopora meandrina. Communities were surveyed in >1500 P. meandrina colonies across 44 sites in the Hawaiian archipelago. Preliminary analyses suggest lower biodiversity within the highly protected Papahānaumokuākea Marine National Monument than around the densely populated island of O'ahu. Across all sites, characteristics of the host colony (e.g., coral size, percent live tissue) were highly correlated with community composition. Species co-occurrence analyses identified far more positive than negative species pairs with some noteworthy exceptions; e.g., one common species of guard crab had only negative species associations. To quantify temporal variability, communities within 20 P. meandrina heads were followed monthly at two sites for 20 months. There was lower species turnover within communities over time than between communities over space. The largest temporal shifts occurred within colonies that had recently bleached or were becoming covered with algae. Our results suggest that biodiversity in P. meandrina-associated communities is influenced by regional differences along the Hawaiian archipelago, host coral quality, and species interactions.

MAPK SIGNALING IN CORAL STRESS RESPONSE (Abstract ID: 27820)

Coral reefs are of major ecological and socio-economic interests. They are exposed to a variety of anthropogenic stresses such as ocean acidification and global warming, in addition to natural stresses such as excessive solar irradiance and UV radiations. In the context of climate change, great efforts are made to try to predict and prevent coral reef degradation in response to stresses. Yet, very little is known about the signaling pathways involved in the immediate stress response of these organisms. We identified c-Jun N-terminal Kinase pathway (JNK) as being responsive to thermal and UV stresses. In particular, JNK is activated when corals are exposed to high temperature (30 °C) with or without UV radiations. Using a specific inhibitor, we showed that JNK is required for corals to down-regulate temperature and UV-induced reactive oxygen species production. A comparable phenomenon was observed in human fibroblasts exposed to the same stresses. Together, our results show that an ancestral stress response pathway involving JNK is conserved from corals to mammals to protect cells from adverse events induced by temperature and UV stresses.

CHANGES IN THE INTENSITY OF DAMSELFISH ALGAL GARDENING IN BOCAS DEL TORO, PANAMA OVER 7000 YEARS (Abstract ID: 29927 | Poster ID: 3)

Damselfish (Pomacentridae) often engage in a mutualistic behavior of plant-herbivore gardening with filamentous algae. Fish deliberately damage patches of coral, permitting space for the colonization of algae, which they then "farm". In response to the bites of damselfish, the staghorn coral,*Acropora cervicornis*, produces distinct protuberances, or "chimneys". These chimneys preserve well in fossil corals enabling a quantitative analysis of chimney frequency between fossil and modern *A. cervicornis* assemblages. Using modern and 7000 year old corals from Bocas del Toro, Panama, we found that the occurrence of chimneys on coral branches is twice as frequent today as it was 7 ka, and that the maximum density of chimneys in modern reefs is 10 times greater than it was 7 ka. These data indicate that a significant shift has taken place in the interaction between damselfish and staghorn coral over the last 7 ka. Possible causes include: (1) A change in the relationship between fish, coral, and algae, (2) More damselfish per coral caused by release from predation by overfishing, (3) More damselfish per coral caused by a reduction in the abundance of living A. cervicornis, (4) A decrease in the growth rate of *A. cervicornis* resulting in an apparent increase in chimney density. Further work is needed to quantify natural variation in chimney density, understand the process of chimney formation, and expand the fossil sampling.

COMPARING CHEMISTRY AND CENSUS-BASED ESTIMATES OF NET ECOSYSTEM CALCIFICATION ON A RIM REEF IN BERMUDA (Abstract ID: 29793)

Coral reef net ecosystem calcification (NEC) has decreased for many Caribbean reefs over recent decades primarily due to a combination of declining coral cover and changing coral reef community composition. Chemistry-based approaches to calculate NEC utilize the drawdown of seawater total alkalinity (TA) between the reef environment and offshore waters to calculate an instantaneous measurement of NEC. Census-based approaches combine annual growth rates with benthic cover and reef structural complexity to estimate NEC occurring over annual timescales. Here, we calculated NEC for Hog Reef in Bermuda using the chemistry and census-based NEC procedures to compare the mass-balance generated by the two methods. NEC was calculated via the chemistry-based approach using reef TA data from a carbonate chemistry monitoring project and offshore TA data collected by the Bermuda Atlantic Time-Series Study. To calculate NEC with the census-based approach, we used benthic surveys of line transects conducted at Hog Reef coupled with literature reported mean annual coral growth rates aggregated by the *ReefBudget* project, in-situ growth rates of *Porites astreoides* and *Diploria labyrinthiformis* during the time of the study, carbonate sediment dissolution rates from benthic chamber experiments, and photographic measurements of reef rugosity. Our initial findings indicate the annual mean NEC calculated by the two methods agrees within the range of uncertainties and highlights the high temporal variability of reef NEC in response to changing environmental conditions.

PREDATION ON CROWN-OF-THORNS STARFISH LARVAE BY DAMSELFISHES (Abstract ID: 27890)

Examining the functional response of predators provides insight into the role of predation in structuring prey populations and ecological communities. We explored feeding behaviour and functional response of planktivorous damselfishes when offered captive reared larvae of crown-of-thorns starfish, Acanthaster spp. with the aim of determining whether these predators could play a role in moderating outbreaks of Acanthaster spp. With 11 species of planktivorous damselfish, we tested: the relationship between predator size and predation rate, both within and among fish species; consumption rates on larvae of Acanthaster spp. vs. larvae of a common, co-occurring asteroid Linckia laevigata; maximal feeding rates upon both Acanthaster spp. and L. laevigata; and functional responses of planktivorous fishes to increasing densities of Acanthaster spp. This data revealed that a wide range of planktivorous fishes prey upon larvae of Acanthaster spp. Consumption rate of Acanthaster spp. larvae by damselfishes was independent of predator size, however there was a significant negative relationship between predator size and consumption rate of L. laevigata, when pooling across all predatory species. Two species, Acanthochromis polyacanthus and Amblyglyphidodon curacao, consumed larval Acanthaster spp. at a greater rate than they consumed L. laevigata. Most fishes exhibited a Type II functional response, suggesting that they may have the capacity to buffer against population fluctuations of Acanthaster spp., however abnormally high larval influx may swamp these predators, potentially contributing to the characteristic population fluctuations of Acanthaster spp.

INVESTIGATING MULTIPLE CORAL REEF STRESSORS ON A SHOE-STRING (Abstract ID: 29324)

The decline of reef health and resilience has been recorded in many locations, but the causes of this decline are less clear. The ecologically complex and dynamic nature of coral reefs means that identifying the factors contributing to coral decline is difficult, and requires measuring numerous indicators. In this study, indicators of reef resilience to coral bleaching were collected on 40 different sites in Kenya, Mozambique, Maldives and Sumatra. All parameters used in this study were collected either during a single visit to the reef or from freely available online data sources. The resilience of these reefs in terms of recovery potential and resistance to bleaching were compared with five explanatory factors, intended to encompass a range of human stressors, past climatic stress and natural variation in resilience: local human population density, distance to the mainland, past acute thermal stress, protected status and reef zone. Local population, distance to the mainland and zone were significantly correlated with reef resilience. Reefs with the highest recovery potential were associated with low population densities, and offshore locations. Sites with the highest resistance were in lagoons and nearer to the mainland. This study demonstrates how multiple stressors on coral reefs can be investigated and analysed using minimal resources. The findings of this study point towards conservation actions, including the prioritisation of protecting Enggano, Sumatra, as an MPA, and boosting resilience in Vamizi, Mozambique, through increasing herbivore biomass.

CONNECTIVITY OF THE PULLEY RIDGE - SOUTH FLORIDA CORAL REEF ECOSYSTEM: PROCESSES TO DECISION-SUPPORT RESOURCES (Abstract ID: 29838)

The coral reef ecosystem of the southeast United States is a complex system of interconnected, deep and shallow reefs stretching along the western, southern and southeastern coasts of Florida. Given its economic and ecological value, there is a strong need to develop effective management options that encompass the entire ecosystem and its complex interactions. The goal of the Pulley Ridge research program is to provide the key scientific information needed to rigorously address this management challenge with a specific focus on the mesophotic reefs located on Pulley Ridge. We adopt an interdisciplinary approach (physical oceanography, bio-physical modeling, population genetics, population dynamics of key species) and yield a quantitative understanding of the scale and extent of connectivity. Building on this information we then incorporate studies on the community structure and valuation of ecosystem services (e.g., fisheries) to further refine management options and help establish priorities. Through consultation with state, federal and private stakeholders, we are integrating our findings into a Decision Support Resource to aggregate findings and archive data.

TEMPORAL PATTERNS OF ENDEMISM AND PROVINCIALITY IN TROPICAL REEF FISHES (Abstract ID: 29433)

There is a general consensus that a large marine biodiversity hotspot straddles the Indian and Pacific Oceans. Centered on the Indo-Australian Archipelago, this biodiversity hotspot forms a steep gradient in species richness from this center to the periphery. This gradient is characterized by over 5000 species of reef fish. Yet the origins of this pattern and how it is maintained across two-thirds of the world's oceans remains unclear. Traditional 'hotspot' assessments based on endemism have had little success, with areas of species richness decoupled from centers of endemism. While there is a gradient in species richness across the Indo-Pacific, provincial schemes have been identified based on numerous delineating criteria. But, so far these delineations have not accounted for the phylogenetic and biogeographic history of taxa. Here, we present an overview of the origin of endemism in reef fishes, and combine ancestral biogeographic estimation and phylogenetic dissimilarity clustering methods to explore past and present provinciality. While phylogenetic sampling of endemism is low, most ecoregions contain both old and young endemic species. Phylogenetic dissimilarity clustering of extant assemblages identifies a large Indo-West Pacific cluster, but also clusters distant Pacific island together based on peripherally isolated, but phylogenetically close lineages. Through time, clustering of estimated ranges reveals the dynamic nature of reef assemblages with provincial changes reflecting large scale tectonic rearrangement of the tropical belt.

THE ROLE OF REEF COMMUNITY COMPOSITION AND PARROTFISH PROTECTION IN PHASE SHIFT REVERSAL (Abstract ID: 30034)

Protecting parrotfish species from fishing is a central conservation strategy designed to reverse shifts in reef community structure from coral to algal dominance. However, the response of reef communities might not be that simple. Here we evaluate the response of parrotfish populations and benthic communities to protection from marine protected areas and a national ban on herbivorous fish harvesting. From 2009 to 2013, we annually surveyed 16 reefs in Belize, including 8 MPA sites (Fully Protected or General Use), and 8 unprotected control sites. At the reefs surveyed, macroalgal communities were dominated by Lobophora sp., Dictyota sp. and Halimeda sp. and parrotfish communities were dominated by Sparisoma viride and Sparisoma aurofrenatum. Parrotfish biomass increased in protected zones over the five-year study period; however, recovery in Belize has not followed the trajectory of other regions of the Caribbean. The increase in S. viride and S. aurofrenatum was relatively greater in the General Use zone, which corresponded to reductions in Dictyota sp. and Halimeda sp, but not Lobophora sp. We found no relationship between mean parrotfish biomass and mean macroalagal cover across all sites and year. Additionally, mean total macroalgal cover remained above 40% in all years suggesting that the amount of macroalgae on Belizean reefs may simply be greater than the consumption capacity of herbivorous fishes. We suggest that protection of parrotfish may not be a panacea and community composition is an important consideration for the success of phase shift reversal.

SOCIAL FRAGMENTATION INHIBITS LOCAL MANAGEMENT IN A DOMINICAN FISHERY (Abstract ID: 28831 | Poster ID: 597)

Like many artisanal fishing communities around the globe, the village of Buen Hombre in the Dominican Republic is struggling to sustainably manage its coral reef fishery. An effective local management regime reported in the community in the 1980s and 90s has since deteriorated, and the present-day marine ecosystem indicates heavy overfishing. We integrate current and historical data to assess social changes within the Buen Hombre fishery and their implications for current fishing practices. Our findings indicate that an increase in social divisions among the Buen Hombre fishers poses a significant barrier to management in the community today. We conduct social network analyses to measure unity among the Buen Hombre fishers and identify factors contributing to social fragmentation. These analyses reveal strong social divides among the Buen Hombre fishers and indicate that choice of fishing gear and membership to the Buen Hombre Fishermen's Association are key drivers of these social factions. Our analyses also enable us to identify key individuals within the community that have high degrees of social connections within or between different social subgroups. Reestablishing local management of the Buen Hombre fishery will require communication and cooperation among the entire fisher population. Social network analyses provide invaluable insight for bridging social factions and facilitating effective management not only in Buen Hombre but in artisanal coral reef fisheries around the world.

PROJECT CORAL – DEVELOPING PROTOCOLS FOR PREDICTABLE BROADCAST CORAL SPAWNING IN CAPTIVITY (Abstract ID: 28671)

While brooding coral species commonly release planula in aquaria, broadcast spawning events in captivity are rare and highly unpredictable. Spawning correlates strongly with a number of environmental signals, (seasonal temperature, lunar and diel cycles) however few robust experimental studies have examined the role of these putative cues in triggering spawning. Project Coral, an innovative coral sexual reproductive research project, run by the Horniman Museum and Gardens, London, in collaboration with S.E.A Aquarium, Singapore and SECORE International aims to better understand the drivers of coral reproduction and to develop protocols to facilitate predictable broadcast spawning events in captivity. In March 2015 14 large *Acropora hyacinthus* fragments were transported from a reef off Singapore to the Horniman in London. Corals were kept in a microprocessor controlled aquarium to replicate conditions on their native reef (i.e., seasonal temperature, photoperiod and lunar cycles). Collection was purposefully timed to occur 1 month before the predicted annual mass spawning event to initially to see if spawning timing would remain in synchrony with the remnant parent colonies from which the fragments were removed. In April 11 of the 14 corals spawned in the tank at approximately the same time as corals remaining on the reef demonstrating that natural rhythms had been maintained. The long term aim is to see if we can maintain spawning rhythms over longer periods and ultimately manipulate environmental signals to investigate their role in triggering spawning.

PREHISTORICAL AND HISTORICAL DETERIORATION OF CARIBBEAN REEF ECOSYSTEMS LINKED TO DECLINES IN REEF ACCRETION, HERBIVORY, AND WATER QUALITY (Abstract ID: 30050)

Caribbean reefs have declined dramatically over the past decades, suffering mass mortality events that have transformed them from coral- to algae-dominated habitats. Debate is ongoing about the initial timing and dominant drivers of recent change due to lack of baseline data. To help resolve the underlying mechanisms of recent and widespread reef declines, we produced a high-resolution 3,000 year record of reef ecosystem state from the analysis of fish, coral, urchin, bivalve, and benthic foraminifera subfossils within reef matrix cores from Caribbean Panama. This whole-ecosystem approach allowed us to determine ecological linkages among different faunal groups and to infer environmental causes and consequences of observed community change. At each site, declines in reef accretion rates and fish and coral abundance were initiated in the prehistorical or historical period, characterized by remarkably consistent patterns of change in fish, urchin, and bivalve composition. Historical ecosystem shifts were accompanied by a decline in water quality, implicating local human activities. Accretion rates were tightly coupled with parrotfish and urchin abundances throughout the cores. Our results suggest close integration of multiple components of the reef community, suggesting feedbacks between corals and herbivores in particular are making it difficult to reverse reef phase shifts.

DIVERSITY OF THE INDO-PACIFIC NETWORK: INSIGHTS INTO LINKS BETWEEN GENETIC AND SPECIES DIVERSITY. (Abstract ID: 29110)

The tropical Indian and Pacific oceans form the world's largest and most speciose marine biogeographic region: the Indo-Pacific. Due to its size and political complexity, the Indo-Pacific is rarely studied as a whole, yet comprehensive studies of the region promise to teach us much about marine biogeography. Molecular methods can provide substantial insights into the processes that create and maintain biodiversity in the region. Although many research groups have independently amassed considerable genetic data much can be learned from capitalizing upon these efforts in a larger, unified, multispecies context. The Diversity of the Indo Pacific Network (DIPnet) seeks to promote open data exchange and collaboration among researchers working in the Indo-Pacific region; to this end, we have assembled the most extensive database of georeferenced mitochondrial DNA sequences for any biogeographic region comprising over 30,000 individual haplotypes from over 200 coral reef associated species sampled at over 1,500 locations. Initial analysis of the database reveals a significant correlation between coverage-corrected haplotypic richness and species richness. Moreover, bioregionalizations based on coral community composition explain genetic structure in a majority of tested species better than those based on fish. Both results suggest common mechanisms for structuring marine biodiversity at the molecular and species level. We will discuss these preliminary results and promote DIPnet as a vehicle for open science and international collaboration.

PARTNERSHIP FOR SUCCESS IN A CHANGING SEASCAPE: COMBINING INDIGENOUS PRACTICES AND WESTERN SCIENCE FOR SUSTAINABLE REEF MANAGEMENT IN THE YAP OUTER ISLANDS (Abstract ID: 29987)

The Yap outer islands (Federated States of Micronesia) encompass more than 250,000 Km2 of the tropical western Pacific. Outer Islanders depend on their coral reefs for food and other environmental services, but cultural and ecological change are compromising the reef ecosystems. A lack of scientific knowledge from the region coupled with a decline in traditional management knowledge and frameworks have left communities with a lack of knowledge to effectively manage their reef systems in the face of rapidly changing ecological and social systems. In recognition of this, communities on Ulithi Atoll - the fourth largest atoll in the world, are working with a team of scientists to combine western science with traditional practices to address ecological and resource issues while strengthening communities and governance. It is a unique partnership to identify changes in resource extraction and management, and the impacts of those changes on the reef system–leading to depleted resources and in some cases poor reef health. Timely implementation of management has seen rapid results, and may well be key to reef recovery after the recent devastating typhoon Maysak. This successful model has inspired other outer island communities to model Ulithi, and has great potential to enhance adaptive management throughout the region. We will present findings from the science team, the fisheries data team (Ulithi science team), and how both western and indigenous teams are informing each other.

DECIPHERING MULTIPLE CONTROLS ON CARBONATE CHEMISTRY IN COASTAL REEF SYSTEMS: AN EXAMPLE FROM A BACK REEF LAGOON WITH GROUNDWATER DISCHARGE (Abstract ID: 28908 | Poster ID: 95)

Understanding dynamic reef ecosystem processes is a critical step in determining he impacts of ocean acidification on coral reef communities. The Puerto Morelos coast of Quintana Roo, Mexico presents a unique opportunity to explore natural fluctuations in carbonate system parameters along the Mesoamerican Barrier Reef. Specifically, diurnal and seasonal patterns lead to natural fluctuations in community reef metabolism (respiration, photosynthesis, and calcification) that in this system are further complicated by the addition of brackish groundwater discharge into the back reef lagoon. We present data of from two instruments deployed over a period of six months to explore the relationships between physical and biological processes impacting carbonate chemistry on dynamic reef systems influenced by groundwater discharge.

CARICOMP: TWENTY YEARS DESCRIBING PATTERNS AND TRAJECTORIES OF CARIBBEAN CORAL REEFS (Abstract ID: 28156)

Long-term monitoring programs are valuable to describe the natural dynamic of coral reef ecosystems in space and time. The Caribbean Coastal Marine Productivity program (CARICOMP) represents the largest and longest cooperative effort to monitor synoptically coral reefs in the Wider Caribbean. Here we present a summary of trajectories of 42 reef sites spread out across the region from 1992 to 2007. The analysis also includes few countries where the program is still active. Results indicate that in 1993, mean coral cover in the region was 21 ± 6 % (CI 95%). Only 11 sites (26%) had mean live coral cover above the regional average and remained in this way for the study period. In addition, ten sites (24%) were within the confidence interval of average live coral cover and kept this condition until 2007. More than 50% of the sites lost between 2 to 30% of their live coral cover from 1992 to 2007, with the largest coral mortality recorded at Morrocoy National Park (Venezuela) and Pinnacle reef (Cayman Islands). We found a weak but significant negative correlation ($r = -0.49$, $r2 = 0.19$, $p < 0.05$) between the mean live coral cover and mean macroalgae cover at all sites between 1993 and 2007. These results further indicate that lost of coral cover was not always followed by an increase of macroalgae. Overall, our results support that coral cover in the monitored Caribbean reefs had been declining over the past decades; however, degree of community structure change varied strongly across the 42 reef sites and relatively few showed a clear algal phase shift.

HIGH THROUGHPUT MICROSATELLITE GENOTYPING CONTRADICTS THAT ACROPORA HYACINTHUS WAS EXTIRPATED ON PALAU AND RECOLONIZED FROM YAP. (Abstract ID: 29137)

The catastrophic loss of corals, particularly the Acropora spp., around the island of Palau following the 1998 El Niño had profound ecological and social impacts. The result of which included the formation of a network of marine protected areas (MPAs) with the goal of ensuring reef recovery and resilience to any such future events. MPA networks rely on population connectivity to persist, but measuring connectivity to support the design of MPA networks remains challenging because it is nearly impossible to track pelagic larval dispersal directly. A detailed oceanographic model, developed to evaluate the current MPA network design, predicts larval dispersal between Palau and Yap and led to the conclusion that recovery of Acropora spp. on Palau likely resulted from a pulse of larval recruitment from Yap. This result has been used to argue for cooperative MPA networks spanning Palau and Yap. We used high throughput microsatellite genotyping of the coral Acropora hyacinthus and show that recovery in Palau did not come from a pulse of recruits from Yap. Instead, we find as much differentiation within Palau as between Palau and Yap, with significant population genetic structure among all of the 25 sites sampled around Palau. These results indicate that recovery most likely originated, at least in large part, from sites within Palau, and suggest high rates of localized self-recruitment. In light of these results there seems to be little effective dispersal among sites around Palau, which argues for increasing the number and size of MPAs within Palau.

"THIS IS WHO WE ARE": NATIONAL CAMPAIGN COMPETITION IN THE CARIBBEAN INCREASES COMMUNITY AWARENESS OF MARINE CONSERVATION AND MANAGEMENT (Abstract ID: 28977 | Poster ID: 608)

In 2015, six Eastern Caribbean islands competed to implement the most effective public awareness campaign that fosters pride in ocean resources and promotes environmental stewardship. The campaigns were an innovative strategy to address evidence of low support for marine managed areas (MMAs) among fishers and coastal communities. The initiative is a key component of the Climate-Resilient Eastern Caribbean Marine Managed Areas Network (ECMMAN). ECMMAN's goal is to build a network of effective MMAs in the region, which will protect critical ecosystems like coral reefs, and sustain healthy fisheries. Preliminary assessments in 2014 indicated more effectively managed MMAs will require increased public awareness to improve community acceptance and compliance. A campaign competition was designed to motivate community engagement, while maximizing regional impact through a shared campaign theme, "This is Who We Are." With regional training on campaign methodology and on-going support, marine resource representatives developed and implemented culturally relevant campaign strategies that targeted specific audiences, behaviors and outcomes. Campaign outputs include school presentations with mascots, beach clean-ups, fishing tournaments, music videos, radio shows and more. The campaign competition is a unique and successful model that can be replicated and modified both locally and internationally.

LINKING PHASE SHIFTS TO ENVIRONMENTAL DIFFERENCES USING CORAL REEFS IN MARGINAL CONDITIONS (Abstract ID: 29601)

Phase shift, the change in dominance from corals to non-reef building organisms, is a dramatic consequence of coral reef degradation. Climate changes has been proposed to increase the frequency of phase shifts, leading to further loss of their ecosystem services. Higher resistance to climate changes has been theorized for reefs that formed in regions at the limit of tolerable environmental conditions (marginal reefs). Most previous phase shift assessments have been focused on non-marginal reefs, however, which could lead to potential bias in forecasts of the possible reef response to these environmental changes. Using datamining and meta-analysis, we examined the extensive marginal reef complex in the Southwest Atlantic to identify types of phase shift, the extent of their presence and also possible associations with natural and anthropogenic influences through statistical analysis. We used an index of phase shift through principal component analysis to define phase shift types and magnitudes for those previously studied reefs. Our results point two phase shift, one, more restrict, to dominance of zoanthid and another to dominance of macroalgae. Macroalgae phase shift is correlated with distance of coast and human density while zoanthid phase shift was found only on dredging influence areas. On Southwest Atlantic coral reefs, the sum of the proportion of reefs defined as exhibiting phase shifts was higher than for Caribbean reefs, suggesting that marginal reef are more sensitive to human impact and climate changes than non-marginal reef systems.

GENDER-RELATED DIFFERENCES IN THE GROWTH CHARACTERISTICS IN SKELETONS OF THE REEF-BUILDING CORAL DICHOCOENIA STOKESI IN THE MEXICAN CARIBBEAN. (Abstract ID: 29699 | Poster ID: 385)

Mean annual growth characteristics (bulk density, skeletal extension rate and calcification rate) were determined using annual density growth bands found along slabs of skeletons of three females, and two males form the reef building coral Dichocoenia stokesi, collected at 4 m depth at Puerto Morelos Reef, Mexican Caribbean. No significant difference was observed for mean annual density between females and males (t-test for independent samples, $p > 0.05$). Annual skeletal extension and annual calcification rates showed a significant difference between both genders (t-test for independent samples, $p < 0.0001$). Despite these differences, for the time span represented by these slabs (1993-2013), calcification rate showed a negative relationship with increasing sea surface temperature (SST), decreasing around 0.19 g cm-2 yr-1 for each 1 oC increase in SST for both females and males. The slopes were not significantly different (F-test, $p > 0.05$) although the intercepts were significantly different (F-test, $p < 0.0005$). The intercepts indicated calcification would cease in females at 28.9 and at 29.9 oC in males. Similar to other coral species, the differences observed here in D. stokesi could be do to different energetic costs for reproduction between females and males, and must be taken into account when skeletons of gonochoric corals are used for environmental reconstructions.

ECONOMICS, CONSUMER DEMAND, AND LOCAL ENVIRONMENTS INTERACTIVELY DRIVE CORAL-REEF FISHERIES EXPORTS ACROSS MICRONESIA (Abstract ID: 28425)

Coral-reef fisheries have historically played a central role in island societies, yet advances in fishing technology and growing commercialization are creating new and challenging fisheries paradigms. In Chuuk, Federated States of Micronesia, the combination of high unemployment, extensive coral reef systems, and proximity to the large commercial market on Guam has led to the development of the largest commercial reef fishery in the region. Export datasets revealed a fishery driven by foreign demand, with exports accounting for half of commercial landings over the last 12 years. Fishing effort matched Chuuk-Guam connecting flights, and exports became increasingly coupled with demand peaks associated with monthly disbursements of Guam's Supplemental Nutrition Assistance Program (SNAP). Large increase in SNAP issuance in the late 2000's corresponded with a "boom" of coral-reef fish exports, followed by a gradual decrease since 2010 that was associated with diminishing profits from rising costs and stagnating retail prices. While Chuuk stocks remain in better condition than other Micronesian jurisdictions,

strong gradients were found between catch success and proximity to human populations. Similarly, large-bodied species preferentially targeted for exports (but with little local demand) were most targeted and impacted by fishing pressure. Our findings suggest the need to transcend disciplinary and geo-political boundaries when managing small-scale fisheries in increasingly globalized markets.

CELL TYPE-SPECIFIC TRANSCRIPTOMIC ANALYSIS ON *AIPTASIA SP.*(Abstract ID: 28662 | Poster ID: 15)

The symbiotic relationship between cnidarians and dinoflagellates forms the basis of coral reef ecosystems. Despite the ecological importance of this symbiosis, we know relatively little about the underlying cellular and molecular mechanism. The close relative of corals, the sea anemone *Aiptasia*, has been used widely as a model organism in the study of the cnidarian-dinoflagellate symbiosis. Like reef-building corals, *Aiptasia* establishes a stable symbiotic relationship with photosynthetic dinoflagellates of the genus *Symbiodinium*. However, in contrast to corals, *Aiptasia* can be maintained with or without symbionts and is easily kept and manipulated in common molecular biology labs. This makes it an ideal system to study the interaction of the partners in this symbiosis. To date, several publications have provided transcriptomic information for this model organism, but all the research was conducted on whole organism level. In this study, we applied laser microdissection to isolate endodermal and ectodermal cells from both symbiotic and aposymbiotic *Aiptasia*. We developed a protocol to extract RNA from this minute amount of cells and are in the process of generating tissue-specific transcriptomes and differential gene expression analyses for these four cells layers. This is the first study on cell type-specific transcriptome level in *Aiptasia* and the approaches we developed are expected to improve our understanding of the molecular and cellular basis of the cnidarian-dinoflagellate symbiosis.

HETERARCHIES: CONNECTING HIERARCHIES AND NETWORKS FOR MARINE PROTECTED AREAS (Abstract ID: 27850 | Poster ID: 593)

Social-ecological systems research currently suffers from a disconnect between hierarchical (top-down or bottom-up) and network (peer to peer) analyses. The concept of the heterarchy unifies these perspectives in a single framework. I briefly review the history and application of 'heterarchy' in neuroscience, ecology, archaeology, multi-agent control systems, business and organizational studies, and politics. Recognising complex system architecture as a continuum along vertical and lateral axes ('decentralised vs. hierarchical' and 'individual vs. networked') suggests four basic types of heterarchy: egalitarian, polycentric, pyramidal, and individualistic. Each has different implications for system functioning and resilience, and systems may shift predictably and abruptly between architectures. I illustrate the value of this perspective using examples of institutional change in marine governance and differences in the ecological connectivity between reef ecosystems. Heterarchies suggest new ways of contextualising and generalising from case studies and new methods for analysing complex structure-function relationships.

SIMPLE DYNAMIC ENERGY BUDGET MODELS FOR CORAL-ALGAL SYMBIOSIS (Abstract ID: 29000)

Coral-algal symbioses are functional across a range of environmental conditions, yet show significant variation in architecture, mechanics, and performance as conditions change. A mechanistic understanding of dynamic coral-*Symbiodinium* interactions is necessary to understand and predict coral responses to environmental change. Dynamic Energy Budget (DEB) theory offers a framework to integrate effects of multiple abiotic factors on holobiont performance by tracking the flow of energy and mass through time within a syntrophic symbiosis. Here, we develop a simple DEB model describing the acquisition and exchange of carbon and nitrogen resources by both symbiotic partners based on the principle of sharing the surplus. The model qualitatively reproduces patterns in *Symbiodinium*biomass ratios and coral growth rates observed over a range of light, nutrient, and prey availability levels, suggesting the major mechanisms have been captured. The model can be expanded in a modular fashion to test hypotheses regarding how photoinhibition, host carbon-concentrating mechanisms, symbiont self-shading, nitrogen-recycling, or other phenomena influence symbiosis stability and coral performance under various conditions. Additional symbiont types may be modeled to test conditions under which symbiont shuffling occurs, and its effects on coral performance. DEB models may be used to generate wide-ranging hypotheses and predictions regarding coral-*Symbiodinium* symbioses, and may ultimately provide a mechanistic understanding of coral responses to environmental change.

EMPIRICAL ASSESSMENT OF CLIMATE-INDUCED RANGE SHIFT IN AN ENDEMIC AND EXPLOITED REEF FISH (Abstract ID: 28978)

Climate change is causing range shifts of marine species, calling for adaptive management of fisheries resources and conservation of marine biodiversity. The waters off Western Australia (WA) are a model system to study range shifts. They present consistent environmental clines and are also a hotspot for endemism and ocean warming. Recently this region experienced rapid warming during the 2011 marine heat wave. We assessed demographic responses to rapid warming of baldchin groper Choerodon rubescens, a wrasse endemic in WA and a fisheries target, which occurs from tropical to temperate reefs. Range-wide data on abundance, recruitment, size structure, ecology and genetic connectivity are presented. Subsequent to the 2011 heat wave, the abundance distribution of recruits showed a displacement to the south when compared to that of adults. We found high recruitment at the temperate edge and no recruitment at the tropical edge. Recruits were consistently associated with habitats at the margin between reef and sand, indicating availability of this habitat type is likely to limit expansion at the cooler edge. Unique use of genomics traced the origin of this southern recruitment pulse to central populations 400 km upstream that experience different environmental conditions. Juveniles at the southern end are feeding on common prey and have survived over five winters. Whether they grow to maturity and reproduce is yet to be determined but crucial to their poleward range shift. C. rubescens shares a similar distribution to many WA marine endemics and may serve as a model species for managing this vulnerable group in a changing climate.

LIONFISH FEEDING HABITS AND THE IMPLICATIONS FOR REEF BENTHIC COVER (Abstract ID: 30077)

The lionfish invasion has become an issue of critical concern in the Western Atlantic. There is substantial research demonstrating the negative effects of the invaders on native reef fish. Surprisingly, little is known about the long-term impacts of invasive lionfish on fish assemblages and the cascading effects on reef benthic cover. We monitored lionfish, their prey, and benthic composition on 16 patch reefs over a five-year period in South Eleuthera, The Bahamas. On half of the patches, lionfish were removed quarterly. Reef ecosystems are notoriously complex. Thus, to isolate if the alteration in the fish assemblage and secondary impacts (e.g., change in coral/algae cover) were a result of lionfish predation, lionfish feeding habits were investigated in a lab setting. We identified which prey species lionfish preferred by comparing the gut contents of wild caught lionfish to available prey on the reef. This information was used to design experimental choice trials using species frequently found in lionfish stomachs and species present on the reefs yet avoided by lionfish. We also experimentally examined the role of prey abundance on lionfish feeding choice. Collectively, established monitoring programs and improved understanding of lionfish feeding behaviour are fundamental to understanding and predicting the long-term impacts of lionfish and can be used to inform conservation and mitigation strategies throughout the region.

PRINCIPLES FOR IMPROVING KNOWLEDGE EXCHANGE AMONG SCIENTISTS AND DECISION-MAKERS TO FACILITATE THE RESILIENCE-BASED MANAGEMENT OF CORAL REEFS (Abstract ID: 29107)

The resilience-based management of coral reef ecosystems requires knowledge exchange between scientists and decision-makers, however, the uptake and integration of science into decision-making processes remains a significant challenge. Rather, evidence suggests that decision-makers rely on individual experience or other secondary sources of knowledge in isolation from scientific evidence when formulating decisions, potentially compromising the effectiveness of their decisions. Using both quantitative and qualitative research approaches, we survey coral reef scientists and decision-makers from around Australia to identify, and develop strategies to overcome, the barriers prohibiting knowledge exchange among the two groups. We find that barriers include cultural differences between scientists and decision-makers, the inaccessibility of science to decision-makers, and institutional barriers that limit the extent to which coral reef scientists and decision-makers can prioritise knowledge exchange activities. We also identify guiding principles that should be implemented as part of any applied coral reef research program including: (i) stakeholder mapping prior to the commencement of research programs to identify all stakeholders, (ii) research questions to be co-developed by all stakeholders, (iii) implementation of participatory research approaches, (iv) use of a knowledge broker, and (v) tailored knowledge management systems. Finally, we articulate the individual, institutional and financial capacities that must be developed to underpin knowledge exchange strategies.

PUSH-CORE SAMPLING IN MICRONESIA: USING PALEOECOLOGICAL DATA TO RECONSTRUCT GUAM'S CORAL REEF COMMUNITY (Abstract ID: 28387 | Poster ID: 14)

Since the early 1970's, the coral reefs of Guam have been declining with a measurable reduction in live coral cover, a trend documented elsewhere and attributed to a range of anthropogenic stressors. To determine both the nature and extent of decline, we extracted push-cores from back reef coral holes (i.e., coastal karst formations that have since been inundated with water and marine sediment due to rising sea levels) from two sites on the western side of the Guam. The cores ranged from 70 – 125 cm and the oldest was carbon dated back to approximately 500 years. The cores were separated into 5 cm sections processed using 2000, 4000, and 8000 µm sieves to separate out coral fragments. The coral fragments were identified to family to create a long-term record of Guam's near shore reef communities and to provide historical context for evaluating both the rate and magnitude of change. We also discuss key assumption in our novel application of push-coring and its potential for future studies.

UNDERSTANDING THE BIOGEOCHEMICAL FUNCTION OF THE WORLDS CORAL REEFS (Abstract ID: 30004)

Coral reefs throughout the world are under increasing pressure from anthropogenic perturbations which threaten to shift reefs from a state of net $CaCO_3$ production to net dissolution. Once a reef becomes net dissolving it can no longer maintain the growth of $CaCO_3$ structures critical for sustaining the diversity and abundance of life on coral reefs. Therefore it is critical to monitor and predict how anthropogenic forcings will affect the balance of net ecosystem calcification in reef ecosystems. Currently, most coral reef monitoring projects rely on visual measurements of benthic composition and do not measure seawater chemistry parameters such as total alkalinity (TA) and dissolved inorganic carbon (DIC). Vector analysis of TA and DIC can be used to determine the relative influence of organic (photosynthesis/respiration) versus inorganic ($CaCO_3$production/dissolution) processes occurring on a coral reef. Results from a mesocosm study demonstrate that benthic community composition is reflected in the TA-DIC slope of the overlying seawater. An analysis of 23 coral reef locations around the globe showed that there is a diverse range in TA-DIC slopes (0.24 to 1.36), indicating a large range in the biogeochemical function of reef ecosystems. A simple model demonstrated that reefs with slopes greatly different from 0.95 have a dramatic increase in the diel variability of seawater pH, which is exacerbated by ocean acidification. Monitoring the pulse of coral reefs via TA and DIC measurements through time and space could help to better inform conservation and management efforts.

LAYER BY LAYER – TRANSCRIPTOMIC AND PROTEOMIC ANALYSIS OF HEAT-STRESSED STRAINS OF AIPTASIA PALLIDA (Abstract ID: 29364)

Corals and their endosymbionts Symbiodinium, are key building blocks of the coral reef ecosystem. However, environmental stress imposed by increasing temperatures lead to the breakdown of symbiosis, known as bleaching. The capacity of corals to maintain their symbionts through acclimatization is crucial for coral reef resilience. Comparative heat-stress studies of coral species capable of inhabiting wide environmental gradients, have shown different gene expression patterns possibly linked to bleaching resistance in individuals from warmer regions. Transcriptomics is used as a proxy for gene activity and associated protein content. However, with growing knowledge of post-transcriptional regulation (e.g. miRNAs), it may be erroneous to make such assumptions. Our preliminary study showed that the increased expression of some genes was not reciprocated at protein level. This study explores heat-stress associated changes in transcriptome and proteome layers of the cnidarian model organism Aiptasia from three distinct geographical locations: Red Sea, Florida and Hawaii. Also, the role of the symbiont in thermal stress response was investigated by comparing the same Florida strain infected with Symbiodinium from different clades. Analysis of both layers allows for a better understanding as to what extent transcript levels are an accurate reflection of protein levels. This combination increases our understanding on which genes and associated proteins play crucial roles in acclimatization and further, elucidate factors driving variations in coral thermal tolerance.

INVESTIGATING SOCIAL DRIVERS OF FISHING AND MARKET INFLUENCES ON INCREASINGLY EXPLOITED SMALL-SCALE CORAL REEF FISHERIES (Abstract ID: 29061)

Many coastal communities in the Pacific are part of complex social-ecological systems that have relied on coral reefs for centuries. Recent pressures including changing climates and economies are threatening the resilience of these systems. This study seeks to better understand drivers of social-ecological resilience and how they are linked through asking: 1) What are the social drivers of fishing effort? and 2) How do markets influence artisanal fisheries (i.e., fishing pressure, gears, target species, distribution of catch)? Data were gathered in 20 Fijian villages using a mixed methods approach including household and fisher interviews, catch logs, and ecological surveys. Structural equation modeling was used to identify the significant drivers of fishing effort and examine links between drivers. While environmental factors are expected to play a large role in driving indicators of reef resilience, social factors (e.g., livelihood diversity, traditional ecological knowledge, resource sharing), although typically ignored in the fisheries literature, explain ~25% of the variation in household fishing effort. Between 50-75% of household catches are used for subsistence, while the remainder is used for sharing and sale. Top predators and larger fish are targeted for sale, often using spears, while a wide range of species and sizes are used for household consumption. The results of this study stress the need to consider the human dimension in coral reef fisheries management and call attention to potential consequences of limited fisheries yields on social resilience.

MARINE RESERVES LAG BEHIND WILDERNESS IN THE CONSERVATION OF KEY FUNCTIONAL ROLES (Abstract ID: 29182 | Poster ID: 640)

Although marine reserves represent one of the most effective management responses to human impacts, their capacity to sustain the same diversity of species and functional roles

and the same biomass of reef fishes as wilderness areas remains questionable, particularly in regions with deep and long-lasting human footprints. . Here we show that fish functional diversity and biomass of apex predators are significantly higher on coral reefs located at more than 20 hours travel time from the main market compared to even the oldest (38 years old), largest (17,500 ha) and most restrictive (no-entry) marine reserve in New Caledonia (South-Western Pacific). We demonstrate that wilderness areas support unique ecological values with no equivalency as one gets closer to humans, even in large and well-managed marine reserves. Wilderness areas may therefore serve as benchmarks for management effectiveness and act as the last refuges for the most vulnerable functional roles.

AUTOMATED CHANGE DETECTION IN CORAL REEF IMAGES CAPTURED BY MULTIPLE CAMERAS OVER TIME (Abstract ID: 29244 | Poster ID: 551)

Towards the goal of automatically quantifying significant changes in shallow and wide coral reef areas, we developed a change detection algorithm which can identify presence or absence of benthic objects in the same quadrat. The quadrats were imaged by different cameras under varied capture perspective, illumination, and water condition. Our change detection algorithm is novel because it uses shape detection and feature extraction to process images of life forms with arbitrary shapes having little or no sharp corners from which image registration can be performed. Previous techniques were not as flexible to variations in capture settings and do not take into account real underwater situations where drastic changes can happen such as those caused by typhoons, massive bleaching, and groundings. The algorithm was developed and tested on a set of coral reef images taken within a span of five years from a quadrat in Lian, Batangas, Philippines. Shape features were extracted from the reference images to isolate objects of interest. Local binary pattern (LBP) texture feature histograms were obtained from random patches within the boundaries of these objects across all images in the set to determine presence or absence of reef benthos. The texture vector angle matrices consistently showed small angles when the object of interest is present in the images over time and relatively large angles when the object is absent. Validation resulted to 81% accuracy for presence and 97% for absence.

THE LINKS BETWEEN CORAL REEF FISH BODY SIZES, THEIR HOME RANGE SIZES, AND STRUCTURAL COMPLEXITY ON A CORAL REEF OF KOH PHANGAN, LOWER GULF OF THAILAND (Abstract ID: 28707)

Decreases in coral reef structural complexity result in the reduction of available shelter to the functionally important fishes. This may strongly impact and restructure reef associated fish communities and subvert functional integrity. Recent research suggests that reduced structural complexity could result in a higher relative representation of fishes with larger body sizes and larger home range sizes. The present study aims to link body and home range sizes of herbivores and corallivores to structural complexity and benthic cover of a small scale habitat. Observations were conducted from 16/03/2015 to 10/06/2015 in 30x5m belt transects on the reef crest of Mae Haad, a bay (~800m length) of Koh Phangan in the Gulf of Thailand. Each belt transect was assessed for: fishes (species, abundance, size classes; visually assessed), structural complexity (rugosity of vertical reef crest contour; chain-and-tape method), and benthic cover (three-dimensional structural elements; line-point-intercept method). The results confirm suggestions of previous studies. Small scale coral reef habitats of low structural complexity (rugosity ~ 1.4) show significantly higher relative representation of fishes with larger home range and body sizes. Corallivory decreases with declining structural complexity while herbivory increases. Fish-habitat interactions with a specific site weaken as structural complexity reduces. These findings have the potential to develop spatial and species-specific management tools that assist in sustaining the ecosystem integrity of Koh Phangan's reefs.

PATTERNS, CAUSES, AND CONSEQUENCES OF MARINE LARVAL DISPERSAL (Abstract ID: 27896)

Quantifying the probability of larval exchange among marine populations is key to predicting local population dynamics and optimizing networks of marine protected areas. The pattern of connectivity among populations can be described by the measurement of a dispersal kernel. However, a complete empirical dispersal kernel has been lacking for any marine species. We use genetic parentage analysis to quantify a dispersal kernel for the reef fish*Elacatinus lori*, demonstrating that dispersal declines exponentially with distance. The spatial scale of dispersal is an order of magnitude less than previous estimates—the median dispersal distance is just 1.7 km and no dispersal events exceed 16.4 km despite intensive sampling out to 30 km from source. Neither pelagic larval duration nor direction is associated with the probability of successful dispersal. Given the strong relationship between distance and dispersal, we show that distance-driven logistic models have strong power to predict dispersal probabilities. Moreover, connectivity matrices generated from these models are congruent with empirical estimates of spatial genetic structure, suggesting that the pattern of dispersal we uncovered reflects long-term patterns of gene flow. These results challenge assumptions regarding the spatial scale and presumed predictors of marine population connectivity. We conclude that if marine reserve networks aim to connect whole communities of fishes and conserve biodiversity broadly, then reserves that are close in space will accommodate species that are short-distance dispersers.

MANIPULATING PROKARYOTIC SYMBIONTS TO ENHANCE CORAL STRESS TOLERANCE (Abstract ID: 27936 | Poster ID: 149)

Coral reefs are suffering massive declines due to anthropogenic and other environmental disturbances. While it is urgent to mitigate the effects of climate change, it is also essential to explore ways of augmenting coral tolerance to stress. Here we investigate whether this is achievable by manipulating prokaryotic symbionts. Corals are colonized by a huge diversity of prokaryotes, which exert various beneficial functions, including nutrient cycling and protection from pathogens, thereby directly influencing the health of their host. Acropora tenuis larvae reared in UV-treated and filtered seawater were exposed either to filtered seawater, or to microbiomes isolated from the mucus of coral species known to be resistant or sensitive to heat stress. To assess the feasibility of microbial community manipulations and stability of acquired microbiomes, prokaryotic communities of coral larvae and recruits were regularly sampled for characterization by 16S rRNA gene sequencing. Samples were also collected to quantify the ratio of 16S rRNA to 16S rRNA gene copy number, often used as an indicator of metabolic activity. In addition, samples were fixed for analysis by fluorescence in situ hybridization in order to localize prokaryote groups within coral tissues. In parallel, survival and growth of coral recruits was monitored to evaluate how microbiomes influence coral fitness. The potential to enhance coral tolerance to stress via the manipulation of prokaryotic symbionts is expected to provide promising approaches for coral reef restoration.

NPC PROTEINS ARE KEY PLAYERS IN MOLECULAR INTERACTIONS BETWEEN CNIDARIANS AND THEIR DINOFLAGELLATE ENDOSYMBIONTS (Abstract ID: 29721 | Poster ID: 131)

Cnidarians host their photosynthetic dinoflagellate symbionts in gastrodermal cells, in a phagosome-derived vacuole. The establishment and maintenance of the symbiotic interaction is dependent on intimate molecular communications, including recognition and tolerance of symbionts, as well as adaptations for mutual transport and exchange of nutritional resources. However, environmental perturbations, such as an increase in seawater temperature, may disrupt this partnership, leading to the severe worldwide decline of coral reefs. Here, we will especially focus on the sterol-binding proteins Niemann-Pick C (NPC1 and NPC2), which have been identified by transcriptomic analyses in symbiotic sea anemones. While only one NPC2 gene is present in many metazoans, this gene has been duplicated in cnidarians (at least four copies of NPC2 are detected). However, only one gene (NPC2-d) was upregulated in symbiotic relative to aposymbiotic sea anemones. We investigated the subcellular localization of NPC proteins in the symbiotic sea anemones Anemonia viridis and Aiptasia. We demonstrated that NPC1 is a biomarker of the perisymbiotic membrane and highlighted a subfunctionalization of NPC2-d protein. Potential ligands of NPC2 proteins were also investigated using Isothermal Titration Calorimetry. In symbiotic cnidarians, NPC proteins may be involved in sterol trafficking but may also participate in symbiont selection and/or symbiont persistence, for example by recognizing dinoflagellates cell-surface glycans. This may explain why several NPC2 genes have been retained in cnidarian genomes.

APPLYING BIG DATA TO CONSERVATION: AN INDO-PACIFIC SNAPSHOT OF 2300 CORAL REEFS TO INFORM CLIMATE RISK AND REFUGE (Abstract ID: 29953)

Threatened by climate change and anthropogenic impacts, tropical coral reefs face unprecedented losses in biodiversity and ecosystem services in the coming decades. Adaptation, resilience and survival are possible, but a coordinated strategy to guide investments in conservation and management remains unclear. Here, we take a 'big data' approach and compile the largest snapshot of contemporary reef coral biodiversity in the Indian and Pacific Oceans from over 2300 sites in 51 counties and territories provided collaboratively by 100 coral reef scientists (*the "Indo-Pacific Coral Collaboration"). We evaluate Scleractinian coral taxonomic, functional and phylogenetic diversity from over 30,000 mixed-effects models to show that climate-driven ocean warming and local anthropogenic stressors are the strongest drivers of regional coral biodiversity, and that gradients of threat and biodiversity can inform conservation decisions. Our results provide a data-driven portfolio that balances climate risk and refuge in one of the world's most threatened ecosystems, and calls for continued application of collaborative technology and big data science for coral reef conservation. We also discuss an emerging collaboration of field scientists and technologists to develop a standardized open-source database for global coral reef information.

DARWIN, PIONEER OF REEF TRANSECTS, REEF ECOLOGY AND ANCIENT REEF MODELLING: SIGNIFICANCE OF HIS COCOS (KEELING) SPECIMENS IN THE NATURAL HISTORY MUSEUM, LONDON (Abstract ID: 29356 | Poster ID: 1)

David Stoddart made stimulating contributions to the history of coral reef studies and Darwin's work in particular, including reproduction of important MS material not previously published. We give interim results of our study of Darwin's NHM reef specimens from 'his' atoll, Cocos (Keeling). For Darwin this was his last chance during the Beagle voyage to test his subsidence theory of coral reefs. He needed to show that reef-builders were restricted to shallow water and grew most vigorously along reef fronts and edges since this explained the saucer-like surface topography of atolls. He made qualitative reef transects across the atoll rim, and with FitzRoy and crew made soundings on the deeper reef front. Darwin put his results on to sketched profiles, pioneering the idea of reef zonation in relation to depth and strength of water movement. We relocated his NHM specimens on these profiles. Darwin also sketched two conceptual reef cross-sections at Cocos (Keeling) to model his ideas on reef accretion on a subsiding foundation. They show the influence of Lyell his mentor in using his then new uniformitarian principles to suggest how his model might apply to ancient reefs. While Darwin's model has proved too simple because glacioeustasy in particular was unknown at that time, many of his other ideas, like subsidence, have lasted. His model is also notable for its time for being based on evidence from fieldwork and specimens. Darwin pioneered studies of reef ecology, reef zonation and a unifying approach to the sedimentology of reef growth, ancient and modern.

SEDIMENT ON REEFS: WHO IS TO BLAME? (Abstract ID: 28139)

Watershed land-use plays a crucial role in the amount of sediment that ends up on the reefs. Remotely-sensed images make evident the interplay of land-use and atmospheric disturbance resulting to higher sediment discharge. Coarse-grid numerical modelling further demonstrates the role of wind-driven currents in influencing the fate of the sediments with some ending up onshore providing new land for mangrove to colonize, others offshore contributing to iron fertilization and others nearshore where they end up smothering seagrass and corals. We contend however, that this coarse model and the paradigm that it supports paint only part of the sedimentation story. Nearshore anthropogenic activities (such as mangrove conversion, coastal structure design and mariculture intensity) equally, if not more significantly, contribute to the sedimentation stress of coral reefs as demonstrated by RS time-series, finer-scale numerical models and sediment budget calculations.

IS YOUR SCIENCE GETTING THROUGH? COMMUNICATING SCIENCE-BASED INFORMATION ON ECOSYSTEM BIODIVERSITY AND CLIMATE/DISASTER RESILIENCE (Abstract ID: 28127 | Poster ID: 706)

Now more than ever, each and every one need to have some understanding of science, which demands scientists to reach out to the public and communicate the science they generate to help make informed decisions. To bridge communication gaps between scientists, policy makers, and the public, we developed a wide array of communication materials by first identifying (1) who we need to inform (target audience), (2) what they need to know, and (3) what is the most effective way of conveying the critical information. It was crucial to distinguish effective means of delivering specific messages to specific target audiences. We aimed to convey topics of ecosystem biodiversity interconnectivity, disaster risk reduction and management (DRRM), and climate change adaptation (CCA) to our identified groups (primary to tertiary school teachers and students, decision makers and local stakeholders, and the general public). Specific communication materials were developed for each particular group (interactive website, mobile app and tabletop games, animations, media training for scientists, infographics, primer booklet, postcards, telenovela). We also identified that the convergence of knowledge domains is imperative for effective science communication. For each of the communication material developed, we emphasized the contributory role of coral reefs in biodiversity and in providing ecosystem services such as food source; coastal integrity and protection; and tourism and recreation.

QUANTIFYING DAMAGE TO CORAL COLONIES BY WATERBORNE DEBRIS DURING HYDRODYNAMIC DISTURBANCES (Abstract ID: 29085)

Physical bombardment by waterborne debris is a common disturbance in shallow coral reef systems. Bombardment is especially ubiquitous during extreme hydrodynamic disturbances, such as tropical storms. During a hydroydnamic disturbance, increases in water velocity elevate drag forces acting on unattached objects—ranging in size from sand to unattached coral colonies—propelling them into nearby coral colonies. Bombardment can cause scouring and damage to coral tissue, intra-colony breakage (e.g., branch pruning), and dislodgment of the entire colony. Little is known about the process of bombardment given that it difficult to observe in situ during hydrodynamic disturbances. Therefore, we quantify the damage to coral colonies during such disturbances using photogrammetric scans of coral colonies and finite element analysis (FEA) software. FEA models were created using 3D meshes derived from the scans for a range of different coral growth forms. Models were attached at the base, and estimates of substrate and coral skeleton strength were downloaded from the Coral Trait Database and applied to the models. Bombardment scenarios consisted of spheres of a given size being randomly shot at the FEA models at a range of velocities and the probability of different damage types recorded. The model was validated using imagery of damaged corals following a Category 3 tropical cyclone at Lizard Island on the Great Barrier Reef. We were able to make accurate predictions about the extent of damage caused to corals through bombardment during an extreme hydrodynamic disturbances.

ACCLIMATION CAPACITY OF A CORAL-ALGAL SYMBIOTIC PARTNERSHIP TO LONG-TERM WARMING AND ACIDIFICATION (Abstract ID: 28017)

Elucidating the responses of symbiotic partners to environmental stressors is becoming increasingly important as climate change disrupts biotic interactions worldwide. We exposed the Caribbean coral *Siderastrea siderea*and its Clade C symbiont to temperature and $pCO_2$ treatments for 95 days and quantified the transcriptomic responses of each

partner using RNAseq. Both elevated temperature and $pCO_2$ elicited strong but divergent responses of the host's transcriptome. High temperatures disrupted molecular homeostasis and substantially reduced calcification rates. Conversely, elevated $pCO_2$ enhanced host transcription of genes associated with respiration and hydrogen ion transport, with only minimal effects on calcification rates—underscoring the role of proton transport in calcification maintenance under elevated $pCO_2$, while also suggesting costs associated with this acclimation. Contrary to the host, the symbiont's transcriptome exhibited little change in response to elevated $pCO_2$. Instead, population-specific transcriptomic responses were observed across fore-reef and near-shore environments—consistent with observed differences in symbiont photosynthetic efficiency across these two reefs. We conclude that host transcriptomic plasticity promotes acclimation to ocean acidification, but not necessarily warming. Given the host's strong transcriptomic responses to acidification and warming, coupled with the symbiont's lack of response, we hypothesize that hosts actively buffer their symbiont's environment.

THE CHALLENGES OF MANAGING SUGARCANE CULTIVATION IN THE GREAT BARRIER REEF CATCHMENT AREA (Abstract ID: 28420)

Sugarcane cultivation represents one of the primary land uses in Australia's Word Heritage Listed Great Barrier Reef catchment area. With it's identification as a key contributor of coastal nutrient and pesticide exports to marine environments, the sugarcane industry has been the target of considerable natural resource management investment and regulation by various levels of government for more than two decades. Recent combinations of water quality and land use (on-farm) practice change monitoring and modelling suggest results of this considerable long-term investment have been mixed in terms of demonstrable progress towards desired water quality targets. A number of emergent lessons and information gaps are increasingly emerging as critical challenges in addressing these shortfalls including; the challenge of water quality communication extension strategies at the science-industry interface; the spatial variability and development of pollution 'hotspots' from 'diffuse' agricultural pollution, the often locally specific (and in some cases directly contrasting) nature of appropriate on-farm best-management-practices to reduce pollutant losses from farms; and the need for carefully considered, strategic development of on-farm practices to avoid the potential for unanticipated, perverse outcomes from regulation. These themes underline the complexity of managing diffuse agricultural pollution, the general lack of 'silver bullet' solutions to agricultural pollution in the Great Barrier Reef, and the need for flexible, adaptive management frameworks.

U.S. CORAL REEF TASK FORCE DRAFT HANDBOOK ON CORAL REEF IMPACTS (Abstract ID: 28216)

A handbook on coral reef impacts: avoidance, minimization, compensatory mitigation, and restoration summarizes the present governmental US compliance practices. The handbook represents practices from the 19 US Coral Reef Task Force members (12 federal and 7 local government jurisdictions). This includes practices for planned and unplanned in-water events such as dredging, filling and ship groundings. For planned events a two tiered approach that manages mapping, characterization, alternatives analysis, and compensatory mitigation is presented. For unplanned events, the Natural Resource Damage Assessment process, emergency response, and restoration are addressed. Both consider replacement of lost ecosystem functions and restoration of public trust resources. The Handbook addresses the spectrum of federal and local statutory and regulatory policies for coral reef impacts and the challenges of applying these to coral reefs. It serves as a compendium of practices, case studies, and references. The target audience for this document is agency natural resource managers, proponents of development projects, and incident responders.

CORAL REEFS IN THE (INTERNAL) SURF ZONE: EXTREME VARIABILITY IN WATER PROPERTIES ON DONGSHA ATOLL, SOUTH CHINA SEA. (Abstract ID: 28301 | Poster ID: 307)

Internal waves are an important process affecting water properties in the coastal ocean and have been observed to influence physical variability on many shallow reefs exposed to deeper waters. Shoaling internal waves can drive strong flows and transport dense, subthermocline water into shallow depths, changing not only the temperature of the water on the reef, but also pH, oxygen, and nutrient concentrations. In June 2014 we used a Distributed Temperature Sensing (DTS) system to give a continuous cross-shelf view of nonlinear internal wave dynamics on the fore reef of Dongsha Atoll, a coral reef in the northern South China Sea. A DTS system measures temperature continuously along the length of an optical fiber, resolving meter-to-kilometer spatial scales at 1-minute temporal resolution. This unique view of cross-shelf temperature structure made it possible to track internal waves across the shallow fore reef and onto the reef flat and to quantify spatial patterns in temperature variability.

40 YEARS OF BENTHIC COMMUNITY CHANGE AT THE FORE-REEF SLOPE (10 – 40 M) OF THE CARIBBEAN REEFS IN CURACAO AND BONAIRE: THE RISE OF CYANOBACTERIAL MATS (Abstract ID: 28326)

In the past decades benthic sessile communities of tropical coral reefs have undergone significant changes worldwide. Generally, there was a shift from stony corals to fleshy macroalgae. Long-term studies documenting changes in other benthic reef groups, however, are scarce. We have studied change in dominant benthic groups at 4 reef sites in the Caribbean islands of Curaçao and Bonaire over a time-span of 40 years. Permanent 3 x 3 m quadrats at 10, 20, 30 and 40 m depth have been photographed at intervals since 1973. The temporal and spatial dynamics in cover of dominant benthic groups [corals, macroalgae, sponges, cyanobacteria, algal turf and crustose coralline algae (CCA)] were assessed based on image point-analyses. Our results show a strong decrease in the cover of calcifying groups averaged over all sites and depths from 32.9% [1973] to 9.2% [2013] for coral and for CCA from 6.4% to 0.95%. Initially, coral cover is replaced by turf algae (24.5% to 45.3%) and fleshy macroalgae (0% to 12%). These new dominants are however largely reduced from 2000 to 2013 (10.8% and 2.2%, resp.), signalling the rise of benthic cyanobacterial mats (BCM). BCM become the most dominant component increasing from a mere 0.1% [1973] to 22% [2013]. This is accompanied by a small increase in sponge cover (0.5% to 2.3%). Strikingly, the observed pattern of degradation and phase change was seen down to mesophotic depths of 40 m. These results suggest that reefs dominated by algae may be less stable than previously thought and that the next phase may be the domination by slimy cyanobacterial mats.

NOVEL SURVEY METHOD FOR BIOFLUORESCENT FISHES FINDS LOW ABUNDANCES OF PYGMY SEAHORSES IN INDONESIA (Abstract ID: 28158 | Poster ID: 501)

Pygmy seahorses (*Hippocampus spp.*) are iconic species which are important to SCUBA diving tourism in Southeast Asia. They have been shown to be one of the main drawcards for tourists visiting dive destinations and make significant contributions to the income of local coastal communities. Seahorses are considered vulnerable and all species are protected under CITES. However, information on the life histories and threats of pygmy seahorses is limited and all IUCN- assessed species are listed as data deficient. Research is hampered by the cryptic nature of pygmy seahorses. Their very small size and excellent camouflage makes it difficult to find them using traditional survey methods. We report a new method using biofluoresence for surveying pygmy seahorses. Three pygmy seahorse species (*H. bargibanti, H. denise, H. pontohi*) were found to fluoresce. Further research showed that this biofluorescence could be used as an efficient survey method for *H. bargibanti*. Using this method, extensive surveys at 63 sites across Indonesia (Bali, Nusa Tenggara, North-Sulawesi, Raja Ampat) revealed very low occupancy rates (13.7%) of host seafans (*Muricella sp.*). Additional surveys revealed that this method is not limited to pygmy seahorses. Another 84 cryptic fish species fluoresced at the survey sites, opening up the possibilities of using fluorescence as a survey tool for a wide variety of understudied cryptic species.

HOW FAST AND EFFICIENT SPONGE ENGINES DRIVE AND MODULATE THE FOOD WEB OF SHALLOW AND DEEP-SEA REEF ECOSYSTEMS (Abstract ID: 28696)

Ever since Darwin's early descriptions of reefs, it has been a mystery how one of earth's most productive and diverse ecosystems thrives in oligotrophic seas, as an oasis in a marine desert. The recently discovered sponge loop pathway shows how sponges efficiently retain and transfer energy and nutrients on reefs, recognizing their (so far neglected) role as key ecosystem drivers. Evidence now accumulates on sponge loops in other ecosystems, such as deep-sea coral reefs. As a result, current reef food web models lacking sponge-driven resource cycling are incomplete and need to be redeveloped. However,

mechanisms that determine the capacity of sponge 'engines', how they are fuelled, and drive communities are unknown. I will discuss the establishment of a novel reef food web framework, integrating sponges as key ecosystem drivers. To this end, existing critical knowledge gaps at both organismal and community scale will be identified. Sponges will be evaluated on functional traits (morphology, associated microbes, pumping capacity) in the processing of dissolved food, the main fuel of the sponge engine. To what extent these different functional traits are a driving force in structuring reef ecosystems, from fuel input (primary producers), to engine output (driving and modulating the consumer food web) will be assessed at the community level. The resulting framework will be implemented in a sponge-driven food web model, a much-needed foundation to test and predict future scenarios of changes in shallow tropical and temperate as well as cold-water deep-sea reef communities.

RECOGNIZING BEST PRACTICES IN MPA AND MPA NETWORK MANAGEMENT IN THE PHILIPPINES: THE PARA EL MAR (MPA AWARDS AND RECOGNITION) (Abstract ID: 29276)

Marine protected areas (MPA) and MPA networks have been proven to achieve conservation and fisheries goals. Improving the management of these MPAs and networks is crucial to better achieve these goals. In 2007, the Philippine MPA Support Network (MSN) developed the biennial Para el MAR ( MPA Awards and Recognition) to provide incentives for good MPA management by giving recognition and awards to the best-managed MPAs and networks in the Philippines. This paper highlights the experiences and learnings of the Para el MAR. One of the best practices of effective MPAs and networks is when governance mechanisms such as legislation, effective management body and management plans are in place. Consistency of key management activities such as enforcement, information education and communication, capacity building, as well as monitoring and sustainability mechanisms such as financing, are crucial in effective management. The Para el MAR has become a sharing and learning venue for these best practices. This has encouraged the MPAs and networks to increase their efforts and improve management. The Para el MAR has enhanced their pride of place and has helped leverage support from private and public partners to improve management in Marine Key Biodiversity Areas (MKBA) where the MPAs and networks are located such as the Verde Island Passage and Lanuza Bay.

APPLICATION OF NOAA CORAL REEF WATCH'S NEAR-REAL-TIME SATELLITE AND MODEL-BASED DECISION SUPPORT SYSTEM TO LOCAL CORAL REEF MANAGEMENT (Abstract ID: 27989 | Poster ID: 619)

The National Oceanic and Atmospheric Administration's (NOAA) Coral Reef Watch (CRW) program uses satellite, in-situ, and modeled data to deliver online a global decision support system (DSS) that helps managers prepare for and respond to coral reef environmental stress. Near-real-time satellite products are derived from sea surface temperature, light, wind, and ocean color data. Weekly to seasonal forecasts project future reef conditions, informing national and international assessments, management responses, and conservation planning. CRW's DSS is the only global early-warning system for the reef environment. It assists environmental impact monitoring, bleaching risk assessments, and preparation/implementation of timely, effective protective responses and adaptation actions. CRW's alerts of mass bleaching, such as the ongoing global bleaching event, allow managers to communicate quickly with decision makers and the public to reduce local stressors; certain countries have even closed major dive and fishing areas (e.g., 2010). CRW also incorporates climate model predictions to identify regions potentially resilient to climate change, aiding marine protected area planning. This poster discusses applications of CRW's DSS to local coral reef management. CRW directly engages local stakeholders and incorporates user feedback into product development and enhancement. This ensures CRW can provide coral reef managers worldwide with climate-quality, consistent, authoritative information on present and future severity of threats that lead to coral bleaching, disease and other impacts.

MANAGEMENT IN SAN FELIPE KEY, A CUBAN NATIONAL PARK, BASED ON ASSESSING CORAL REEF CONDITION AND FISHERIES. (Abstract ID: 28912 | Poster ID: 654)

The San Felipe Keys are located in the Southwest platform of Cuba and were declared National Park in 2010, due to its high ecological value. However, the management plan did not take into account coral reef condition and present fishing activities for more than 60 years. Monitoring of coral health indicators and reef fish associations was conducted with visual census and stereo video between 2013 and 2015. An annual finfish fisheries assessment (2014) was obtained based on catch sample, using length-frequency and gonads maturity analysis. Results showed that bioerosion processes, like bleaching, coral diseases and incrusting organisms, were more active than accretion, especially in zones with higher reef complexity. Fish associations are dominated by small fish and large commercial species are rare (parrot fish, groupers, snappers and other top predators). Also, evidence of snapper's reproductive migration and spawning aggregation sites in areas inside and outside the Park were obtained. Close to 25% of fish catch are unreported and snappers were the most abundant group caught. Overall, 40% of annual catches occurred during reproductive season and 70% of individuals were caught with mature gonads. Yet, a high percentage was captured before reaching the first maturity length, especially Lutjanus analis (80%) and Lutjanus cyanopterus (95%) due to problems in its minimum size. Responding to the confounded local situation, we provide management advice to aid in the conservation of ecosystem biodiversity and to promote sustainable fishing practices to deal with overfishing.

IMPACT OF LAND USE AND NONPOINT SOURCE POLLUTION ON CORAL REEF ECOSYSTEM HEALTH IN WEST MAUI, HAWAII (Abstract ID: 27860 | Poster ID: 421)

Coral reef health is affected by multiple factors. Although coral reefs are resilient systems, the combination of stressors is proving disastrous. In the past 17 years, West Maui coral cover in near shore reefs declined an average of 37%. Nonpoint source pollution is one of the most prevalent sources of contaminants, which affect aquatic organisms by disrupting ecosystem functions, causing changes in the food chain dynamics and altering species reproduction, growth and behavior. Corals respond to the presence of pollutants by expressing and activating detoxification enzymes. By measuring these enzymes, we can identify the stress level of corals, prior to outright death. The goal of my project is to study which pollutants reach the ocean in West Maui, their availability to marine biota and the corals' molecular responses. I will determine water and sediment contaminant load by Gas Chromatography-Mass Spectrometry (GC-MS), below two sites, during two years. I will be measuring the amount of contaminants in algae, corals, and echinoderms as bio-indicators for coral reef ecosystem health, by GC-MS, to determine bioaccumulation and biomagnification. Expression and activity of detoxification enzymes in coral samples will be assessed by Western Blot and spectrophotometry, respectively. Results from this study will provide information about the quality of the runoff reaching the ocean in West Maui, its bioavailability, and corals' sublethal responses. This knowledge is essential to make adjustments in ecosystem management, to prevent further decline and allow its recovery.

DIFFERENTIAL EFFECTS OF LIGHT AND FEEDING ON NEW RECRUITS OF PORITES ASTREOIDES FROM TWO REEF SITES WITHIN BERMUDA (Abstract ID: 29522 | Poster ID: 204)

Early life history stages of corals may be more susceptible to environmental changes than adults. Furthermore, inter-site variations in environmental parameters may promote differen-

tial responses to changes. Larvae were collected from *Porites astreoides* colonies from two sites in Bermuda, an offshore rim reef and an inshore patch reef, and the settled recruits were reared for 6 weeks in replicate aquaria under two light levels (mean 200 and 30 μE $m^{-2}$ $s^{-1}$) and were either unfed or fed brine shrimp three times a week. Larval size at collection and new recruit size at 10 days, 4 weeks and 6 weeks were measured by photographic image analysis. Rim reef colonies produced significantly larger larvae and new recruits. When unfed, mean recruit size significantly increased only under the low light treatment, irrespective of reef site of origin. When fed, recruits from the patch reef larvae significantly increased in size under both light levels. In contrast, whereas fed recruits from the rim reef larvae increased in size under low light, there was no size change for fed recruits reared under high light. Feeding increased survivorship, although all recruits held under high light had greater mortality. Feeding also increased zooxanthellae density except for recruits reared from the larger rim reef larvae that remained sensitive to higher light. This study provides insight into factors affecting coral recruitment success and documents the occurrence of functional variability in larvae and recruits of the same species between different reef sites.

IS PAGODA CORAL TURBINARIA MESENTERINA (LAMARK, 1816), A SUCCEEDER OF RECENT CORAL BLEACHING EVENT IN THE SOUTH EASTERN ARABIAN SEA? (Abstract ID: 29040)

To monitor 2014-15 El Niño driven coral bleaching,we studied species specific variations of bleaching severity and settlement of turf algae on bleached colonies at two near shore shallow (3-7m) reef,i.e. Malvan Sanctuary(MS)and Grande Island (GI)in the Arabian Sea by conducting monthly underwater surveys. The combination of 25sq.m permanent photo quadrat with coral colony tagging and 50m Line Intercept transects were carried out to determine bleaching extent. Both the sites were characterized by low scleractinian diversity (18 and 15 species, respectively), high macroalgae cover(66% and 39%),fewer herbivores(average <50 nos/100 sq.m) and high coastal pressure (fishing and tourism). Massive and encrusting colonies of Porites lutea, P. lichen, P. compressa,Plesiastrea sp.,Favites sp.were susceptible to bleaching, while foliaceous Turbinaria mesenterina colonies mostly unaffected.Bleaching severity was estimated to be 80% and 60% in the MS and GI. In both sites,>90% of the massive Porites were bleached followed by Plesiastrea sp.(79% and 62%),Favites (91% and 45%). By contrast, <3% colonies of T.mesenterina found to be bleached. Insitu observation revealed significantly higher settlement of filamentous turf algae on the bleached colonies(80-95%) subsequent to the bleaching event in both the study sites, further hasten coral mortality. Considering our observations,we point out that ruinous impact of this bleaching event could shift coral community structure from massive and encrusting species to foliaceous species by in an increase in the relative abundance of T.mesenterina.

INTERACTION BETWEEN COMMUNITY METABOLISM AND REEF WATER PH ON A CORAL ATOLL IN THE SOUTH CHINA SEA (Abstract ID: 28930)

The $CaCO_3$ skeletons of reef calcifiers comprise the building blocks that form coral reef structures. In laboratory and mesocosm experiments, calcification rates of corals and other reef calcifiers decline under elevated $CO_2$ concentrations, raising concerns for the future of coral reef ecosystems under 21st century ocean acidification. However, the chemical environment on coral reefs is strongly modulated by the benthic community and can be quite different from the open ocean. This complicates efforts to project ocean acidification impacts on coral reefs. We investigated the drivers of reef water pH and net community calcification (NCC) on Dongsha Atoll, a remote coral reef ecosystem in the northern South China Sea. In June 2014, diurnal-average NCC was 420 ± 80 mmol CaCO3 $m^{-2}$ $day^{-1}$, greater than any other coral reef studied to date, despite comparable calcifier cover (25%) and open ocean pH (~8.0 – 8.1). Such high NCC rates are likely driven by high daytime on-reef pH (~8.5), which is significantly elevated above that of the adjacent open ocean. Elevated on-reef pH is a consequence of high daytime net community productivity (NCP), most likely caused by high benthic cover of algae (19%) and seagrass (16%). A transient coral bleaching event reduced NCC and daytime NCP by ~50% and in turn decreased average on-reef pH by 0.2 units, in the absence of such changes in open ocean pH. Our findings highlight the interactive relationship between community metabolism (NCC and NCP) and reef water pH that will modulate the sensitivity of coral reefs to future open ocean acidification.

SUCCESSIVE PHASES OF REEF FLAT DEVELOPMENT THROUGHOUT THE HOLOCENE: INFLUENCE OF HYDRODYNAMIC ENERGY AND SEA-LEVEL CHANGE ON THE GREAT BARRIER REEF (Abstract ID: 28525)

The response of platform reefs to sea-level stabilization over the past 6 ka is well established for the Great Barrier Reef (GBR), typically accreting laterally from windward to leeward. However, this interpretation is based on few cores spread across a range of reef zones and may not fully capture the response of reefs to the Holocene stillstand, including the timing of when they first approached sea-level and the direction, rate and continuity of reef flat accretion. We present a new record of reef flat accretion based on 49 U/Th ages from closely spaced transects at Heron and One Tree reefs, combined with all available published C14 ages from reef flats across the GBR. A distinct hiatus occurred in growth from 3.6 ka to 1.6 ka in the northern, south-central and southern GBR. However, no such hiatus occurs in the central GBR, with ages from 7.6 to 0.9 ka. We conclude that a relative fall in sea-level (~0.5 m), 4-3.5 ka is the most likely explanation for why reef flats in the north and south turned off during this period. Greater hydro-isostatic adjustment of the central GBR and subsidence of the Halifax basin may have provided greater vertical accommodation for the mid-outer platform reefs of the central GBR, allowing them to continue to accrete vertically, despite a relative sea level fall. Further, our results demonstrate that hydrodynamic energy is the main driver of accretional direction, with exposed reefs accreting primarily lagoonward, while protected reefs accrete seawards, contrary to the traditional GBR growth model of windward to leeward directed accretion.

CARIBBEAN SPONGE PATHOLOGY – THE DIAGNOSIS IS NOT ALWAYS SIMPLE (Abstract ID: 28815)

Despite increasing reports, little is known about the pathologies of coral reef sponges. When sponges die, they leave little evidence of their presence behind; therefore, studying sponge pathologies requires temporal monitoring. For example, long-term monitoring of the Caribbean giant barrel sponge *Xestospongia muta* led to the characterization of sponge orange band (SOB), which often kills the sponge and leaves nothing behind. Despite a decade of research, no specific pathogen or environmental stressor has been identified as the cause of SOB. To date, only two studies have succeeded in confirming Koch's postulates for a sponge disease. Given the diversity of sponges and their variable responses to biotic and abiotic factors, a broader approach is required that considers disease-causing microorganisms, environmental stressors, or a combination of these two. Here we report a new pathogenic condition, Agelas Wasting Syndrome (AWS) of the brown tube sponge, *Agelas tubulata (cf. conifera)*. The tissue loss from AWS was previously interpreted as predatory bite-marks on sponges until individual sponges were monitored over time. This example is the converse of that recently described for the yellow tube sponge *Aplysina fistularis*, which displays pathogenic tissue damage that was found to be the result of predation by cowries that live at the base of the sponge tubes and feed nocturnally. Sponge pathologies need to be studied carefully and on a species-by-species basis, with particular attention paid to sponge ecology and temporal monitoring.

AN OASIS IN THE DESERT: SOURCING CORALS FROM HARBORS FOR REEF RESTORATION (Abstract ID: 28212 | Poster ID: 306)

The continuous decline of coral reef throughout the world due to anthropogenic activities has encouraged the development of different mitigation strategies, many of which

involve the creation of artificial reefs or the transplantation of corals onto impacted reefs. Both of these strategies involve the need for source corals for the mitigation, as the natural recruitment and growth of coral larvae into adult colonies displaces lost ecological services for too great a period. In Hawaii, where corals grow only a few centimeters a year, this issue is pronounced. Hawaii's Division of Aquatic Resources (DAR) has introduced an innovative strategy to source coral material from boat harbors by removing coral colonies from man-made structures within the harbors, thereby minimizing the impact to wild colonies while selecting coral colonies that have already shown to be resistant to higher SSTs, sewage discharges, pollutants, sedimentation and survival under these dynamic conditions. Such corals may be one answer to improve rehabilitation success on deteriorated reefs. Harvested corals are fragmented down into small fragments and grown out with an exceptional fast growth rate under high maintenance conditions; once they reach an optimal larger size they are re-aggregated into adult colonies which are then transplanted onto natural degraded coral reefs.

MASS CORAL LARVAL RESEEDING IS A VIABLE OPTION FOR ENHANCING RECRUITMENT AND RESTORING DEGRADED REEFS (Abstract ID: 28445)

Restoring degraded ecosystems is essential for mitigating the effects of anthropogenic impacts and for maintaining biological diversity to ensure the continuous flow of ecosystem goods and services. For coral reefs, innovative restoration technologies aimed at larger scale interventions are considered to be one of the primary potential solutions to the rapid and increasing global problem of reef degradation. This study used low-cost mass larval settlement enclosures to significantly increase coral recruitment on degraded coral reef areas in northwestern Philippines. *Acropora tenuis*larvae were cultured *ex-situ* after colonies spawned, and approximately 400,000 competent larvae were transported and retained in each of four replicate 6 x 4 m reef 'reseeded' plots. Four adjacent 6 x 4 m plots were used as non-seeded control plots for comparison. Immediately after the settlement period, recruitment on tiles in the reseeded plots was very significantly higher (mean 27 ± 13 spat per tile) than in control plots, in which no single recruit was record. There was no recorded mortality of seeded *A. tenuis* juvenile corals on the natural reef substrata or on tiles during subsequent monitoring up to 24 mo. After 2 years, a mean of 24 ± 12.4 *A. tenuis* coral colonies, with ecological volume of 938 ± 288 $cm^{-3}$, survived on the reef substrata within reseeded plots and no *A. tenuis* corals in control plots. The results show that mass coral larval 'reseeding' is an effective method for quickly enhancing larval settlement and stimulating recruitment on degraded but recoverable reef areas, and can rapidly initiate new coral populations.

SUSTAINING STAKEHOLDER PARTICIPATION IN MARINE PROTECTED AREA NETWORKS IN LANUZA BAY, SOUTHEASTERN PHILIPPINES (Abstract ID: 28567)

Developing innovative ways to increase stakeholder participation and sustainable financing of marine protected area (MPA) management are the focal areas of work in Lanuza Bay. It is in Southeastern Philippines, facing the Pacific Ocean and managed by the Lanuza Bay Development Alliance (LBDA). The primary threat to Lanuza Bay arises from illegal, unregulated and unsustainable fishing. Runoff and pollution from land-based activities such as mining, logging, and wood processing and forest conversion are also a growing threats. At least two reef-associated fish species are depleted and near local extinction. In response, an ecological network of 16 MPAs was established with sizes ranging from 21 to 75 hectares. Each MPA has a fisher organization managing it with support including accident and health insurance, and monthly stipend from the local government, and the LBDA, and Nagkahiusang Mananagat na Nag-amping sa Kadagatan sa Lanuza Bay (NAMANAKA), a baywide social network of fisher organizations. NAMANAKA was established to address issues facing each MPA, capacity-building, organizational development, and sustainable financing. Using the Management Effectiveness Tracking Tool (METT), scores range between 12 to 29, and an overall score of 18 out of 45. Among the identified needs include women participation in decision-making in the overall baywide management, strengthening the LBDA and NAMANAKA, developing new financing mechanisms for MPA management, and increasing awareness of legislators and the general public on biodiversity and MPA information.

UNIQUE STRUCTURE OF REEF FISH COMMUNITIES IN EAST AFRICA- A STUDY ACROSS 24 DEGREES OF LATITUDE (Abstract ID: 29041)

The coral reefs of East Africa are some of the last to receive in depth surveys and assessments of the structure of their reef fish communities. To date there have been no broad scale studies conducted within a single time period. From Kenya to Mozambique across 24 degrees of latitude, 2,496, 25 m transects at 208 sites structured hierarchically with four sites nested in four locations within 13 regions were performed. This structure allowed us to assess latitudinal patterns, and the spatial scales that are significant in structuring reef fish communities. Data revealed that typical patterns of decreasing diversity, species turn over, and gradual shift in assemblages structure were not as defined as they are on other coastlines. Diversity peaked at ~11°S, and decreased towards 15°S, where it increased again at the most southern region ~26°S. Assemblage structure did not consistently change with latitude and only two main groupings were revealed, a northern group and southern group splitting at ~15°S. There was very little species turnover with over 60% of the species shared across all regions, and between the most northern and southern region over 68% of species were shared. Reefs were highly heterogeneous at spatial scales <10 km. Spatial variability at this scale overrides the processes operating at larger spatial scales leading to the high level of homogeneity scene across the entire coastline. These results have implications for trans-boundary conservation and management efforts, and the definition of biogeographic boundaries. http://www.movingsushi.com

AN INTEGRATIVE INVESTIGATION INTO THE IMPACTS OF ANTHROPOGENIC STRESSORS ON DEEP-SEA CORALS (Abstract ID: 28388)

As critical inhabitants of deep-sea ecosystems, corals produce complex, heterogeneous habitat and positively influence biodiversity. Further study of these long-lived, slow growing animals is urgently required for conservation purposes, as they are becoming increasingly affected by anthropogenic disturbances like the Deepwater Horizon (DWH) oil spill disaster in the Gulf of Mexico. An unprecedented amount of oil and chemical dispersants were released into the deep-sea during the spill and subsequent cleanup efforts. Detrimental effects have since been documented including impacts to deep-water corals. Live exposure experiments were conducted to investigate the toxicity of oil and dispersants on two coral species, *Callogorgia delta* and*Paramuricea type B3*. The treatments containing dispersants had a more pronounced effect than oil treatments alone. In addition, transcriptomic investigations using DWH spill-impacted corals revealed exposure-induced variations in gene expression including the over-expression of genes coding for Cytochrome p450 (CYP1A1), Tumor necrosis factor receptor-associated factors (TRAFs) and additional genes involved in toxin processing, innate immunity and wound repair. These genes among others found in our expression data serve as useful biomarker candidates for assessing and monitoring future anthropogenic impacts. Our results also provide insights into the stress responses of deep-sea corals, implications of applying dispersants to oil spills and a novel reference assembly for a relatively understudied group of cold-water corals.

CONTRASTING HABITAT UTILIZATION OF TARGETED REEF FISH SPAWNERS AND JUVENILES: SUPPORT FOR ARCHIPELAGO SCALE MANAGEMENT OF THE MAIN HAWAIIAN ISLANDS (Abstract ID: 28480)

Spawning capacity and survival of juveniles are critical determinants of fish population fitness and depend on habitat characteristics, such as refuge availability. Spatially explicit models, which can predict spawner and juvenile abundance while identifying habitats important for spawning and recruitment success, can provide important information for marine spatial planning. This study coupled fish surveys and remotely sensed maps of habitat complexity and composition, wave exposure and human influence at multiple

scales, with geographical information systems and machine learning methods to predict and map targeted reef fish spawner and juvenile abundance, with a focus on surgeonfishes and parrotfishes, for the Main Hawaiian Islands (MHI). This process revealed that: (1) predictive performance varied by life stage and family across islands; (2) areas with very abundant spawners and juveniles rarely overlapped; (3) key environmental factors included distance to human population, wave exposure, and longitude, with spawners influenced by habitat complexity at multiple scales and juveniles driven by latitude, mesoscale habitat complexity and habitat composition (coral cover); and (4) predicted abundance of surgeonfish and parrotfish spawners were highest on the islands of Maui and Molokai respectively, while surgeonfish juveniles were concentrated on Hawai'i Island, with juvenile parrotfishes being most abundant on Oahu. This study provides high-resolution, spatially-explicit information regarding fisheries production and supports managing the MHI at the archipelago scale.

COMPARATIVE REPRODUCTION AND GROWTH OF THE PARROTFISHES OF HAWAII: INPUT FOR MANAGEMENT REGULATIONS AND STOCK ASSESSMENT (Abstract ID: 27810)

Parrotfishes (Labridae, Scarinae) rank among the most economically important reef fishes in Hawaii and throughout the tropical Pacific. Many of these protogynous (female-first, sex-changing) fishes are also major habitat engineers of great ecological significance. Yet few data exist on their reproductive dynamics or vital rates in Hawaii or elsewhere. A single minimum body length (12 inches fork length) for the take of parrotfish ("uhu") is presently in effect in the State of Hawaii even though the multiple species contributing to the fishery differ in their fundamental life histories. For this reason we estimated body sizes at female sexual maturity and at sex change from female to male, plus growth rates and longevities, using specimens collected during 2005-2007 and 2012-2014 on Oahu, for the five major (of seven total) species of parrotfishes in the local fishery. Median sizes at maturity (from immature to adult female) differed greatly among the five major species, and sizes at sex change (from adult female to secondary male) were proportional to lengths at female maturity and estimated maximum lengths of the respective species. Growth rates and longevities likewise differed greatly among species but with less proportionality among species than did length-at-maturity and length-at-sex change. Changes in minimum size regulations, in concert with a slot-size limit that protects the largest individuals of both sexes, are suggested for the two largest, fishery-dominant species.

THE CONTRIBUTION OF DIFFERENT PHOTOTROPHIC ORGANISMS TO THE PRIMARY PRODUCTIVITY OF A CARIBBEAN CORAL REEF COMMUNITY (Abstract ID: 27782 | Poster ID: 279)

While many coral reef communities worldwide have shifted from coral to algal dominance, not much is known on whether these changes in community composition have affected the primary productivity of altered reef communities. Using 13C labeling, we quantified the primary production (PP) rates for several dominant benthic and planktonic autotrophs at 5 and 20 m depth on a typical modern Caribbean coral reef. Primary productivity per unit biomass (in mg C [g dry weight]-1 h-1) was lowest for corals (0.03-0.05), followed by macroalgae (0.41-1.89) and turf algae (0.82-1.68), and highest for benthic cyanobacteria (4.48-6.02). By combining taxon-specific PP rates with estimates of their area-specific biomass, we found that turf algae contributed most (>65%) to the total primary productivity of reef communities at 5 m depth. At 20 m depth, macroalgae and phytoplankton each contributed ~40% to the productivity of the entire reef community while the contribution of corals, turf algae and benthic cyanobacteria was <10%. Comparison of our findings to those of a similar study conducted at the same location 40 years ago shows that turf algae and macroalgae have replaced corals and crustose coralline algae as main contributors to the total productivity of Caribbean reef communities.

SELF-REPORTED BEHAVIOR, INTENTIONS AND CONTROL MEASURES OF SNORKELERS IN THE MOMBASA MARINE PARK-DO SNORKELERS DO WHAT THEY INTEND TO DO, AND SAY THEY DO? (Abstract ID: 29166 | Poster ID: 628)

Recreational marine resource use is conducted by a varied group of visitors. Regardless of how minimal this resource use is, or what intentions these visitors have, impacts on these resources are unavoidable. Management authorities of these resources need to know the extent of these impacts to further steer management towards protection of these resources. Traditional monitoring of visitors in the past has relied on self-reported behavior by visitors themselves. Self-reporting is not always accurate and cannot be relied upon. This study gathered data on snorkeler's intentions, attitudes, and perceived control to not damaging the coral reef when snorkelling. Furthermore, snorkelers were monitored to obtain actual snorkel behavior These snorkelers were then asked if they contacted the reef during their snorkel activity (the self-report measure for comparison). This research paper shows that even though snorkelers in the Mombasa Marine Park had intentions not to disturb the reef when they snorkel, and also indicated having positive attitudes about not disturbing the reef when they snorkel, they still created impacts on the reef. Furthermore, their self-reported behavior did not correspond with their actual monitored behavior. Monitoring snorkeler behavior is time-consuming and is therefore paired with financial investment, however, if this method is the most accurate method of gathering impact data to be used for management purposes, no other data collecting method should be considered, definitely not one that has been shown to be inaccurate (such as self-reported behavior).

FUNCTIONAL DIVERSITY OF THE REEF FISH FAUNA ALONG THE LATITUDINAL GRADIENT OF TAIWAN (Abstract ID: 28296 | Poster ID: 508)

The functional diversity (FD), i.e. the diversity of role in the biological communities, is a major determinant of the ecosystem resilience. For the global reef fish fauna, FD has been shown to be sensitive to species loss and a particularly good indicator of environmental disturbances. In Taiwan, reef fish fauna decreases from South to North correlated to the distribution of Sea Surface Temperature. We analyze how this latitudinal gradient affects the functional redundancy and vulnerability of reef fish communities around Taiwan. Ecological niches of 1,447 reef fish species were described using a combination of 6 functional traits known for influencing ecosystem processes. Most of traits values were obtained from database and others were allocated based on authors' knowledge of the species. The number of functional entities (FEs), the functional redundancy (FR), and functional vulnerability (FV) were derived from species richness in 3 regions spanned between 21.9°N and 25.3°N. Our first results show that the number of FEs decreases with increasing latitudes. It was accompanied by a decrease of FV and an erosion of FR. Together, it suggests that the functions provide by high latitude reef fish communities are less sensitive and could demonstrate higher resilience abilities than tropical ones. However, abrupt decrease of species recorded at some high-latitude sites along the last decade suggests that environmental modifications around Taiwan could even imperil the fewer highly redundant functional entities in those locations.

TYPHOONS AND THE MANAGED REEFS: IMPACTS AND RECOVERY PATTERNS OF REEF BENTHOS AND THEIR ASSOCIATED FISH ASSEMBLAGES (Abstract ID: 29295 | Poster ID: 417)

Super typhoon Bopha (Pablo) hit and devastated large areas in Southern Philippines in December 2012 profoundly affecting their associated reef areas. This study examined the impacts and recovery patterns of reef benthos and their associated fish assemblages in two Marine Protected Areas (MPAs) in Surigao del Sur. The benthic cover and their associated reef fishes were monitored 2 years before and 4 years after typhoon. Coral covers of both MPAs were affected after typhoon resulting to decline coral cover while dead coral with algae and rubble increased. Hard corals such as branching and foliose lifeforms were severely affected. Uba MPA had lower coral cover than Ayoke MPA potentially due to its exposure to wave action. Uba is more exposed while Ayoke is relatively sheltered. In addition, the abrupt decline in coral cover at Ayoke was exacerbated by Crown-of-Thorns outbreak. Fish species richness, abundance and biomass at both MPAs were not affected by the typhoon. In fact abundance and biomass increased despite of these disturbances. After 4 years, coral cover continued to decline with no

signs of coral recovery. Fish abundance and biomass continued to increase until the recent surveys. Increase can be attributed to the protection of the reefs where target or commercially important species contributed much of the increase. Herbivore biomass was also found to be increasing. Hence, protection is essential to increase resiliency from typhoons and other climate change-related disturbances, which are expected to be more frequent and severe in the future.

A VICIOUS CORAL REEF PREDATOR: MORPHOLOGICAL SPECIALIZATION BROADENS THE DIET OF A MANTIS SHRIMP (Abstract ID: 29795)

Mantis shrimp are ubiquitous predators in tropical coral reefs. "Smasher" mantis shrimp have specialized predatory appendages that produce among the fastest, most powerful strikes ever reported in the animal kingdom. These forceful strikes are particularly effective at breaking hard-shelled prey, such as snails and hermit crabs, and have a large impact on the abundances of these prey. However, some anecdotal observations suggest that smashers also consume soft-bodied, evasive prey. We examined the diet of a Caribbean coral reef flat smasher, *Neogonodactylus bredini*. We coupled studies of prey abundance in the field and feeding behavior experiments to inform a stable isotope analysis of diet using a Bayesian mixing model (MixSIAR). Unexpectedly, we found that soft-bodied prey, primarily fish but also worms and snapping shrimp, comprise a large proportion of the diet, in addition to clams, crabs, hermit crabs, and snails. This result held even when informative priors were constructed to reflect a specialist diet on hard-shelled prey and prey abundances in the field (30-50%, depending on the informative prior). Thus, counter to expectation, the specialized feeding morphology of *N. bredini* corresponds to a broad diet of both hard-shelled and soft-bodied prey. Despite their powerful punch, mantis shrimp are the major diet item of common reef animals. Given that they are very abundant and consumed by a diversity of larger predators, while also consuming many different prey themselves, *N. bredini* are likely an important link in coral reef food webs.

SPECIES-LEVEL VARIABILITY IN SUPEROXIDE PRODUCTION BY SYMBIOTIC CORALS (Abstract ID: 28193 | Poster ID: 107)

Superoxide, a reactive oxygen species (ROS), is both beneficial and detrimental to biological systems. In corals, superoxide has been implicated in bleaching, while also having a potential role in defense against pathogens. However, an understanding of the superoxide dynamics and sources within corals is currently missing due to a lack of direct *in situ* superoxide measurements. By conducting the first direct measurements of superoxide produced by corals on a natural reef during a bleaching event, we show substantial species-specific variation in external superoxide levels, which reflect the balance of production and degradation processes. *Porites lobata*,*Porites compressa*, *Pocillopora damicornis*, and *Fungia scutaria* maintained average external levels of superoxide that were approximately 100, 50, 20, and 2 nM above background seawater concentrations, respectively. However, superoxide levels adjacent to *Montipora capitata* were below levels present in the surrounding seawater, pointing to net degradation of superoxide and possible involvement of extracellular antioxidants. In all species, external superoxide levels were decoupled from the abundance of the photosynthetic endosymbiont *Symbiodinium*. However, aposymbiotic coral larvae and cultures of bacterial symbionts produced extracellular superoxide and may contribute to external superoxide levels. These results suggest potential species-specific roles for extracellular superoxide dynamics in the health, development and recruitment of symbiotic corals.

RESPONSE OF CORAL ASSOCIATED BACTERIA TOWARD THERMAL STRESS (Abstract ID: 27872 | Poster ID: 150)

The coral holobiont includes the coral animal, its dinoflagellate symbionts, and its associated microbial community. Symbionts complement the host genome by providing metabolic precursors that the coral itself cannot synthesize. In exchange, the host provides its symbionts with material that they can catabolize and feed into their own biosynthetic pathways. The inability to maintain these symbiotic interactions when challenged by an environmental stressor, such as increased sea surface temperature, leads to a decline in coral health that is observed as a rise in the incidence of coral bleaching and coral disease. In this study, we examine the effect of thermal stress on the natural microbial community associated with the outer mucus layer and tissues of the coral, Acropora digitifera. High-throughput sequencing of the 16S rRNA V4 hypervariable region revealed that prolonged exposure to thermal stress causes a shift in the diversity of the coral microbial community. Notably, there is an increase in the population of bacteria often found associated with diseased and stressed corals.These changes may correlate with shifts in the metabolic function of the coral holobiont and may have detrimental effects on the health and resilience of the coral. Taken together, our findings highlight the impact of elevated seawater temperature on the bacterial composition and diversity in corals and the effects of this on host metabolism.

THERMOTOLERANCE AND PHOTOACCLIMATION IN *SYMBIODINIUM*: PHYSIOLOGICAL AND TRANSCRIPTOMIC APPROACH OVER A TEMPORAL SCALE (Abstract ID: 30028)

We quantified thermotolerance in 11 cultures from different populations of five species of *Symbiodinium* clade A. We grew cultures at 26°C and 32°C over 18 days, measuring growth and photochemical efficiency (Fv/Fm). Thermotolerance was not restricted to a single species but it was widespread across species and cultures, showing a gradient from susceptible to tolerant. All cultures at 32°C decreased growth and Fv/Fm. To test the synergistic effect of temperature and light, we cultured three strains (tolerant, intermediate, and susceptible) in five different light intensities at 26°C and 32°C. Strains surviving stressful light and temperature exhibited less growth and quicker damage by light. To investigate the mechanisms behind thermoacclimation, we cultured *S. microadriaticum* (CassKB8) with intermediate thermotolerance at 26°C and 32°C. Gene expression was explored first using cDNA microarrays before (day -2), and during acclimation (day 6 & 16). Differentially expressed genes (DEG) due to increased temperature were time dependent. DEG on day 16 were likely a result of the start of the stationary phase in culture. Similarly, RNA-Seq data (day 5 and 7) suggest temporal variation in gene expression with major changes in heat-shock proteins and chaperones. Retrotransposons were highly expressed on day 7, indicating high stress during thermal exposure. Adaptation to higher temperatures is not restricted to a single clade or species but it is widespread within species. However, acclimating to higher temperatures compromises health and increases chaperone activity.

ENGAGING MILLENNIAL NON-SCIENTISTS IN CORAL REEF CONSERVATION THROUGH DIGITAL MEDIA STRATEGIES (Abstract ID: 30088 | Poster ID: 708)

Skandha is a project aimed at raising climate change awareness. Our focus is communicating science to the general public, particularly millennials, as they are digital natives well versed in the language of online media. In collaboration with more than 30 volunteers from different disciplines, Skandha has run several successful campaigns in Mexico City, including raising awareness of energy consumption, and organizing climate change talks with undergraduates. In an online campaign, we repurposed marketing techniques originally developed for commercial needs, and applied them in digital communication of climate science. With these methods, we designed a new digital communication strategy for the Mexican Coral Reef Society (SOMAC), using a Facebook fan page. In the first 3 months we reached more than 1,000 organic likes. In 6 months, 80 posts were published, reaching at least 1,300 people each, resulting in an average of 60 engagement actions per post. For each post in the fan page linked to the SOMAC website, daily visits increased 6-fold, with 86% being new users. The fan page audience is 91% Mexican,

and 78% of the audience belongs to the millennial generation (ages 18-34). Initial results demonstrate that using methods developed for commercial marketing can enhance climate science communication by encouraging social media engagement, leading to increased traffic to environmental organizations' web sites for further learning. Skandha is taking novel steps toward improving climate change awareness and preservation of Mexican coral reefs.

MACROALGAE AND CO2: EXPERIMENTAL APPROACHES TO UNDERSTANDING CABON-USE STRATEGIES AND COMPETITIVE MECHANISMS BETWEEN ALGAE AND CORALS (Abstract ID: 28677)

Understanding the drivers and mechanisms leading to increased macroalgal (seaweed) abundance in coral reefs is of critical importance. Human-induced ocean acidification (OA) due to elevated carbon dioxide (CO2) concentrations in seawater has been suggested to stimulate macroalgal growth and abundance on reefs. However, little is known about the physiological mechanisms by which reef macroalgae use CO2 or bicarbonate (HCO3-) from the bulk seawater for photosynthesis, or, what species could benefit from increased CO2 under OA. Also, previous experiments have suggested that elevated CO2 benefit macroalgae over corals in competitive interactions, contributing to reef degradation. However, the mechanisms used by algae to outcompete corals under elevated CO2 are unknown. In this talk, I will show how we are using experimental approaches to tackle these questions. For example, the use of carbon isotopes in macroalgae from the Great Barrier Reef (GBR) shows that algae have diverse carbon-use strategies granting them flexibility in the context of OA. Red and brown algae could potentially benefit from increased CO2 and GBR offshore reefs seem more sensitive to impacts of OA induced algal proliferation. Our experiments on how algae outcompete corals under OA show a variety of mechanisms including increased algal allelopathy, elevated algal DOC production and increased coral susceptibility to algal overgrowth. These experimental outcomes are providing key information to fill gaps in our understanding of the impacts of elevated CO2 on the ecology and resilience of coral reefs.

ARE MARINE SUTURE ZONES EVOLUTIONARY LABORATORIES? INSIGHTS FROM GENETIC STUDIES OF REEF FISH HYBRIDISATION (Abstract ID: 28609)

Closely related species can provide valuable insights into evolutionary processes through their ecology, distribution, and the history recorded in their genomes. In the Indo-Pacific, many reef fishes are divided into sister species in the Indian Ocean and Pacific Ocean, with a zone of overlap in the eastern Indian Ocean; this often leads to hybridisation between them. More recent work has characterised marine suture zones in the Western Indian Ocean and Pacific Ocean. The aim of this presentation is to review genetic studies of reef fish hybridisation in recognised suture zones, and address whether the patterns therein represents incomplete speciation, secondary contact, an evolutionary dead-end (for hybrids) or some combination of the above. Further comparison to studies in the terrestrial realm and the potential application of emerging genomic technologies are discussed.

THE CONTRIBUTIONS OF SOCIOECONOMIC MONITORING FOR CORAL REEF CONSERVATION IN THE US (Abstract ID: 28085)

NOAA's Coral Reef Conservation Program, in partnership with the National Centers for Coastal Ocean Science, is leading an effort to incorporate social and economic monitoring into a new, integrated national monitoring plan for US coral reef jurisdictions. The National Coral Reef Monitoring Program includes three components: biological, climate, and socioeconomic. The socioeconomic component includes gathering information on population change, use of coral reef resources, and knowledge, attitudes, and perceptions of coral reef resources and management. The overall goal of the socioeconomic monitoring is to track relevant social and economic information for each jurisdiction in order to investigate the impacts of society on coral reefs and the contributions of healthy corals to nearby communities. Data collection is complete for South Florida, Puerto Rico, American Samoa, and Hawaii, while efforts in Guam, the Commonwealth of Northern Mariana Islands, and the US Virgin Islands are in development. The three data streams, biological, climate and socioeconomic, are intended to be combined into a single comprehensive monitoring program for the coral reef ecosystem. As a first step towards integration, the data will be analyzed and scored through the use of indicators in a report card for each jurisdiction. Future steps might include using the data to: understand gaps between actual and perceived resource condition, predict the populations most likely to engage in pro-environmental behaviors, and assess the importance of reef species to the provision of food and livelihoods.

DERMAL DENTICLES AS A TOOL TO RECONSTRUCT HISTORICAL SHARK COMMUNITIES (Abstract ID: 28658)

What were shark communities like before humans? Ecological surveys and historical records demonstrate significant declines in Caribbean shark populations, yet pre-exploitation baselines are nonexistent. Fossilized dermal denticles – tiny, tooth-like scales lining the skin of elasmobranchs – may offer insight into pre-human shark communities on reefs. Denticles are well-preserved in fossil reef sediments, but their identification represents a major challenge. We built a large reference collection from museum and local collections comprising 215 denticles from 37 species within 16 families. Morphometric analysis revealed that denticle morphology is loosely tied to clade, making species-level identification impossible. We found, however, that denticle traits are strongly correlated with life habit and feeding mode. Fast, predatory sharks possess thin, ridged 'drag reduction' denticles, whereas demersal sharks, such as nurse sharks, are characterized by thick 'abrasion strength' denticles. We extracted 254 denticles from a 7,000-year-old fossil reef and 602 denticles from comparable modern reefs in Bocas del Toro, Panama and classified them using the reference collection. Both denticle assemblages corresponded well with families documented in the region. Preliminary data showed a significant decrease in the relative abundance of 'drag reduction' denticles and an increase in 'abrasion strength' denticles over the past ~7,000 years. This suggests that, irrespective of changes in the number of sharks, an important shift in shark community composition has occurred.

UNDERSTANDING THE TAXONOMY OF THE MESOPHOTIC CORAL GENUS LEPTOSERIS: THE NEXT CHAPTER (Abstract ID: 28274 | Poster ID: 339)

Growing interest in mesophotic coral reef ecosystems (MCEs) has stimulated interest in the taxonomy and biology of mesophotic corals. A key example is the agariciid genus Leptoseris which is often a dominant coral in MCEs. Historically, Leptoseris has not been well represented in museum collections, and despite the systematic review of Leptoseris by Dinesen (1980), from a taxonomic perspective it has not been widely studied. However, advances in molecular techniques and integrated systematic approaches, combining molecular and micro-morphological studies with traditional macro-morphological approaches, have enabled new insights into Leptoseris. This integrated taxonomic approach has certainly facilitated understanding of mesophotic agariciid corals such as species of Leptoseris and Pavona in Hawai'i (Luck et al. 2013). However, there have been challenges in reconciling traditional morphological characters with the results of molecular genetic analysis for Leptoseris from other geographic areas. Recent research has also highlighted the importance of access to original type material to resolve key taxonomic questions, such as with L. fragilis, the type species of the genus Leptoseris. Here we provide an update on progress in unravelling the taxonomic status of Leptoseris species, in light of the latest research and following the rediscovery of the three syntypes of L. fragilis.

GENOMIC INSIGHT INTO HOST-ENDOSYMBIONT RELATIONSHIP OF ENDOZOICOMONAS MONTIPORAE CL-33T WITH ITS CORAL HOST (Abstract ID: 29147)

The bacteria Endozoicomonas are commonly detected in healthy corals in coral associated bacteria studies. They are likely to be a core member of coral microbiota, however, little is known about their roles inside corals. To decipher interactions between the bacteria and their coral hosts, we conducted genomic and physiological approaches on the first culturable Endozoicomonas isolated from the coral, E. montiporae. The genome (5.43Mb, 99.8% in completeness) revealed abundant mobile elements than the other Endozoicomonas species. A number of genes potentially related to bacteria-host interactions were identified. Testosterone degrading genes and type III secretion system were commonly present in Endozoicomonas species and that might assist to recognize or deliver effectors to their hosts. Several secreted eukaryotic domain proteins identified, such as myosin-tail domain protein and serine/threonine protein kinases, suggesting this bacterium may modulate its host's signaling pathways and vesicle trafficking. Moreover, the genes of eukaryotic ephrin ligand B2 were surprisingly found in its genome, inferring that the bacterium could enter coral cells by endocytosis via binding to host's Eph receptors. In addition, some T3SS effectors encoded by the bacterium, such as 7,8-dihydro-8-oxoguanine triphosphatase and isocitrate lyase, might prevent mitochondria dysfunction and aid gluconeogenesis efficiency, especially under stress. All those findings suggest that E. montiporae would be a facultative endosymbiont who can recognize, translocate, communicate and modulate its coral host.

PARTICIPATORY MAPPING: TOOLS FOR INTEGRATING LOCAL KNOWLEDGE INTO MARINE PLANNING (Abstract ID: 28072)

Coastal communities harbor a wealth of social knowledge about their ocean spaces that can lend critical insight to marine planning and MPA design and management. Participatory mapping is an evolving tool that combines traditional stakeholder engagement strategies with GIS techniques to capture and transform place-based knowledge into socio-spatial planning information. When integrated with conventional marine planning strategies, participatory mapping works to translate social perspectives about the ocean and coast into a spatial context while providing a forum for sharing opinions, historical perspectives and perceptions about potential social or ecological impacts of proposed planning strategies. NOAA's Marine Protected Areas Center has designed a participatory mapping strategy to engage marine communities in the documentation of social knowledge to inform a wide range of marine planning efforts. This flexible process has been applied at varying scales and with a wide range of partners and funding scenarios, all with the intent of gathering community perspectives while building relationships and local trust and support for developing marine plans. Participatory mapping promotes collaborative planning, giving communities a voice throughout the decision-making process while yielding valuable, spatial human dimensions information. This presentation will highlight NOAA's participatory mapping efforts, discuss the tools and techniques, and share common challenges and solutions for planning and implementing participatory mapping efforts for marine planning and management.

RESPONSE OF FISH AND SNAIL CORALLIVORES TO AN OUTBREAK OF ACUTE TISSUE LOSS DISEASE ON THE REEFS OF VAAN ISLAND IN THE GULF OF MANNAR, INDIA (Abstract ID: 28496)

Outbreaks of tissue loss diseases in corals are becoming more common resulting in direct colony mortality and also affecting the animals that depend on corals for food and shelter. We documented an outbreak of an acute tissue loss disease on a reef in the Gulf of Mannar, India and compared the density of fish and snail corallivores in the outbreak area to an adjacent control area. Line-intercept on three transects within each area (outbreak and control) found both areas dominated by the coral, *Montipora digitata*. In the outbreak area, an average of 50% of the *M. digitata* cover was affected by acute tissue loss as compared to 0.33% in the control area. This is the first report of a disease outbreak on the reefs in the Gulf of Mannar. Coral-feeding butterfly fish were observed feeding directly on diseased coral tissue in the affected area but belt transects found the density of butterflyfish to be similar between the outbreak and control area. In contrast, drupellid snails were also observed feeding on disease margins of affected colonies but densities were significantly higher in the outbreak area (avg. 2.2±0.9 snails/m2 coral) as compared to the control area (avg. 0.003±0.001 snails/m2 coral). Drupellids are attracted to damaged coral tissue and our findings suggest that it is likely that snails actively migrated into the affected reef area and were taking advantage of the dying coral tissue. Our observations add further evidence to the potential importance of corallivores on disease processes.

PREDATOR-PREY INTERACTIONS ON CORAL VS ALGAL DOMINATED REEFS: BEHAVIORAL PLASTICITY AND SURVIVORSHIP OF JUVENILE FISHES (Abstract ID: 27906)

Many healthy reefs dominated by corals have transitioned to degraded reefs dominated by seaweeds. Impact of this phase shift on the behavior and survivorship of coral reef fishes is poorly understood, but could affect survival of recruits and export of juveniles from healthy to degraded locations where fishes could enhance reef resilience and recovery. Using experimental patch reefs in pairs of adjacent healthy (MPAs) and degraded (non-MPAs) reefs, we identified between-habitat differences in predators, patterns of attack, and prey behaviors that affect survival in these divergent habitats. Primary predators in MPAs were rapidly moving wrasses attacking from above; prey here selectively used higher portions of the reefs to visually monitor predators. Conversely, predators in seaweed dominated, non-MPAs were sit-and-wait predators that ambushed upward from the benthos. Prey here selectively used lower portions of reefs where they could presumably better detect chemical cues from sit-and-wait predators. In both situations, prey seemed selected to detect, rather than spatially avoid, predators. Prey fishes reciprocally moved from MPA to non-MPA, or vice versa, experienced a 3-16 fold increase in mortality compared to fishes relocated within their initial habitat. Prey that survived relocation adjusted behaviors to match fishes naturally found within the new habitat. Our findings suggest that habitat quality, predator community composition, and prey behaviors interact to affect prey survival, and that prey behavior is dynamic and crucial as reefs under-go regime shifts

*TRIPNEUSTES GRATILLA* AS A POTENTIAL DISPERSAL AGENT OF THE CORAL *MONTIPORA DIGITATA* IN BOLINAO, PANGASINAN, PHILIPPINES (Abstract ID: 29894 | Poster ID: 196)

*Montipora digitata* propagates primarily by fragmentation and occurs in isolated yet extensive patches in sandy, shallow reef flats in the northwestern Philippines. The sea urchin *Tripneustes gratilla*, also common in these areas, is known to pick up fragments of rock and algae to conceal itself in the sandy habitat. This study tests if sea urchins can act as dispersal agents of coral fragments by determining whether *T. gratilla* can potentially pick up live corals when presented with live and dead coral fragments, measuring the distance travelled by urchins carrying different sized fragments, monitoring the short-term survivorship of coral fragments after deposition on the unconsolidated substrate, and test tissue histocompatibility among established colonies within the same coral patch. Results suggest that, although *T. gratilla* picked up dead coral fragments more frequently (61%) than live ones (39%) ($X^2$ test, $p<0.05$), it had no particular aversion to picking up live corals. The distances travelled by the sea urchin while carrying coral fragments were not significantly different with respect to fragment size (ANOVA, $p>0.05$). The survival experiment showed that *M. digitata* fragments of different sized survived and continued to grow during the 2-month observation. Fragments from different colonies in the same patches exhibited tissue fusion indicating that growing, established coral colonies tested may have the same colony origin. These results indicate that mobile macrofauna may be crucial in the successful establishment of sessile, clonal organisms such as corals in physically unstable reef areas.

RECOVERY OF MONTIPORA CAPITATA AND PORITES COMPRESSA FROM BLEACHING UNDER OCEAN ACIDIFICATION CONDITIONS (Abstract ID: 29624)

We experimentally investigated the effects of pCO2 (ambient, 364 micro atm vs. elevated, 750 micro atm) and feeding (fed zooplankton vs. not fed) on the recovery of M. capitata and P. compressa from bleaching over one year to test the following hypotheses: 1) ocean acidification (OA) increases recovery time from bleaching, and

2) zooplankton feeding enhances the rate of recovery from bleaching. Preliminary data shows that chlorophyll a was lower in bleached corals than non-bleached corals initially, but no longer differed after 7 months independent of pCO2 or feeding in both species. However, mortality rates were higher for P. compressa than M. capitata over the course of the experiment. Zooplankton feeding did mitigate the negative effects of OA on P:R in both species despite the overall feeding rates being depressed under OA conditions after 7 months of exposure. The maintenance of biomass across all treatments and species suggests that any negative effects of OA on coral recovery from bleaching might be minimal. Overall, our results to date suggest that zooplankton feeding does play a role in mediating elevated pCO2 during recovery from bleaching, but there is yet no clear pattern of the effects of OA on recovery rates. Additional data, including carbon budgets over the course of the year-long experiment, will be presented. This research will provide new insights in understanding the factors that allow certain corals to recover more quickly from bleaching in an increasingly acidic ocean, providing a tool for identifying coral resilience traits.

INVESTIGATING POPULATION GENETICS OF THE SCLERACTINIAN CORAL, *MONTASTRAEA CAVERNOSA*, ALONG THE FLORIDA CORAL REEF TRACT'S NORTHERN EXTENT (Abstract ID: 29063 | Poster ID: 317)

Coral reef populations on Florida's central east coast are located at unique boundaries that are susceptible to many anthropogenic influences including controlled freshwater discharge and agricultural runoff. Natural environmental variability is relatively high as a result of seasonal rainfall and upwelling patterns. Neither coral spawning nor gamete development have been observed at the northern end of the Florida Coral Reef Tract, therefore we hypothesize that this region may represent a population sink for many coral species. To better understand coral population connectivity of reefs in Southeast Florida, populations of the scleractinian coral*Montastraea cavernosa* were examined. This species' wide geographic distribution throughout the Tropical Western Atlantic and broad depth range from 3 to 100 meter depths allow comparisons of both horizontal and vertical connectivity. However, few investigations of this species have focused on southeast Florida. Saint Lucie Reef near Stuart and Breakers Reef near Palm Beach represent the upper latitudinal limits for many scleractinian coral species along the Florida Coral Reef Tract. This study aims to compare microsatellite genetic markers from these reefs to understand their connectivity and determine influences of the Florida current on dispersal, recruitment, and population structure.

INFLUENCE OF ECOSYSTEM COMPONENTS ON QUEEN CONCH POPULATION DENSITIES IN A MARINE PROTECTED AREA IN ST. CROIX, U.S. VIRGIN ISLANDS (Abstract ID: 29788)

The queen conch is one of the most highly valued fishery resources in the Caribbean, but populations throughout its range have declined severely, and available data are insufficient for conducting traditional stock assessments. In most areas, it has been difficult to equally judge the effects of both traditional and spatial management measures. To address this deficiency, we conducted stratified fishery-independent surveys of queen conch in St. Croix, U.S. Virgin Islands, generating habitat-based density data. Regression tree analyses were used to identify relationships between conch densities and measured ecosystem variables. Habitat type was the strongest predictor of juvenile densities, followed by management zone (marine protected area versus open fishing area), and water depth. The model predicted that the highest densities of juveniles would be found in patchy (30-50% cover) and continuous seagrass within the marine protected area in 11-15 m of water (2178 per hectare). Adult densities were predicted to be highest (523 per hectare) across several different habitat types, at depths between 21-30 m also within the marine reserve. This method of extrapolating population densities incorporating multiple ecosystem components represents an innovative approach for assessing the status of this data-limited species. It provides a robust means to evaluate performance of marine spatial protection and can identify key habitat and ecosystem characteristics deserving of additional management consideration.

OBSERVATIONS ON CONTROLLING CROWN-OF-THORNS STARFISH OUTBREAKS BY INJECTION (Abstract ID: 30106)

In 2012, users of the Great Barrier Reef Marine Park began to report numerous outbreaks of the Crown-of-Thorns Starfish (CoTS) on mid-shelf reefs between Cairns and Lizard Island signalling the start of the fourth major eruption of this native pest since the 1960s. In the same year, the Association of Marine Parks Tourism Operators (AMPTO) mobilised funds from the Australian Government and began a program of diver-based hand control that has since killed over 400,000 starfish by injection. Despite efficiency gains from adopting a more effective inoculant than the one available to past control programs and field reports on starfish relative abundance coming from a dedicated surveillance program of unprecedented resolution, the first year of the AMPTO program was able to cull <10% of the large starfish estimated to exist in the outbreak domain. The control program has since contracted to the local defence of reefs critical to the dive tourism market; a scale at which hand control has proven effective at maintaining coral cover. The failed attempt at population-scale control yields insights into the dynamics of these mass eruptions on the GBR and suggests that a different strategy should be attempted to suppress or delay a fifth cycle of outbreaks.

DEVELOPMENT OF ACOUSTIC METHODS TO INVESTIGATE HAWAIIAN SEMI-DEMERSAL FISH DISTRIBUTION AND ABUNDANCE FOR MONITORING STOCKS (Abstract ID: 27965)

Presently, only fisheries-dependent methods are used for stock assessment and management of six economically important Hawaiian snapper species and an endemic grouper (collectively known as 'Deep-7'). Active acoustic methods have been successfully employed for stock assessment of semi-demersal fish in non-trawlable regions elsewhere and have potential advantages over the current assessment methods. Acoustic backscatter data and complementary methodologies involving target strength (TS) measurements of tethered fish, video-camera observations, and fishing were used to model TS and develop acoustic descriptors such as aggregation shape, size, and density, individual swimming pattern, distance from bottom, and bottom depth for Deep-7 species. Paired observations of in situ TS and fork length (FL) gave an estimated TS-FL relationship for Deep-7 species: $23.01 \cdot \log_{10}(FL)$-72.18. Acoustic data indicated high spatiotemporal variability, with higher number of detections during daytime than at night. Most Deep-7 fish were found between 110 and 330 m depths, within 50 m of the bottom, with both tightly aggregated and loosely grouped fish contributing significantly to biomass and abundance. While results are preliminary, they indicate that acoustics could be successfully used to monitor Deep-7 stocks in Hawaii. Abundance and biomass estimates can be improved by fine tuning acoustic descriptors using additional data and improving biomass estimates in the deadzone.

TRANSGENERATIONAL PLASTICITY DEPENDS ON RATE OF WARMING ACROSS GENERATIONS (Abstract ID: 28001)

Predicting the impacts of climate change to biological systems relies on an understanding of the ability for species to acclimate to the projected environmental change through phenotypic plasticity. Determining the effects of higher temperatures on individual performance is made more complex by the potential for environmental conditions experienced in previous and current generations to independently affect phenotypic responses to high temperatures. We used a model coral reef fish to investigate the influence of thermal conditions experienced by adult breeding pairs and their parents on reproductive output and the quality of offspring produced. We found that more gradual warming over two generations resulted in greater plasticity of reproductive attributes, compared to fish that experienced the same increase in one generation. When fish experienced +3.0 °C experienced for two generations reproduction ceased in the expected future summer conditions (31.5 °C). Additionally, we found that transgenerational plasticity to +1.5 °C induced full restoration of previously thermally effect reproductive and offspring attributes, which was not possible with developmental plasticity alone. Our results suggest that transgenerational effects differ depending on the absolute thermal change and during what life stage the thermal change is experienced.

A NEW, HIGH-RESOLUTION GLOBAL MASS CORAL BLEACHING DATABASE (Abstract ID: 28000)

Episodes of mass coral bleaching have been reported in recent decades and have raised concerns about the future of coral reefs on a warming planet. Despite the efforts to enhance and coordinate coral reef monitoring within and across countries, our knowledge of the geographic extent of mass coral bleaching over the past few decades is incomplete. Existing databases like Reefbase are biased by their voluntary nature and the location of prominent science and/or monitoring programs, thus creating a problem

of false negatives. The spatial extent of reported bleaching events is also unclear, as bleaching is reported as a point event (i.e. lat/long coordinates of the field survey). In this project, we have developed the first-ever gridded, global-scale historical coral bleaching database. First, we conducted a targeted search for bleaching reports not included in Reefbase by surveying the academic and grey literature and by personally contacting scientists and divers conducting monitoring in under-reported locations. This search increased the number of observed bleaching reports by 79%, from 4146 to 7429 (through the year 2012). Second, we employed spatially interpolation, using techniques borrowed from species distribution modelling, to develop annual 4 km x 4 km global maps of the probability that bleaching occurred. The database will help the scientific community more accurately assess the change in the frequency of mass coral bleaching events, validate methods of predicting mass coral bleaching, and test whether coral reefs are adjusting to rising ocean temperatures

ECOSYSTEM REGIMES AND RESILIENCE OF HAWAIIAN CORAL REEFS (Abstract ID: 29152)

Coral reefs worldwide face an uncertain future with many reefs transitioning from cover dominated by coral to algae. This binary view of coral reefs is limited in that it does not consider the underlying processes and complexities of the ecosystem that might relate to the resilience of coral or macroalgal dominated states. This study utilized a large database synthesized from multiple sources by collaborating with various monitoring programs and stakeholders, allowing analysis at a scale commensurate with ecosystem- and resilience-based management in the Hawaiian Islands. To better describe coral reef ecosystems in terms of the communities that compose them, fish and benthic assemblages were considered together to define reef regimes. Model-based clustering revealed five distinct regimes that were then mapped to understand the spatial distribution and variation across the Hawaiian Islands. With this nuanced perspective of coral reefs, we identified a regime that was classified by low coral and low macroalgae but high fish biomass, and what was previously considered a single coral regime was broken into several regimes that varied in their ecology and relative resilience to human drivers. This project was co-developed with state and federal agencies, NGOs, and community groups to build partnerships for practical implementation of ecosystem-based management by utilizing monitoring data to understand the effects of human drivers on coral reef ecosystems.

CONTRASTING EFFECTS OF EPIPHYTES ON CALCIFYING VS. NON-CALCIFYING ALGAE IN CLIMATE CHANGE SCENARIOS (Abstract ID: 29159 | Poster ID: 39)

Large benthic foraminifera (LBFs) are vital producers of calcium carbonate, and commonly live as epiphytes on marine algae. Marine algae have large diffusive boundary layers, elevating pH around the algae during daytime photosynthesis. Effects of changing ocean temperature and chemistry on LBFs as epiphytes are unknown. Two macroalgae (a calcifying green algae*Halimeda tuna*, and a non-calcifying red algae *Laurencia intricata*) were incubated with a common epiphytic LBF, *Marginopora vertebralis* in current and future conditions of ocean acidification and warming for 15 days. Increased bleaching of *H. tuna* occured in elevated temperature and acidification when no epiphytes were present, while *M. vertebralis* was resilient to near future conditions. Calcification and growth of *H tuna*decreased in the high temperature and acidification treatment, while those exposed with LBFs were more resilient. Calcification of *M. vertebralis*decreased with increased temperatures, but association with *L. intricata*ameliorated negative effects. Individually, elevated temperature decreased in growth of *L. intricata*, while pH decreased growth of *M. vertebralis*. Incubation together ameliorated these negative effects. Results indicate that in a changing climate, epiphytic LBFs are particularly important to survival of calcifying macroalgae. In contrast, LBFs can benefit from elevated daytime pH conditions in the microenviroment of a non-calcifying macroalgae, ameliorating impacts of climate change.

PREDICTING CORAL GROWTH (Abstract ID: 29283 | Poster ID: 510)

Predicting reef coral demographic rates is a critical part of forecasting the future of reefs under global change. This is challenging for highly diverse communities such as coral reefs, where a species by species approach is logistically unfeasible. A potential solution is to predict demographic rates from species traits. Here, we test this approach to predict coral growth rates. We ask whether most variation in coral growth rates occurs at the species level, morphological group level or at individual level through time. We estimate growth as change in planar area for 11 species of scleractinian corals, across five morphological groups (tabular, branching, digitate, corymbose and massive), and over five years. We show that coral growth scales with size according to a universal power law (that is the power law exponent is constant across species and morphological groups). Coral growth rates are best predicted from colony size and morphology rather than species. However, annual variation in growth rates is greater than variation among morphological groups, with slow growing morphological groups (massive and digitate) having more stable growth rates than faster growing morphological groups (tabular and branching). Finally, we show that colonial corals have pseudo-determinate growth: on average coral colonies stop growing at a certain size, which varies with morphological group. Colony size and morphological group are the most important predictors of coral growth rates.

DISTURBANCE MEDIATED ECOLOGICAL TRADE-OFFS DURING CORAL RECRUITMENT (Abstract ID: 28900)

In 1977, Peter Grubb proposed the theory of the regeneration niche: defining the environmental conditions that allow new individuals to colonise an area successfully and become established in the local population. By doing so, ontogenetic trade-offs can be quantified and the recruitment of individuals predicted under multiple scenarios of biophysical forcing. Here, I present the findings of a two-year study in which we combined field observations with laboratory and field experiments to parameterise an individual-based model aimed at developing a mechanistic understanding of the ecological trade-offs that occur during coral recruitment. The investigation focuses on the individual processes involved in recruitment – beginning at larval settlement and continuing until recruitment bottlenecks are surpassed – and incorporates the microhabitat complexity that is key in understanding benthic recruitment. Our results demonstrate that coral settlement is higher in crevices than exposed microhabitats, but post-settlement bottlenecks differ markedly in the presence and absence of predators. Maximum recruitment occurs in crevice microhabitats of uncaged treatments, being 9-fold higher than caged treatments. Overall, we uncover the trade-offs between growth, competition and predation, highlighting how these change and even reverse during ontogeny and under alternate disturbance regimes.

A HIGH-RESOLUTION CHARACTERIZATION OF SYMBIODINIUM COMMUNITIES ALONG A DEPTH GRADIENT IN THE REEF-BUILDING CORAL SIDERASTREA SIDEREA (Abstract ID: 29615 | Poster ID: 128)

The relationship between corals and their endosymbiotic dinoflagellates, Symbiodinium, is a dynamic yet fragile symbiosis. Understanding the flexibility of this symbiosis is central to predicting the long-term response of corals to climate change. Previous studies have shown corals exhibit different patterns of Symbiodinium community composition between areas of varied susceptibility to environmental fluctuation, such as in shallow versus deeper reefs. Until recently, studies used cloning or electrophoresis-based techniques that are prone to underestimates of diversity. This study applies next-generation sequencing to assess Symbiodinium community composition within the same coral species at different depths. We analyzed the Symbiodinium communities within Siderastrea siderea colonies collected in the Florida Middle Keys reefs at three depths: 11, 18, and 27 m. Symbiodinium community composition was determined using Illumina paired-end sequencing of the cp23S rDNA region. We identified a strikingly diverse Symbiodinium community in S. siderea, comprising multiple types from clades A, B, C, and D. Further, our results demonstrate clear differences in Symbiodinium diversity in S. siderea across depths. S. siderea colonies at shallow and medium depths possessed similar Symbiodinium communities that were in stark contrast to their deeper counterparts. Overall, we provide a considerably more intricate view of the flexibility and specificity of the coral-algal symbiosis across areas with varying degrees of exposure to environmental variability.

INSIGHTS INTO THE EFFECTS OF TEMPERATURE AND/OR ACIDIFICATION ON CORAL REEF ECOSYSTEMS (Abstract ID: 28119)

Coral Reefs are expected to experience reduced rates of calcification in response to projected ocean warming and acidification. The actual impact of different future scenarios, given as representative carbon pathways (RCP), or the separate impacts of ocean warming and acidification on coral reef calcification need to be quantified if we are to correctly assess the long term costs of different pathways and actions to the maintenance of essential ecosystem services such as coastal protection. In the present study, we determined whole system calcification rates for mini reefs reconstructed from the principal components of a southern Great Barrier Reef fore-reef over annual periods that included natural daily and seasonal variability. The results showed that: (i) under present day scenarios, reefs calcified 3-fold faster in summer than in winter; (ii) reefs failed to calcify over the long-term under RCP4.5 and were in a state of decalcification under RCP8.5, with the principal difference between RCP4.5 and RCP8.5 associated with the level of decalcification occurring at night rather than differences in daytime calcification rates; (iii) RCP8.5 warming decreased reef calcification rate as a result of coral mortality and increased microbial sediment abundance, whereas RCP8.5 acidification decreased reef calcification by increasing decalcification in the dark. The results present empirical support for the consensus that CO2 emissions must be curtailed, but also suggests that the negative impact of acidification on the carbonate balance of reefs predominantly occurs at night.

A CNIDARIAN-SPECIFIC IONOTROPIC GLUTAMATE RECEPTOR LINEAGE FUNCTIONALLY INVOLVED IN IMMUNITY (Abstract ID: 28405)

Cnidarians perceive their environment and respond through their innate immune system by recognizing ligands and molecular patterns. Transcriptional evidence underlying immune priming by recurrent bacterial challenges within the anemone, *Exaiptasia pallida* identified an ionotropic glutamate receptor (iGluR) as a highly differentiated protein among immune challenged anemones. iGluRs are transmembrane ion channels involved in invertebrate chemosensing and plant iGluR-homologs are implicated in sensing pathogen- and damage-associated molecular patterns (PAMPs, DAMPs) that act together for hosts to differentiate pathogenic-damaging microbes from beneficial or harmless microbes. To infer the evolution and characterize the molecular function of a proposed cnidarian-specific iGluR, phylogenetic analyses were conducted using the full coding gene. Results indicate *E. pallida* iGluR ligand-binding domain is not specific to classical synaptic-involved NMDA, kainate, or AMPA ligands. *In silico* analysis identified potential ligands for *E. pallida* iGluR, then verified by functional response. These findings support the hypothesis that *E. pallida* iGluR belongs to a cnidarian-specific expansion within the phylogeny of iGluRs, and has retained molecular characteristics to respond to chemical stimuli. Based on this, we postulate that iGluRs may mediate PAMP-triggered immunity via calcium channels by pattern-recognition particles. These findings provide the foundation for further functional analysis to understand the role of cnidarian iGluRs.

PERSONAL CARE PRODUCT POLLUTION ON CORAL REEFS: TOXICOLOGY AND CONTAMINATION OF UV SUNSCREENS, PRESERVATIVES, PLASTIC MICROSPHERES AND OTHER INGREDIENTS (Abstract ID: 29544)

Chemicals from personal care products (e.g., sunscreen lotions, shampoos, soaps) can enter coral reef either through swimmers, or predominantly as sewage effluent. The impact of these chemicals is only now beginning to be discovered. We show the toxic effects to coral, sea urchin embryos, shrimp larvae, and fish larvae exposed to preservatives (e.g., parabens, ethoxyethanol), UV absorbers (e.g., methoxycinnamate, camphor), and different types of microspheres (plastic, castor bean, cellulose). We also show levels of these ingredients in waters of coral reef environments, as well as in corals themselves. We provide a risk assessment as to the threat these ingredients pose to coral reefs. We provide a number of options that local communities, businesses, management agencies, and legislators can implement that will mitigate this source of pollution.

IN-SITU MEASUREMENTS OF SOLAR EXPOSURE DISTRIBUTION ON A CORAL REEF: PRELIMINARY FINDINGS RELATING TO REEF ASPECT, WATER TURBIDITY AND DOSIMETER DESIGN (Abstract ID: 28454 | Poster ID: 545)

Thin film dosimeters have been used for the measurement of solar radiation since the 1970s. Their application includes personal exposure measurement and environmental exposure monitoring. Polyphenylene oxide (PPO) films have recently been developed for use in various underwater environments. These dosimeters are capable of measuring solar ultraviolet-B (UVB, 290 – 315 nm), which is a recognized physical stressor of corals when combined with elevated water temperatures occurring within the irregular structure of a coral reef. We present preliminary findings employing a newly developed PPO dosimeter clamp deployed upon reef building corals situated within turbid inshore waters of the Great Sandy Marine Park, Southern Queensland, Australia. UVB exposures measured over a 24 hour period during peak summer exposure conditions ranged from 12.11 kJ $m^{-2}$ to 21.13 kJ $m^{-2}$. This preliminary data showed a clear dependence on reef aspect with the highest exposures incident upon north facing (Southern Hemisphere) reef surfaces. We conclude that exposure stress to corals may still occur in shallow turbid water with UVB exposure being strongly associated with reef aspect.

THE THREAT OF BOAT ANTIFOULANT PAINTS TO CORAL REEFS: PERMENANT MOORING AND ANCHORING SITES AS A SIGNIFICANT SOURCE OF LOCALIZED CORAL REEF DEGRADATION (Abstract ID: 29605 | Poster ID: 465)

Reports have accrued from all over the world for the past 15 years regarding a zone of mortality and degradation regarding permanent moorings for small boats (less than 30 meters), usually the length of the mooring line. We conducted a two phase investigation. The first phase examined the ecotoxicological effects of two major antifoulant ingredients (cuprous oxide, tributyltin) on major coral reef ecological receptors, including sea urchin embryos (Tripneustes gratilla & Tripneustes ventricosus), coral larvae, adult coral, shrimp larvae, and fish larvae (Pseudochromis fridmani, Orchid Dottyback). Cuprous oxide is much more toxic than ionic copper. Nanoparticles of Cu2O (~10 nanometer) were about an order of magnitude more toxic than micro-particles (~30 micrometer). The second phase was an examination of the level of toxicity and contamination of several coral reef sites that contained or had nearby permanent mooring sites. Porewater toxicity and Toxicity Identification Evaluation indicated that over 90% of the toxicity resulted from the two major antifoulant ingredients. Antifoulant paint from small water craft poses a serious threat to coral reefs. Active management of antifoulant paint, small water craft and environmental mooring buoys is necessary to mitigate the damage done to reefs.

BUILDING MARINE PROTECTED AREA MANAGEMENT CAPACITY AT PRIORITY CORAL REEF SITES IN THE CARIBBEAN REGION (Abstract ID: 29559)

Over the past five years, a successful capacity building partnership has been established between 30 ecologically-connected marine protected areas (MPAs) in the wider Caribbean region, NOAA's Coral Reef Conservation Program and the Gulf and Caribbean

Fisheries Institute. The initiative began with the selection of 10 Caribbean countries to participate in an assessment of MPA management capacity. The assessment applied a new tool for a guided self-evaluation of management capacity by MPA managers covering 25 aspects of MPA management and systematically assessing capacity on a three-tiered scale. Our approach to capacity building has been to facilitate peer to peer learning, strategically targeting the highest priority management needs identified in the capacity assessment. We have formed a learning network of MPA managers and professionals to address needs identified by each MPA through a variety of means, including regional peer to peer workshops, direct technical support, site to site learning exchanges and competitive grants. To date, the partnership has addressed sustainable financing, enforcement, strategic management planning and implementation, outreach and communications, and socio-economic monitoring, while establishing a close-knit network between coral reef MPA managers and organizations with MPA management expertise. Exchanges between the Caribbean and Pacific, and cooperation with other donors and expert partners, have been effective in further building capacity. Site-specific follow-up is helping MPAs increase their management capacity on top priority needs.

THE INFLUENCE OF CO2 ON CALCIFICATION IN CORAL CELL CULTURES (Abstract ID: 29534)

Understanding the cellular and molecular responses of stony corals to ocean acidification is key to predicting their ability to maintain calcification under high CO2 conditions. Biomineralization toolkit proteins have been proposed for several corals and elucidating the connection between expression of these genes and calcification will allow a better understanding of their roles in the mineralization process. We analyzed cell cultures of the stony coral, Stylophora pistillata, by microscopy, qPCR, western blot, and mass spectrometry to test the effects of increased CO2 on the calcification process at the cellular and molecular levels. S. pistillata cells grown at low (400 ppm) and moderate (700 ppm) CO2 re-aggregate into proto-polyps and precipitate CaCO3. When grown at high and very high CO2, (1000 and 2000 ppm, respectively) S. pistillata cells up-regulate genes for several highly acidic proteins as well as a carbonic anhydrase, but down-regulate longterm cadherin protein production and minimize proto-polyp formation; this coincides with a significant decline in CaCO3 precipitation. Boron isotope measurements on the carbonate phase match previously published values for S. pistillata nubbins rather than inorganically precipitated CaCO3, despite the carbonate's formation in contact with the growth medium rather than in a calicoblastic space. These results suggest that coral cells possess compensatory molecular machinery to deal with ocean acidification. However, the ability of these molecular mechanisms alone to compensate for very high CO2 appears limited.

RESOLVING MECHANISMS OF LOCALIZED ENVIRONMENTAL RESILIENCE: A CLOSER LOOK AT OCEAN DYNAMICS IN THE VERDE ISLAND PASSAGE DURING THE 1998 BLEACHING EVENT (Abstract ID: 29592)

Known as the "center of the center" for marine biodiversity, the Verde Island Passage (VIP; Philippines) is valued for its abundance of reef fish and coral species. In 1998, anomalously warm sea surface temperatures (SSTs) associated with the El Niño/La Niña resulted in widespread coral bleaching in the Coral Triangle. However, satellite (CORTAD) data indicate that SST anomalies were less extreme in certain regions, including the VIP. In order to diagnose the dynamical mechanisms underlying this observation, we use a high (500m) resolution Regional Ocean Modeling System (ROMS) model of the VIP from 1996-1999, which includes sub-mesoscale features and previously unresolved vertical structure in this relatively narrow passage. Lower SST anomalies in the VIP appear attributable to strong, seasonal surface currents that cool surface conditions through significant island upwelling and mixing resultant from interactions with internal tides. These findings suggest that the VIP's configuration renders it less susceptible to thermal stress incurred by climatic events such as ENSO 1998, highlight the spatial heterogeneity of physical quantities in this geographically complex region, and emphasize the importance of higher-resolution models when anticipating individual ecosystems' vulnerability to climate variability and change.

GENTOYPING BY SEQUENCING AS A TOOL FOR UNDERSTANDING GENETIC AND GENOTYPIC PATTERNS OF *ACROPORA CERVICORNIS* RESTORATION (Abstract ID: 28176)

Caribbean reef decline has prompted the listing of the coral genus *Acropora* as threatened (ESA) and led to the development of active restoration techniques to facilitate recovery. Expanding efforts demand a better understanding of the genetic drivers of coral growth and survivorship and the implications of active intervention on genetic and genotypic diversity on multiple scales. We describe the use of Genotyping by Sequencing to formulate and resolve genetic questions about *Acropora cervicornis* restoration and conservation in Florida. GBS provides more markers per individual than conventional molecular techniques, enabling a holistic understanding of factors relevant to restoration such as population structure, genotypic diversity within reefs, and genetic diversity of nursery stocks. Using GBS, we resolve novel genetic patterns of *A. cervicornis* in Florida, including high diversity of wild corals and three genetically distinct populations. GBS also highlights large genetic/genotypic diversity within reefs and thickets, suggesting adaptive variation over small distances and providing key information for the development of nursery propagated thicket outplanting. Finally, substantial genetic and genotypic diversity in existing nursery stocks is reflected in variable performance *in situ* and suggests the high diversity of wild and outplanted coral assemblages tempers concerns of reduced fitness due to outplanting. GBS should be incorporated into the restoration 'toolbox' as an important metric for understanding the effects of intervention.

CLONALITY AND LOCAL DISPERSAL: MAJOR COMPONENTS IN POPULATION MAINTENANCE OF FIRE CORALS IN MOOREA REEFS (Abstract ID: 28586)

Asexual reproduction is commonly thought to decrease evolutionary fitness by reducing genetic diversity in populations. Assessing levels of clonality in reef-building organisms is thus crucial to understand population maintenance and resilience of coral reefs. Although *Millepora* hydrocorals are a ubiquitous component of tropical reefs, information regarding ecological processes driving their population dynamics is still lacking. We investigated whether and how the level of clonality varies in *Millepora platyphylla* populations in five habitats with varying wave energy. We used 12 microsatellite markers to genotype 3651 georeferenced colonies. The great majority of colonies are clones (>72% up to 97%) where wave energy is high (upper slope) and where waves and resultant coral fragments disperse (back, fringing and patch reefs). Clonality is reduced (<60%) on the mid slope where wave energy is lower. Relatively high levels of genetic diversity were estimated in all populations, although 328 clonal lineages (~30% of the 1064 multi-locus genotypes) were identified over the five surveyed habitats. Clones of the same lineage were dispersed among habitats with six clonal lineages that strongly demonstrated morphological plasticity among clones in response to wave energy. Parentage analyses provided the first evidence of larval retention processes in shaping the genetic make-up of *M. platyphylla* populations. This study reveals that clonal propagation combined with phenotypic plasticity and local larvae dispersal is highly successful for population maintenance of fire corals in a marginal reef.

FORE REEF SPUR AND GROOVE GROWTH AND IMPLICATIONS FOR REEF PLATFORM EVOLUTION (Abstract ID: 28873 | Poster ID: 386)

Coral reefs protect islands and coastlines around the world from the effects of waves and storms. The spur and groove (SaG) zone is a characteristic geomorphic zone occurring on the seaward slope of modern reefs globally. Given the location of SaGs at the seaward fringe of modern reef flats, the direction, rates and mechanisms of SaG formation and growth are critical to understanding reef platform development throughout the Holocene and into the Anthropocene. Our recent research shows the existence of several types of SaGs primarily related to wave energy exposure (both intensity and direction). Here we investigate the formation and evolution of different types of SaGs in the southern Great Barrier Reef (One Tree and Heron Reefs, Australia) and French Polynesia (Moorea). A total of 46 short cores (< 70 cm long) were obtained using a pneumatic drill at ten locations; drilling was undertaken on top of spurs, into spur walls and into groove floors in a planimetric layout across the zone. We present down-core sedimentologic, coralgal assemblage and calibrated 14C AMS age data from SaG features in high, moderate, and low wave energy settings. Preliminary data reveal that high energy spur features in Moorea are typically younger (maximum age 762-945 cal BP) than lower energy spur features in the southern Great Barrier Reef (maximum age 4134-4445 cal BP). Vertical and lateral accretion patterns obtained at these three sites also differ; these patterns are currently under investigation taking into account the dominant energy regime, regional sea-level and reef growth histories.

EVALUATING PATTERNS OF GENE FLOW IN THE PRECIOUS CORALS*HEMICORALLIUM IMPERIALE/LAAUENSE* ACROSS THE PACIFIC OCEAN (Abstract ID: 28804 | Poster ID: 329)

Soft barriers, as are oceanic currents and large distances between populations, have been considered biogeographical filters rather than physical barriers. Their sporadically permeability shows that dispersal is the main mechanism responsible for biogeographic patterns, but their role in the diversification of marine taxa is not completely understood. Hemicorallium sp. have broad distributions throughout the Pacific Ocean. Recent studies suggest that H. imperiale and H. laauense could comprise a complex given that they are indistinguishable by molecular and morphological methods. Using three populations of H. imperiale/laauense from the North Pacific (NP), South Pacific (SP) and Southern Ocean (SO), we evaluated the potential role of geographic distance and the Antarctic Circumpolar Current (ACC) in structuring gene flow patterns for these deep-sea octocorals. For this purpose, we obtained 75 sequences from three mitochondrial genes and used a combination of population genetics and phylogenetics methods. Shared haplotypes were found between NP and SP, and between SP and SO. Fst values showed no genetic differentiation between SP and SO, however NP had significant genetic differentiation when compared to the other two population; the highest value against the SO. We found low but significant correlation between geographic distance and genetic distance. These preliminary results suggest that the ACC has no effect in the genetic structuring of populations of H. imperiale/laauense. However, the genetic patterns may respond to a scenario of isolation by distance.

EASTER ISLAND (RAPA NUI) CORALS TRACK 19TH AND 20TH CENTURY DECADAL AND LONGER PERIOD VARIANCE IN SE PACIFIC SEA SURFACE TEMPERATURES (Abstract ID: 29937)

The southeastern subtropical Pacific has been implicated in the modulation of the El Niño-Southern Oscillation (ENSO) over decadal time scales, yet this region is almost entirely devoid of high-resolution paleoclimate archives, making analysis of such climate connections difficult. Here we present 3 new coral stable isotopic records from Easter Island (Rapa Nui) that extend back in time to 1800 CE. Coral growth irregularities are found throughout the three cores, but the use of multiple transects, U/Th dating, and replication across cores has allowed us to develop credible chronologies and replicated isotopic time series. Our primary finding is that Easter Island coral del 18O closely tracks Southern Hemisphere and global instrumental SST during the 20th century. We furthermore suggest that the SST rise associated with global anthropogenic forcing may have been underestimated in this sector of the ocean. We observe multi-decadal variability in the seasonal amplitude of Easter Island coral del 18O throughout the time series. We compare the new Easter Island data sets with previously published coral isotopic records from the Pacific. All records reveal a similar long-term trend towards warming/freshening in modern times, suggestive of a basin-scale increase in the strength of the hydrological cycle. Based on frequency domain analysis and comparisons with other coral records, we see greatest support for the null hypothesis that basin-wide Pacific decadal variability arises from the tropics and is expressed in a symmetrical fashion to the north and south.

VOICE OF THE SEA: USING TELEVISION TO TEACH CORAL REEF SCIENCE AND PROMOTE STEM CAREERS ACROSS THE PACIFIC (Abstract ID: 29621)

Voice of the Sea is an innovative 30-minute, weekly TV show broadcast throughout the Pacific Region that highlights ocean research and careers in a local context, incorporating traditional knowledge into the STEM cannon and striving to create interest in ocean science research and careers. Voice of the Sea provides a venue for coral reef researchers to share their work with local audiences—those most affected by and with potentially the most to gain from increased understanding of current ocean and climate research in their geographic region. The goal of Voice of the Sea is for viewers to become more science, technology, engineering, and mathematically (STEM) literate in the context of ocean and climate issues. Preliminary research indicates significant increases in viewer interest and understanding of episode content across age groups, with implications for formal and informal communication of science topics. We will share excerpts of Voice of the Sea coral reef research episodes and audience feedback.

CLIMATE CHANGE STUDIES CAN DIRECT RESTORATION TECHNIQUES TO ENHANCE CORAL REEF RESILIENCE (Abstract ID: 29508 | Poster ID: 470)

By year 2100, the carbonate chemistry of the world's oceans will be profoundly different, yet little is known about how the stress of ocean warming and acidification will influence coral restoration efforts. At Mote we are currently outplanting thousands of *Pseudodiploria clivosa* and*Orbicella faveolata* fragments each year in our efforts to restore Florida's Reef Tract. This study evaluated the physiologic response of *P. clivosa* and *O. faveolata* to address which species and genotypes are most resistant to thermal stress combined with ocean acidification. We measured changes in physiological performance in a full-factorial experimental design with three pHT treatments (control 8.01, mid-century 7.79, and end of century 7.68), distributed between two temperatures (30°C and 27°C) for two genotypes of each species and for two different fragment sizes. After two months, there were no significant differences in net calcification due to temperature or pH conditions; however, there was a significant effect of species ($p > 0.0062$) and genotype ($p > 0.0076$) on net calcification with *O. faveolata* calcifying less than *P. clivosa*. There were also significant differences ($p > 0.0001$) for both species in growth rates due to fragment size, where microfragments grew faster independent of temperature or pH. Data generated from this project greatly improves our ability to predict which coral species and genotypes are likely to persist under chronic environmental change and adjust restoration practices to maximize reef resilience.

GREEN TURTLE REPRODUCTIVE FAILURE AND MANAGEMENT INTERVENTION AT RAINE ISLAND, GREAT BARRIER REEF (Abstract ID: 30153)

Raine Island is the world's largest green turtle rookery. The future of this population is under threat. Mortality of adult female nesters is up to 2000 individuals in a peak season. Nesting and hatching failure are also occurring on a grand scale. Nesting success is low, around 20%, due to two main causes. Dry sand causes nest collapse and high-density nesting results in frequent inter-turtle nesting disturbance. Re-nesting efforts deplete stored energy reserves and result in fewer clutches laid in a season. Emergence success is low, from 20 – 56%, with embryonic death mostly occurring in early development. Tidal inundation at nest level is widespread and is being investigated as a major cause of hatching failure. With very low hatching success producing a large decomposing biomass there is concern that unsuitable nest environment conditions may also be contributing to hatching failure. Trial re-profiling of the nesting area was carried out in 2014. This produced a more gradual slope and raised height above inundation level within the nesting area. Comparison of trial and control nesting beach areas showed an increase in nesting success (47% vs 26%), more even distribution and reduced disturbance of nesting turtles and increased hatchling production within the trial area. Comparison of nests marked by dGPS and excavated post-hatching however showed no difference between trial and control areas with an average emergence success of 56%. This indicates that hatching failure occurs above inundation level and that inundation is not the sole cause of hatching failure.

CORAL SKELETAL Δ15N RECORDS PROVIDE A HISTORICAL PERSPECTIVE ON COASTAL CORAL REEFS EUTROPHICATION (Abstract ID: 29131)

Human-driven eutrophication is thought to be a major threat to coastal coral reefs worldwide. Yet, we only have a limited understanding of the causes and the consequences of this problem, preventing the application of adequate mitigation policies. Indeed, we lack crucial environmental baselines to identify the sources of nutrients and understand how these nutrients might have changed the coral reef ecosystem over time. The natural abundance of nitrogen isotopes in coral skeleton-bound organic matter (CS - δ15N) may be a promising tool to identify environmental nitrogen (N) sources and to track their changes over time. Until now, such studies have been prevented by the lack of adequate methodology, mainly due to the low N content in coral skeleton. A recent study provided a sensitive and precise method for analysing CS- δ15N (Wang et al., 2015), paving the way for a new field of investigation. To further explore the ability of the CS - δ15N to track human-driven eutrophication we have generated two annually-resolved CS - δ15N records from cores collected in historically eutrophic places: Guam USA, (56 years) and

Hong Kong SAR (150 years). These two cases revealed that the CS - δ15N recorded significant changes in the N sources on decadal to centennial scales, in response to increasing human activities. The two records showed that sewage-derived N has been present in the environment for more than 50 years. Although these records come from hand-picked locations, they suggest that some coastal reefs worldwide could have been under eutrophication stress for half a century.

INFLUENCE OF CORAL REEF STRUCTURE ON BEHAVIOR OF CARIBBEAN HERBIVOROUS FISHES (Abstract ID: 29890 | Poster ID: 585)

Grazing activity of herbivorous fishes are essential for resilience of coral reefs. Their specific feeding preferences on turf, crustose and standing fleshy algae complement each other and provide an effective overall control on algal assemblages of coral reefs. However, it's been shown that grazing activity of herbivores can be influenced by resource availability and habitat structure. In this study we evaluated feeding habits and behavior of herbivorous fishes in two distinct Florida reefs, Molasses reef and Conch reef. We characterized fish communities of both sites using 30x2 m lineal transects (n=20) and surveyed benthic community using photo-quadrats (n=200/site). To study fish behavior, we followed target species for 10 minutes (n=156/reef) and recorded interactions and grazing activity of eight parrotfishes. Molasses is a high relief reef with higher density and biomass of herbivorous fish as well as greater abundance of crustose algae and turf-forming species. Conch has lower rugosity with half of the benthos covered by turf algae associated with sediment (TAS) and other 30% dominated by brown upright algae. We found large variability species feeding preferences between both sites. At Conch approximately 50% of fish bites targeted TAS while at Molasses this benthic group was contacted less that 20% of the time. Contrarily, turf, crustose algae and corals were greatly more consumed at Molasses apparently caused of higher resource availability. We found that parrotfish interact more often at Molasses but and spend more time camouflaging at Conch reef. We discussed the implication of these results for coral reef functioning and management strategies.

FACTORS CONTROLLING SHORELINE CHANGES IN THE NORTHERN TUAMOTU REEF ISLANDS, FRENCH POLYNESIA (Abstract ID: 28598)

This study provides new data on shoreline changes on 111 reef islands of 4 atolls of the Tuamotu archipelago, French Polynesia (Rangiroa, Tikehau, Takaroa and Mataiva), over a 33- to 52-year period characterised by rising sea levels (+2.5 to 2.9 mm y-1). Results show that 75.7% of the islands were in stable condition while 16.8% expanded and 7.5% contracted. Accretion occurred across all island sizes and atoll sides, with the highest rates (>10%) occurring on highly modified islands as a result of land reclamation and of the disruption of sediment transport by causeways and transversal coastal structures. Eighty-two per cent of the islands that have decreased in area are less than 5 ha; most of them are undisturbed by human activities and located on the windward side of atolls. Twelve per cent of the islands have migrated, either lagoonward or oceanward. Three factors contributing to shoreline change are investigated: human factors, sediment supply, and tropical and extra-tropical cyclones. Although they erode islands (with shoreline retreat exceeding 30m in places), cyclones also increase their elevation; after such events, beach resilience occurs over a 10 to 20-year period. The good state and high resilience of coral reefs after destruction, mainly by cyclones, suggests that natural reef islands may continue to be resilient in the next decades. On the contrary, most developed islands have lost their capacity to grow both outwards and upwards. Their situation is therefore concerning in the face of accelerated sea-level rise.

SPATIAL COMPARISONS OF ZOOPLANKTON ABUNDANCE ON CORAL REEFS IN BOCAS DEL TORO, PANAMA (Abstract ID: 29686 | Poster ID: 358)

Climate change is increasing the decline of coral reef health as rising temperatures result in coral bleaching, often leading to death. Increased heterotrophy has recently been identified as a potential recovery mechanism for certain corals. This study investigates the abundance of zooplankton communities over a large spatial scale (km) across reefs in Bocas del Toro, Panama, to further investigate how heterotrophy may aid in recovery from bleaching. Zooplankton were collected at three depths in both offshore and nearshore reefs, using tows during the day and traps set on the substrate at night to include vertical migration. Nearshore reefs show higher total abundance of zooplankton in comparison to offshore reefs throughout the entire water column. During the day, abundance differs by less than two-fold, whereas at night abundance differs by over an order of magnitude. Additionally, both sites show increased zooplankton abundance in the middle of the water column during the day but more variability and no distinct pattern within the water column at night. These results indicate clear spatial variability, not just patchiness of zooplankton, and suggest further research is needed for plankton dynamics on coral reefs to better understand heterotrophy as a recovery mechanism for bleaching corals. As zooplankton are a critical source of energy to corals, and many other species in coral reef ecosystems, it is important to understand the dynamics of zooplankton on coral reefs to aid in their recovery from potentially negative consequences of a changing climate.

HERITABILITY AND GENOMIC BASIS FOR VARIATION IN THERMAL TOLERANCE OF THE CORAL HOLOBIONT IN *ORBICELLA FAVEOLATA*(Abstract ID: 29877 | Poster ID: 29)

Sea surface temperatures are predicted to rise 1-2C by the end of the century, and thermally sensitive organisms like reef-building corals will require substantial adaptive responses in order to persist well into the future. Genetic variation that might support adaptive responses has been documented in larval stages of some corals, but the contribution of genetic variation of adult corals and its functional basis remains unclear. In this study, we focus on mechanisms that may enable long-term adaptation by investigating heritable variation in thermal tolerance and its genomic basis in *Orbicella faveolata*, a dominant reef-builder in the Caribbean. Thermal stress experiments were conducted at the Smithsonian Tropical Research Institute in Bocas del Toro, Panama, using coral fragments collected from natural populations. Bleaching responses were quantified and combined with genome-wide SNP genotyping to estimate heritability and test for associations between thermal tolerance and genotypes. Using the linkage map and draft genome assembly for this species, we searched for genomic regions underlying variation within more thermally tolerant phenotypes. We profiled transcriptional responses in the same corals to evaluate whether genomic regions associated with tolerance include genes differentially expressed in heat-tolerant and susceptible genotypes. Integrating genomic and transcriptomic data with quantitative genetic analysis provides a new perspective on the mechanistic basis for thermal tolerance phenotypes and the potential for adaptation to rising ocean temperatures.

TWO YEARS AND COUNTING: MONITORING AND DOCUMENTING THE ONGOING GLOBAL CORAL BLEACHING EVENT (2014-2016 AND BEYOND) (Abstract ID: 28819)

Regional- to global-scale coral bleaching events have been occurring for more than 30 years. In that time, bleaching has worsened as global ocean temperatures warmed. Unlike the bleaching events in 1983 and 1998, strong El Niüo/Southern Oscillation (ENSO) conditions are no longer needed to cause widespread bleaching but certainly can exacerbate bleaching. The current global bleaching event began in Guam and the Northern Mariana Islands in mid-2014 (following 2013 bleaching there). Thermal stress brought bleaching back to previously impacted reefs and reached areas largely missed by past events (e.g., Hawaii),. Some locations suffered consecutive bleaching in 2014-15 (Hawaii, Florida) or prolonged stress that may last over a year (Kiribati). With the strong 2015-16 ENSO, bleaching may continue through much of 2016 in the Pacific and Indian Oceans and return to the Caribbean. It may even continue into 2017, and will likely spread even more broadly if a strong La Niüa develops. Unfortunately, some key international monitoring efforts (Global Coral Reef Monitoring Network, ReefBase) are no longer fully functional. This places greater pressure on other international (Reef Check, XL Catlin Seaview Survey), regional (e.g., AGRRA), and national efforts to document the bleaching

event. NOAA's Coral Reef Watch is coordinating global data collection and analysis of this event to make sure key scientific information is not lost. This presentation discusses the latest satellite and field data on the ongoing global bleaching event and its impacts on coral reefs worldwide.

SPATIAL AND HOST-GENETIC FORCES STRUCTURE THE MICROBIOME OF THE SPONGE *CLIONA DELITRIX* (Abstract ID: 29669)

Sponges are important members of benthic communities throughout the world. They host diverse symbiont communities with compositions that are largely species-specific and structured by host evolutionary history. However, little is known about how microbiomes vary among spatially distributed populations within a species. In the current study, we investigated how the microbiome of the coral-excavating sponge *C. delitrix*varied in relation to genetic differentiation and habitat location. Sponge samples from four distinct populations in the Caribbean were collected, and 16S rRNA amplicons were Illumina-based sequenced as part of the Earth Microbiome Project (EMP). Our analysis revealed that microbial diversity was consistent among all locations and populations, while both genetic and environmental forces influenced the microbial composition of sponges. Additionally, we found that *C. delitrix* maintains a "core" community across all sites in the Caribbean, with 62 microbial taxa found in at least 85% of all samples. Most of these microbial taxa were unique to *C. delitrix* or were only additionally found in the congener *C. celata* . Interestingly, all of the genera- and species-specific taxa were rare in the host microbiome. Our results indicate that *C. delitrix* microbiomes are a complex consortia of microbial taxa structured by both host-genetic and environmental forces, while maintaining a core group of microbial symbiont taxa reflective of broader host evolution.

REEF ECOLOGY – REEF ISLAND CONNECTIVITY ON HUVADHU ATOLL RIM, MALDIVES (Abstract ID: 28321)

Coral reef islands are low-lying (typically <3 m above MSL) accumulations of bioclastic sediment produced by the surrounding coral reefs. Given their low elevations and reliance upon locally generated sediment, they are regarded among the most vulnerable environments to sea-level rise. Understanding the linkages between reef ecology and reef islands is thus crucial for assessing future island resilience. Here, we present a holistic study of reef ecology-reef island linkages within a section of Huvadhu Atoll rim. This is the first detailed study of marine-island connectivity to be undertaken in an atoll rim setting in the Maldives. Sediment production rates were quantified using ecological survey data of sediment producers. Connectivity was assessed through comparisons of marine, beach, and island (from a series of cores) sediment samples (n = 157). Estimated annual sediment production was 382,000 kg across an area of 1.3 km2. Sediment production rates ranged from 0.05 kg m-2 yr-1 in the oceanward sand zone to 0.84 kg m-2 yr-1 on the lagoonward reef crest. Excavating parrotfish were identified as the dominant sediment producers, accounting for 79.4% of production. Marine, beach and island sediments were dominated by sand-grade coral (63%, 61%, 74% respectively). As parrotfish are the most likely source of sand-grade coral, this reflects the reliance of rim island systems on a limited range of sediment producers. Hence, ecological shifts associated with environmental change may have a critical impact upon future reef island vulnerability in the face of sea-level rise.

PALEO-GEOGRAPHIC DIVERSIFICATION AND ENVIRONMENTAL DEPENDENCE OF THE LARGER FORAMINIFER HETEROSTEGINA (Abstract ID: 27868)

The worldwide distributed larger benthic foraminifer (LBF) Heterostegina prefers oligotrophic environments in tropic and warm temperate seas. Harboring diatoms enables the broadest distribution along the illumination gradient within LBF. Down to the fair weather wave base Heterostegina protects entrainment by living in holes of structured boulders. The dependence on light intensities is managed by increasing surface/volume ratios correlated with decreasing light. The dependence on hydrodynamics leads to a shift in proportions between schizonts (smaller proloculi) and gamonts (larger proluculi) along the hydrodynamic gradient. The dominance of schizonts in high energetic environments, the mixture between schizogony and gametogony and the dominance of gamonts in low energetic environments leads to an apparently gradual increase of proloculus size with decreasing hydrodynamics. Additionally, the negatively correlated number of operculinid chambers apparently changes along the hydrodynamic gradient. Both characters were used as the most significant metric characters in the evolution of Heterostegina. Beside the environmental dependence, proloculus size can differ between biogeographically different populations (e.g., Okinawa, Hawaii) taken under similar hydrodynamic conditions. Therefore, paleogeographical differences leading to subspecies together with transport, reworking and time-averaging possibly lead to erroneous interpretations of evolutionary lineages. Using growth-independent and growth-invariant characters describing the internal test morphology completely allows a much better interpretation of evolutionary tendencies separated from paleogeographic diversification.

DECADAL TRANSITION IN CORAL REEF STATUS, DISTRIBUTION, ISSUES AND CONSERVATION INITIATIVES IN GULF OF MANNAR, SOUTHEASTERN INDIA (Abstract ID: 29196)

The coral reefs of Gulf of Mannar are distributed around 21 islands and show resilience after complete halt of mining in 2005 and other conservation initiatives. Considerable awareness and capacity building, coral rehabilitation, protection and livelihood support has been provided to coastal communities after the major Indian Ocean coral bleaching event in 1998, and live coral cover increased from 37% in 2005 to 43% in 2009. Though there was loss of 10% live coral in 2010 due to prolonged elevated sea surface temperature (32oC) resulting bleaching and mortality, the reefs showed resilience to reach 39% live coral cover in 2015. Coral recruitment density increased significantly from 0.65 to 0.86 no/m2 between 2005 and 2015 and more recruits dominated by genera like Acropora, Montipora, Pocillopora, Porites, and Turbinaria. Recruits are occupying the nearby sandy and seagrass areas, and in Vaan Island, live coral cover area increased from 2.75 to 3.5 km2. The coral communities shifted from dominance, for example from P. damicornis to Acropora and Montipora in Shingle Island. However, issues like invasion of exotic seaweed, diseases, poaching reef associated ornamental fishes and elevated temperature pose challenge to reef managers. Over 1.2 Km2 reef area was affected by exotic seaweed invasion. Tissue loss disease (white syndrome) and growth anomalies along with several types of lesions was noted in 9% of the corals in 2015. The intensity of 2016 coral bleaching is alarming. To address the issues and to maintain reef health, regular monitoring, coral rehabilitation, capacity building, and community involvement programmes are implemented.

A CHARACTERIZATION OF THE SPATIAL PATTERNS OF SCLERACTINIAN CORALS AT PALMYRA ATOLL (Abstract ID: 29922 | Poster ID: 552)

Coral reefs are spatially complex habitats, yet our understanding of their non-equilibrium dynamics is largely based upon percent cover data using imagery of limited scale (< 1 $m^2$). However, ecological processes leading to differences in the spatial patterns of individual coral colonies cannot be detected from percent cover based analyses. As a result, we lack a robust and highly taxonomically resolved appreciation of landscape-scale patterning in coral reef environments. Here we investigate the spatial patterns of hard coral assemblages at Palmyra Atoll using large scale photomosaic images, each covering 100 $m^2$ of benthic habitat. All individual coral colonies were mapped and identified to the lowest taxonomic level possible, and using spatial-analytical techniques we investigated departures from spatial randomness. While patterns of dispersion were variable, all taxa showed some degree of clustering. Despite this, the distributions of a number of taxa did not significantly depart from randomness. We did not observe over-dispersion in any of the observed taxa. Further for many taxa, the level of clustering was linearly related to abundance, suggesting density dependence in dispersion. These patterns, at least partially,

result from important biological processes such as differences in reproductive strategies. The data provided by photomosaics allows us to not only quantify ecosystem state, but also identify patterns in spatial structure, which can lead to critical inferences about the underlying processing structuring a variety of natural systems including coral reefs.

IMPLEMENTATION OF LARGE SCALE MONITORING PROGRAMS AS A PLATFORM FOR TERRITORIAL CONSERVATION AND MANAGEMENT (Abstract ID: 28352)

Development and implementation of large spatial scale monitoring programs is a complex process requiring advance planning and strong partnerships. Project goals include, building a scientifically sound monitoring platform that compliments current local monitoring efforts within a territory by providing broader spatial resolution to further assist in the management of local resources. When working remotely, resources and personnel become precious commodities, therefore proper planning and coordinating well before implementation is pertinent for execution. The National Coral Reef Monitoring Program (NCRMP) is one such example; a strategic framework funded by NOAA's Coral Reef Conservation Program (CRCP) for conducting sustained observations of biological, climatic, and socioeconomic indicators in U.S. states and territories. This presentation will focus on the development of the biological monitoring plan for Puerto Rico by providing a road map of capacity building and leveraging of resources within the territory wherever possible. Current effort within Puerto Rico include federal, territorial and NGO partners and coalesces these groups to work collectively on a common objective. Integration of NCRMP data into local research and management plan development within the North East Reserve (NER) will be highlighted to emphasize the synergy of this new monitoring program and augmenting local resource management and conservation.

REEF FISH AS POTENTIAL LINKS ACROSS HABITATS IN A BRAZILIAN TROPICAL SEASCAPE (Abstract ID: 28754)

Seascape connectivity is regarded as essential for healthy reef fish communities in tropical shallow systems. Seagrass beds and mangroves often constitute important nursery habitats, with high structural complexity, supplying juvenile fish with food and protection from predation. The Brazilian seascape is considerably different from the Caribbean and Indo-Pacific shallow seascapes, particularly regarding seagrass beds, which in Brazil cover small areas and have very low structural complexity. Macroalgal beds may therefore be of more importance as nursery habitat for juvenile coral reef fishes in Brazil. Here, we investigate the extent to which fish communities demonstrate habitat connectivity and identify possible nurseries in a Brazilian seascape within three shallow reef systems. Fish communities were surveyed on the fore reef, back reef, in seagrass beds and Sargassum-dominated algal beds. Seagrass beds contained very low abundances and species richness of fish, while algal beds contained significantly more juveniles than all other habitats, including species that are found on the reef as adults. Fish species associated exclusively with seagrass were not observed. Connectivity and thus pathways of nutrient transfer seem to function differently in Brazil compared to the Caribbean and Indo-Pacific, with Sargassum-dominated beds being important as nurseries for a larger number of species than mangroves and seagrass beds. Results suggest that macroalgal beds are important nursery grounds for many reef fish species, thereby functionally structuring the adult coral-reef fish community.

WORLDVIEW-2 SATELLITE MAPPING OF THE NEARSHORE ECOSYSTEMS AROUND TIMOR LESTE: GOALS, CHALLENGES AND ACCOMPLISHMENTS (Abstract ID: 29124 | Poster ID: 537)

Timor Leste and the Coral Triangle region in general represent a hotspot of marine biodiversity. Coral reefs in the region provide an important source of food and income for local economies and provide coastal protection from storm and tsunami events. NOAA, along with partners from U.S. Agency for International Development (USAID), the U.S. Department of State, and the multilateral partnership of 6 countries in the Coral Triangle region, have been providing technical assistance to support implementation of an Ecosystem Approach to Fisheries Management (EAFM) in Timor Leste. Despite numerous challenges, this project utilized high resolution World View-2 satellite imagery to provide seamless regional shallow water bathymetry and benthic habitat data and maps for nearshore waters around Timor Leste. Prolonged high turbidity on the southeast and portions of the northeast coasts resulted in poor visibility and limited usability of some of the satellite images. The lack of relevant bathymetric and benthic habitat ground-truthing data has also been problematic. We addressed these issues by continuously adapting data processing methods to the quality of each satellite image. Here we present an overview of our seafloor depth derivation and habitat characterization methodology, which we use to obtain partially complete bathymetric data coverage and complete benthic habitat data coverage for the shallow (0-20 m) coastal seafloor around Timor Leste. These data layers are an integral part of the EAFM under development for Timor Leste.

CORAL-ALGAL COMPETITION INDICATES A NEGATIVE IMPACT OF LAND RUNOFF FROM RURAL COMMUNITIES ON CORAL REEFS IN FIJI (Abstract ID: 29749)

Coral-algal competition is ubiquitous in coral reefs worldwide and has the potential to provide a useful snapshot of the state of the benthos. The majority of people in Small Island Developing States live along the coast, yet little is known about the effects of runoff from these communities on coral reefs. Here, we investigated the abundance, composition and apparent outcome of different types of coral–algae competitive interactions on lagoonal reefs in Fiji. Surveys were conducted at three sites with increasing distance from each of two rural villages. Data also included monitoring of water quality and herbivorous fish biomass. Findings revealed that declining water quality was correlated with an increase in contacts between turf algae and corals. Macroalgae were generally better competitors than corals, suggesting an ongoing community shift towards algal dominance. The most common macroalga in contact with corals was *Lobophora variegata*. Epiphytes growing on *L. variegata* increased the likelihood of an interaction being lost by the coral. Furthermore, herbivorous fish biomass decreased in proximity to villages, potentially as a result of high amounts of sediment trapped in algae. This study suggests that rural communities can shift the competitive advantage of corals towards algae, potentially initiating a transition towards algal dominance. It further underlines the importance of water quality management in Small Island Developing States so that they can continue to receive the benefits from the ecosystem services they rely on.

INTEGRATED GENOMIC RESOURCES FOR A TEMPERATE MODEL OF CNIDARIAN-ALGAL SYMBIOSIS (Abstract ID: 29879 | Poster ID: 30)

Corals support diverse reef ecosystems, but are declining because of rising ocean temperatures which disrupt symbiosis between corals and diverse algal symbionts (genus *Symbiodinium*). The symbiont types hosted by corals contribute to thermal tolerance of the holobiont, yet the mechanisms underlying maintenance and loss of symbiosis remain poorly understood. These studies are difficult in coral because of their thermal sensitivity, restricted distributions, and cryptic variation in symbiont types. We are building genomic resources for a temperate anemone *Anthopleura elegantissima* that provides a model for symbiosis and environmental stress tolerance. *A. elegantissima* presents variation in visually distinct symbiotic states, associating with a green alga (*Elliptochloris marina*), a dinoflagellate (*Symbiodinium* sp.), and occurs in an aposymbiotic state. Maintenance of associations in the thermally dynamic intertidal zone and across a wide latitudinal range is a contrast to the more thermally sensitive associations in corals. To establish genomic resources for this model, we collected anemones across their geographic range and conducted genome-wide SNP genotyping to select a relatively homozygous colony to sequence. We have constructed a draft genome assembly for *A. elegantissima* from the chosen accession. Here we describe genome assembly and annotation, genomic patterns of population differentiation across the US west coast, and our efforts to develop and integrate a genetic linkage map, transcriptome, and genome assemblies.

BENTHIC COVER INFLUENCES THE PRESENCE OF CORAL RECRUITS WHILE NOT AFFECTING THEIR ABUNDANCE (Abstract ID: 28501)

Corals pass through three steps to recruit successfully: (1) larval production and dispersal; (2) settlement and (3) post settlement survival. The last two steps are influenced positively and negatively by benthic organisms such as algae and bryozoans. Common methods to quantify recruitment hinder conclusions on which step leads to recruitment failure because they measure recruits that pass through all steps. This study, based at Palmyra Atoll, combined recruitment data with a water flow model and measures of coral and benthic cover to determine if recruitment is driven by larvae supply or the benthic cover on the settlement tiles. Adult coral cover and water flow were used as proxies for larvae supply. We split the data into presence/absence and non-zero abundance for correlation analysis and modelling. The presence of pocilloporid recruits correlated with the tile's benthic cover and its succession stage, adult coral cover, and water flow. It was modelled by a binary logistic model that included adult pocilloporid cover, water flux from the lagoon and benthic succession stage. The abundance of pocilloporid recruits on the tiles correlated with water flow and adult coral cover. It was modelled by an ordinary logistic regression that included adult coral cover and water flux from coral dominated sites. Our results indicate that larvae supply and benthic cover on the tile influence Pocilloporid recruitment. However, the abundance of recruits is almost entirely dependent on larvae supply. Hence, changes in benthic cover affect recruitment failure but do not influence recruit abundance.

## COMPARISON OF GROWTH CURVES OF AGE-BODY LENGTH RELATIONSHIPS OF THREE POPULATIONS OF SCARUS QUOYI ALONG THE SOUTHEASTERN COAST OF MINDANAO, PHILIPPINES (Abstract ID: 29471 | Poster ID: 256)

The parrotfish Scarus quoyi is ecologically and commercially important and widely distributed species in the Philippine seas. Sagittal otoliths of 161 individuals were analyzed to determine any differences in populations at spatial scale. Samples were collected from Pujada Bay, Saragani Bay and Davao Gulf which covers a distance of approximately 300 km within which ecological connection still exists. Age estimates were done by counting the opaque and translucent bands on the sectioned sagittal otoliths. Size-at-age plot generated via Von Bertalanffy growth functions showed close to similar growth curves for 2 of the 3 sites. The exception was Sarangani bay where fish grew faster and reached larger size than those from the other 2 sites. At maximum age of 9 years, fish samples in Sarangani bay reached 22 cm in standard length (SL) while 18 cm and 17 cm SL at age 9 and 8 for Davao Gulf and Pujada Bay, respectively. This 4 to 5cm difference in SL suggests the possibility of growth rate difference in populations of Scarus quoyi at spatial scale and a very important indicator for faster recovery or maintenance of reefs.

## BROAD-SCALE POPULATION GENETICS OF THE HOST SEA ANEMONE, HETERACTIS MAGNIFICA. (Abstract ID: 28773)

Broad-scale population genetics can reveal population structure across an organism's range, which can enable us to determine levels of movement and connectivity. Genetic variation and differences in genetic diversity on small-scales have been reported in sea anemones, but nothing is known about their broad-scale population structure, including those that host anemonefishes, which are increasingly being targeted in the aquarium trade. In this study, microsatellite markers were used to determine the population structure of the host anemone, *Heteractis magnifica*, across nine regions in the Indo-Pacific, ranging from the Red Sea to French Polynesia. More than 280 samples were collected. In addition, two rDNA markers were used to identify *Symbiodinium* types in the samples, and phylogenetic analyses were used to measure their diversity and geographic distribution. Significant population structure was identified in *H. magnifica*, with at least three distinct genetic breaks possibly as a result of factors such as geographic distance, geographic isolation and environmental variation. *Symbiodinium*types were also affected by environmental variation and mostly reflected patterns of regional isolation seen in the host. These results suggest that management of *H. magnifica* must be implemented on a local scale due to the lack of connectivity between clusters. This study also provides further evidence for the combined effects of geographic distance and environmental distance in explaining genetic variance, even in a single biogeographic region.

## SPECIES DIVERSITY IN THE MESOPHOTIC CORAL GENUS LEPTOSERIS: A COMBINED TAXONOMIC AND PHYLOGENOMIC ASSESSMENT (Abstract ID: 29144)

Mesophotic coral ecosystems in the Indo-Pacific are often dominated by members of the genus Leptoseris, particularly in the deepest parts of the mesophotic zone. Although recent molecular studies have shed light on the species diversity of this genus in the Hawaiian archipelago, the genus remains poorly understood when it comes to other parts of the Indo-Pacific. Here, we present a comprehensive study into the species diversity, distribution and ecology of the genus Leptoseris on the Great Barrier Reef and Coral Sea. We conducted benthic video transects and extensive specimen collections across a broad depth range (10-125 m depth) at 10 different locations in the region. Through a combined taxonomic and molecular assessment (of both host and Symbiodinium diversity) we established initial geographic and ecological patterns of diversity. These were then further assessed through an in-depth phylogenomic assessment, in which we sequenced 150 Leptoseris specimens on the Illumina HiSeq platform (using a modified RAD-seq approach), including representatives from the different taxonomic species encountered on the Great Barrier Reef and Coral Sea, as well as Hawaii and the Red Sea. This genome-wide approach successfully resolved existing taxonomic species across regions, but also uncovered substantial cryptic diversity (e.g. in L. hawaiiensis and L. scabra) and geographic divergence. Overall this study sheds light on the diversity of this genus across both shallow and mesophotic reefs, and provides a first insight into the evolutionary relationships of its members across the Pacific

## TERRESTRIAL AND FINE SEDIMENTS NEGATIVELY IMPACT STONY CORAL HEALTH IN THE US VIRGIN ISLANDS (Abstract ID: 29981)

Sedimentation can have deleterious impacts on corals and human activities are increasing rates of fine-grained terrestrial sediment deposition to nearshore environments. However, information on natural and modified rates of sediment deposition and specific sediment characteristics that may differentially impact coral health are needed. Rates of trap deposition of total sediments, and the standard size fractions, carbonate, organic, and terrigenous sediment components were sampled on approximately monthly intervals over 3-5 years, across a range of coral reef environments in the US Virgin Islands. Along with these measurements, coral health was assessed as the prevalence of bleaching, disease, partial colony mortality, total colony impairment (all parameters combined), and coral cover. There was high variability in rates of sediment deposition but trap accumulation was highest in nearshore sites and during periods with storm activity, with site-specific characteristics relating to sediment resuspension during the winter Atlantic swell. Only the silt-clay and terrigenous sediment components significantly positively correlated with site average coral bleaching, partial mortality, and overall impairment. For each doubling of the mg cm-2 day-1 of silt-clay and terrigenous sediment there was a 10-20% increase in these coral health responses. This suggests that specific sediment characteristics are more important than total sediment deposition in predicting coral health and provides new benchmarks for determining coral health impacts from sedimentary studies.

## MICRO-CT ANALYSIS REVEALS DEPRESSED NET CALCIFICATION DUE TO ENHANCED BIOEROSION AND REDUCED ACCRETION OF REEF SUBSTRATA AT $CO_2$ SEEPS (Abstract ID: 27953)

Ocean acidification (OA) has been experimentally shown to depress the calcification of some species and to accelerate the bioerosion of carbonate substrata. OA could

therefore upset the tenuous balance between accretion and erosion, tipping a reef system towards net habitat loss. Controlled laboratory experiments have advanced this science but lack the complexity of field settings, where the processes of accretion and erosion involve numerous interdependent functional groups with different susceptibilities to OA. Organisms within these groups may further influence each other through competition, predation, or facilitation, and the net outcome of an OA-altered carbonate budget may therefore not simply be the sum of its parts. Here, we deployed dead coral substrata for two years along an OA gradient at two carbon dioxide seeps on reefs in Papua New Guinea. We used micro-CT to separately quantify the influence of OA on accretion, macroboring, microboring, and grazing. Macroboring, primarily by annelids, was significantly enhanced in high $CO_2$ environments, and secondary accretion was lower at one of the two high $CO_2$ seeps. Grazing and microboring remained unaffected, despite strong experimental evidence for the OA-enhancement of the latter. Alkalinity anomaly incubations of these communities confirm a reduction in net calcification under high $CO_2$conditions, providing further evidence that OA will detrimentally influence the construction and permanence of coral reef habitats.

AN ALLOMETRIC APPROACH TO IDENTIFY THE MAIN CORAL REEF BUILDERS WHILE EXPLAINING THEIR DIFFERENTIAL CONTRIBUTION TO REEF CARBONATE BUDGETS (Abstract ID: 28721)

Scleractinian corals are responsible for building one of the most diverse and productive marine ecosystems on Earth, the coral reef. Coral-reef survival in tropical oceans for the last 200 million years has relied on the mutualistic endosymbiosis established between a simple animal (Phylum Cnidaria, Class Anthozoa) and an unicellular alga, a dinoflagellate, of the genus Symbiodinium. The success of Scleractinian corals in oligotrophic tropical environments has been attributed to their extraordinary efficiency in collecting and processing light for carbon fixation, as Symbiodinium photosynthesis significantly enhances coral calcification and growth, which is critical for the maintenance of the primary framework of coral reefs. However, not all scleractinian corals can be considered coral reef builders, and many other primary producers in the reef system also have the ability to calcify. In this contribution, I present an allometric approach that describes the differential contribution of each photosynthetic calcifier to reef carbonate budgets and explains why Scleractinian corals are the main carbonate producers, but just a few species can be considered the builders of the coral reef habitat.

LONG-TERM VARIATION IN CORAL-ASSOCIATED MICROBIAL SYMBIONTS (Abstract ID: 28265)

Many species of plants and animals harbor unique symbioses with a diverse and abundant variety of eukaryotic and prokaryotic microorganisms crucial to their health and functioning. Scleractinian corals are host to a high diversity of microbial symbionts that include dinoflagellates, protists, fungi, bacteria, archaea and acellular viruses. The dynamics of these coral-associated communities over long time frames are poorly known. Microbial communities of tagged Pocillopora acuta colonies were examined over two years at Orpheus Island, central Great Barrier Reef. Bacterial, archaeal and fungal diversity will be assessed using amplicon next generation sequencing and any temporal patterns in diversity or abundance will be discussed. Sampling will be conducted during this summer (2015-2016) to assess initial changes and potential recovery in coral-associated microbial communities before, during and after a likely bleaching event. Understanding functional and seasonal changes in the microbial community over long time frames, as well as throughout a potential major temperature stress event, will provide insight into how the coral-associated microbiome may be affected by variations in sea surface temperatures due to future climate-related environmental change, and how this may influence the health and survival of the coral host.

PHOTOPROTECTION AND PHOTOSYSTEM II REPAIR OF SYMBIODINIUM IN HOSPITE FOR FOUR REEF-BUILDING CORALS FROM THE CARIBBEAN (Abstract ID: 29967 | Poster ID: 48)

Ecological and evolutionary success of scleractinians relies on the symbiotic association with dinoflagellates from the genus Symbiodinium. Symbiodinium uses solar radiation to contribute 95% of the metabolic requirements of the holobiont. Corals are efficient light collectors, therefore exposure to high levels of irradiance increases energetic pressure on the photosynthetic apparatus, promoting photodamage resulting in severe losses of photosynthetic activity (photoinhibition). In this study we investigated the variation of the capacity for photoprotection and repair of 4 species of scleractinian reef-building corals. Pseudodiploria strigosa showed the highest sensitivity to photodamage acumulation, but also showed the largest support for photosynthetic repair activity. The symbiont population found in Montastraea cavernosa were from the most robust symbionts in preventing the accumulation of photodamage, but have the lowest repair activity, resulting in large levels of photodamage under increasing levels of excessive absorbed energy. Orbicella faveolata and O. annularis showed the highest symbiont concentration, which allowed for photoprotection (self-shading), except under conditions of low pigmentation or rapid cell loss. We defined two different descriptors that allowed for quantification of differences in the photoprotective capacity of Symbiodinium in hospite. First, a fast component that can be assimilated to the NPQ descriptor proposed for green algae and higher plants, and the second a slower component related to the quenching of F0 in the antenna of Symbiodinium.

ASSESSMENT OF SHARKS CAUGHT BY CORAL REEF FISHERS IN THE PHILIPPINES (Abstract ID: 29811)

Removing apex predators like sharks from the wild has cascading effects on the marine ecosystem. They are considered as keystone species and have experienced decline for the past decades, resulting in various management planning and educational campaigns by concerned groups for their population recovery. Despite the reduction in shark fin production and exports, shark fishery is still on going and largely remains unregulated and unmonitored. On-going fisheries assessments in several cities/municipalities across the Philippines under the National Assessment of Coral Reef Environments (NACRE) Program provided an important opportunity to determine the status of sharks caught by coral reef fishers in the areas. Focus group discussions (FGDs) and semi-structured interviews conducted in at least six coastal barangays each in 17 cities/municipalities were used to evaluate whether the fishers also target sharks. Results show that sharks are usually caught as by-catch using various fishing gears while fishers in some sites use spe-argun or modify fishing techniques to deliberately catch them when present. Aside from their fins, meat and oil, sharks are also being targeted for the aquarium industry. Sharks are highly vulnerable to overexploitation which prompts the need to increase awareness as regards the ecological consequences of local extinction in the Philippines, as well as to improve shark fisheries management.

GENOMIC AND BIOCHEMICAL CHARACTERIZATION OF C-TYPE LECTINS IN A MODEL CNIDARIAN AND THEIR ROLE IN SYMBIOSIS ESTABLISHMENT (Abstract ID: 28430 | Poster ID: 106)

The cnidarian-dinoflagellate symbiosis is highly specific: a given host can establish symbiosis with only a subset of Symbiodinium types. However, the molecular mechanisms underlying this specificity remain poorly understood. Several studies have suggested that recognition of compatible Symbiodinium during symbiosis establishment depends on the binding of host lectins to glycans on the dinoflagellate cell surface. Using the anemone Aiptasia as a model system, we have identified several genes encoding lectin-like proteins that are expressed differentially between symbiotic and aposymbiotic anemones. One such gene, encoding the C-type-lectin(Ctl)-like protein Ctl1, shows 8-fold higher expression in aposymbiotic animals. We expressed a recombinant, GST-tagged Ctl1 in bacteria and found that it binds much more strongly to an incompatible than to a compatible strain of Symbiodinium in vitro, consistent with a role in the discrimination between symbiont types. However, eukaryotic Ctl-like proteins may be misfolded after expression in bacteria, so that we are currently attempting to express recombinant Ctl1 also in a eukaryotic system, the yeast Pichia. In addition, the Aiptasia genome sequence revealed that Ctl1 is one of a set of related lectins originating from at least six genes in a tandem array. However, gaps in the sequence have made these loci difficult to resolve. Using PacBio long sequencing reads, we are now attempting to fill these gaps so as to define the full diversity of the Aiptasia Ctl proteins, whose binding properties can then be explored.

STRENGTHENING MARINE PROTECTED AREAS TO CONSERVE MARINE KEY BIODIVERSITY AREAS IN THE PHILIPPINES – THE MKBA PROJECT (Abstract ID: 28547)

An evaluation of the management effectiveness of marine protected areas (MPAs) in the Philippines to address key drivers and pressures identified 3 major challenges in conservation and management of marine resources. These are (1) inadequate species, ecosystems and spatial coverage representation, (2) insufficient and unpredictable funding levels for long-term management, and (3) weak enabling policy framework for marine biodiversity conservation. The Marine Key Biodiversity Areas (MKBA) Project, a 5-year project, was designed to address these challenges and uses an integrated ecosystem approach to strengthen the conservation, protection and management of marine key biodiversity areas in 5 demonstration sites (i.e., Verde Island Passage, Southern Palawan, Tañon Strait Protected Seascape, Lanuza Bay and Davao Gulf) in partnership with key national government agencies, national and local conservation non-government organizations and local government units. The project outcomes include increased management effectiveness of MPAs and MPA Networks, improved financial sustainability and an established enabling policy framework for marine biodiversity conservation. A wide range of activities is undertaken in each of the sites to demonstrate site-specific and integrated approaches for effective marine biodiversity conservation. An important strategy is combining social, governance and ecological components in scaling up the management of existing MPAs to form functional networks. Important metric indicators are used to monitor and evaluate progress of the project.

RESOURCE PARTITIONING AND TROPHIC RELATIONSHIPS OF LARGE PREDATORY FISHES IN A CORAL REEF ECOSYSTEM (Abstract ID: 28720)

Sharks are thought to play an important role in structuring coral reef communities, but their role may be masked by the high level of functional redundancy. For example, coral reefs have a high diversity of predatory fishes that could be sharing similar ecological roles. Therefore, a better understanding the feeding ecology and trophic interactions of large predatory fishes may help define their role within coral reefs. This study used stable isotope analyses to examine trophic relationships and niche overlap of common reef predators in the central Great Barrier Reef. Mean trophic position of reef predators (sharks and teleosts) increased with body size, with larger sharks having higher trophic positions than smaller teleosts. However, sharks typically differed in their mean isotopic values (δ13C and δ15N), and most species examined occupied a relatively unique isotopic niche space. The only exceptions were grey reef (Carcharhinus amblyrhynchos) and silvertip sharks (C. albimarginatus), which showed high degree of isotopic niche overlap. The bull shark (C. leucas), a large seasonal predator, appeared to feed higher in the food web than resident sharks. In contrast, the whitetip reef shark (Triaenodon obesus), a species with strong site-attachment, had similar isotopic niche spaces than smaller teleost predators (Plectropomus leopardus and Lethrinus miniatus). Our findings suggest that although reef sharks occupy relatively high trophic positions, larger non-resident species may be more important in the functioning of coral reef communities.

CONSERVING THE MARINE ENVIRONMENT OF MALUKU BARAT DAYA: A SCENARIO ANALYSIS OF PAST AND FUTURE TRENDS (Abstract ID: 28665 | Poster ID: 677)

The recent establishment of Maluku Barat Daya as a new regency of Maluku province, Indonesia, in 2008, has opened the doors for economic development and population growth. Here, we describe qualitatively the past, present and future trends of environmental impacts on the coastal zone of Maluku Barat Daya to formulate the best management options in light of current and future political conditions. Focus group discussions, key-informant interviews and participatory mapping were carried out in fourteen sample settlements in November 2015 through rapid assessment. Scenario analysis was applied to draw four plausible trajectories of future change until 2035. The exploitation rate of marine resources in Maluku Barat Daya has been stable throughout the past few decades, due to limited access to the market. Traditional and undestructive fishing gears were still commonly used. While traditional fisheries closure system (sasi) is the primary form of marine resource management across all settlements, although it has been strongly influenced by buyers and prices. Social, economic and marine resource use conditions were varied in the future under four different scenarios. Based on future prediction, it is important to design the most suitable management option that can reduce and maintain future environment impacts, while preserve local custom.

GLOBAL BIOGEOGRAPHY OF MARINE ALGAE WITH APPLICATIONS FOR CORAL REEF CONNECTIVITY (Abstract ID: 29568)

The global distribution patterns of marine benthic algae were analyzed with respect to latitudinal and longitudinal gradients, temperature, spatial scales, taxonomic gradients, and patterns of endemism. Global presence/absence records of marine algae were collected from online resources, scientific papers, and gray literature and compiled into a digital database of 131,400 records, with 52,680 unique species-locality records occurring after geographic and taxonomic filters. Records were grouped into 155 unique localities, which were further classified into three temperature regions (temperate, subtropical, and tropical) based on NOAA/NCEP SST data. The Tripartite Similarity Index was used to measure percent similarity between all locality pairs (excluding the Antarctic and Arctic localities), with minimal distances between all locality pairwise combinations calculated by implementation of Dijkstra's algorithm for shortest path problems along a modeled connectivity network. Analyses of variance and covariance were used to ascertain differences in regression patterns between locality records clustered along temperature, geographic, or taxonomic gradients. Endemism metrics were calculated by a corrected weighted measure using two methods: as the proportion of range-restricted species in each 5-degree cell and by localities alone, revealing many regions of endemism ignored previously. Marine algal biodiversity patterns were compared with those for corals and shore fishes. Connectivity patterns for algae have applications for coral reef conservation globally and for MPA design.

USING REEF FISH MOVEMENT INFORMATION TO IMPROVE MARINE RESERVE DESIGN IN POHNPEI, MICRONESIA (Abstract ID: 28039)

Designing reserves must be adequate to ensure the persistence of focal species. Guidelines recommend that minimum reserve size be informed by species' home ranges. We used recently published information on the home ranges of coral reef fishes to inform the design of marine reserves in Pohnpei, Federated States of Micronesia. Key species of interest were identified at an initial stakeholder workshop. Communications products illustrating which species were likely to be afforded protection within existing reserves were used to facilitate discussions about the efficacy of the reserve system with stakeholders. Combined with information on management effectiveness, this information was used to identify which reserves should be prioritised for improving design and/or management. Almost all reserves were found to be too small to adequately protect key species of interest. Though legislation makes it difficult to change the boundaries of existing reserves, recently proposed reserves are larger, and afford greater protection to key species. Furthermore, communities are considering other mechanisms to improve reserve design, for example through larger seasonal closures. Previous approaches to determining marine reserve size have been a trade-off between a conservation mantra of "bigger is better" and social acceptability, with resource users preferring smaller closures. Our approach of using movement patterns of locally important species to determine appropriate reserve sizing resonated more with resource users and better engaged them in the design process.

THE DAMSELFISH DOMINO EFFECT: A COMPETITIVE RELEASE IN A HIGHLY PARTITIONED GUILD REVEALS SUBORDINATES VERSATILITY (Abstract ID: 29078)

Territorial damselfish play an integral role in the structure of coral reefs through their abundant role as small-bodied consumers and aggressive holders of benthic space. Their interactions towards inter- and intraspecific competitors influence the overall community and how resources are partitioned. In Kimbe Bay, PNG, 7 territorial damselfish finely partition space along the reef profile in discrete zones with semi-overlapping perimeters. Previous research suggested that habitat preference alone was insufficient in explaining the distributional patterns and that competition may be an additional driver. This study quantified how subordinates ecological versatility and spatial distribution was altered after an experimental competitive release. 22m by 10m removals of the most abundant species, Pomacentrus adelus, were conducted to assess subordinates versatility and spatial ecology. After removing P. adelus, the surrounding interspecific competitors shifted consecutively into the space previously occupied by P. adelus adults. Movement was observed immediately following the removal and the acquired space was retained 6 months post-removal at higher densities. P. adelus did not regain its original distribution despite recruitment. Thus, demonstrating that competition is a major driver behind fine-scale partitioning and that species can become versatile and alter ecological parameters if competition is decreased and additional space is available. This is ecologically important as habitat loss may force specialists to adapt or move into previously unoccupied areas.

QUANTIFYING THE EFFECTS OF OCEAN ACIDIFICATION ON THE RECOVERY OF CORAL COMMUNITIES (Abstract ID: 28421)

The response of corals to ocean acidification (OA) has been widely studied, with OA predicted to reduce coral reef calcification worldwide. However, coral performance is governed by both abiotic and biotic factors, although only a few studies have investigated OA affects on multiple coral species. We use a spatially-explicit model of coral community dynamics to explore how OA and coral-coral competition affect coral growth (calcification, extension, and density), and how these effects translate to community-level consequences on a reef recovering from disturbances. The model is parameterized using field data and flume experiments from Moorea, French Polynesia, and projections are used to test for different outcomes resulting from competitive dominance attributed to species- or size- effects under ambient conditions. We then include the effect of OA on colony growth, and evaluate its community-level impacts as the frequency of coral-coral competition increases during community recovery. Lastly, we explore the interplay of competition and OA on coral communities with the inclusion of future disturbances, assuming differential risk of dislodgment with changing skeletal density. While coral interactions act synergistically with pCO2 in reducing the skeletal extension of corals and their ability to compete for space, simulations revealed that conspecific aggregations benefit community recovery by mitigating the negative effects of OA. Our results stress the difficulty in predicting community responses to OA due to the complex influence of abiotic and biotic factors on corals.

GENOTYPING-BY-SEQUENCING REVEALS LACK OF STRUCTURE IN THE DEEP-SEA OCTOCORAL SWIFTIA SIMPLEX (NUTTING 1909) ON THE WESTERN COAST OF THE UNITED STATES (Abstract ID: 28826)

Deep-sea corals provide important habitat in the deep ocean and have been recognized as regional hotspots for biodiversity. Despite their ecological importance, little is known about the connectivity and life history of deep-sea octocoral populations. An understanding of the population structure of deep-sea corals is critical to ascertaining the effects of habitat loss and genetic connections between distant populations. Next generation sequencing, including restriction site-associated DNA (RAD) sequencing, has allowed the discovery and application of thousands of novel single nucleotide polymorphism (SNP) markers in non-model species, including marine invertebrates. In this study we utilized high-throughput RAD-tag sequencing to develop the first molecular resource for the deep-sea octocoral Swiftia simplex (Nutting 1909). Using this technique we discovered thousands of putative genome-wide SNPs from twenty-three S. simplex individuals collected along the U.S. West Coast. After quality control, we successfully assayed 1,145 SNPs across all individuals, and analyzed the resulting multi-locus genotypes to assess putative population structure across the region. Across all areas, no geographic genetic structure was detected for this species, suggesting a high degree of connectivity and potential panmixia along the U.S. West Coast.

PHOTOACCLIMATION AND INDUCTION OF LIGHT-ENHANCED CALCIFICATION IN THE MESOPHOTIC CORAL *EUPHYLLIA PARADIVISA*(Abstract ID: 28808)

Depth gradient is characterized by inherent changes in light which lead to several adaptation strategies within corals and their symbionts. In this study, the strictly mesophotic coral *Euphyllia paradivisa* from the Red Sea served as a model to determine the strategies of acclimation to different light conditions and to study photosynthesis and calcification coupling. The coral's physiology was examined after one year of acclimation under three sets of light conditions: shallow (3m); deep (50m, native population); and total darkness. Although photosynthesis was almost similar at both light treatments under a P vs. E curve, light enhanced-calcification was evident only in shallow acclimated corals leading also to six fold larger linear extension rates. The dark treated specimens were completely bleached and photoacclimation to shallow was expressed in enhanced respiration, higher zooxanthellate densities per polyp and lower chlorophyll per cell. We discuss the adaptation mechanisms of mesophotic corals to shallow water and to the aphotic zone. We conclude that *E. paradivisa* can adapt to various light conditions by controlling metabolic rates and growth energy investment and therefore can survive temporal and spatial effects of low light stress. It is generally accepted that ecological advantages acquired by corals in their native habitat may jeopardize their survival in a case of abrupt environmental changes. However to the strictly mesophotic *E. paradivisa* in the Red Sea shallow waters may be advantageous.

INDIVIDUAL ANNUAL FECUNDITY AND REPRODUCTIVE ENERGY INVESTMENT IN MUSHROOM SCLERACTINIAN CORALS (Abstract ID: 28800)

Reproductive investment and growth are often used as indicators of health or stress at the organism level. Knowledge of how such energy investment varies intrinsically among species or morphological types is crucial for the interpretation of physiological responses to environmental factors. Patterns of energy allocation may change in accordance to the degree of sexual maturity of the individual and are often size-dependent processes. Insight into the allocation of energy to reproduction and growth is central to understanding both the life-history strategies of species and the physiological tradeoffs of individual organisms since the reproductive energy allocation strategy affects virtually all other life-history traits. Due to their wide range of module sizes, colony growth forms, and life-history characteristics, scleractinian corals provide an important opportunity to assess how the relative allocation to sexual reproduction relates to morphology, size, and life-history strategies. We examined the reproductive activity and energy investment of two mushroom scleractinian corals, bearing different reproductive strategies; Fungia fungites and Herpolitha limax and surveyed the size frequency distribution of the fungiid populations in their natural habitat in the coral reefs of Okinawa, Japan. Fecundity was found to be highest at middle size (i.e. middle ages) and decline at older ages; sex ratios were more female-biased at middle ages than in early and late life ages and the middle size group showed high settlement rates in comparison to other size groups.

HOW MORTALITY PATTERNS INFLUENCE THE COMPOSITION OF SCLERACTINIAN CORAL COMMUNITIES (Abstract ID: 29931)

It is commonly accepted that coral reef ecosystems possess two dynamically stable states: one dominated by reef-building corals, and another dominated by fleshy algae. The transition between these states has been linked to alterations of herbivore assemblages (e.g. fishing, marine protection), in addition to other environmental forcings. Importantly, global climate change may impact coral reef community trajectories without necessarily leading to the either of the previously described states. Coral communities may suffer mortality from storm events, bleaching, crown-of-thorns starfish outbreaks, disease, sedimentation and anthropogenic destruction. These mortality events represent both local (e.g. reef, island) and global (e.g. archipelago, oceanic basin) phenomena. Understanding how different types of mortality shape coral communities is necessary to better elucidate ecological consequences of global and local stressors. Here, we use a numerical modeling approach to describe how these stressors affect mortality patterns and ultimately shape coral community composition. Importantly, we identify key parameter ranges that define the structure and composition of coral assemblages. In particular, we demonstrate that intense local stresses overwhelm the signature of global impacts by decoupling the functional linkage between morphological characters of coral and nuanced effects of oceanographic events. Such information allows us to explore the possible consequences of changes in mortality patterns and allow us to anticipate its short-term transformation in a changing world.

GLOBAL RESPONSE OF CORAL REEF BENTHIC CALCIUM CARBONATE DISSOLUTION TO OCEAN ACIDIFICATION (Abstract ID: 27791)

Ocean acidification (OA) is predicted to have a significant impact on the future of coral reefs, mainly through the reduced formation of calcium carbonate (CaCO3). However, the dissolution of stored CaCO3 has largely been overlooked in the OA community. CaCO3 sediments represent the largest reservoir of carbonate minerals in coral reefs and result from the accumulation and storage of CaCO3 material over thousands of years. This presentation will demonstrate the in situ drivers of dissolution in coral reef carbonate sands and how they will respond to increasing average pCO2 (ocean acidification). In situ benthic incubations at coral reefs around the world show that aragonite saturation in the overlying water is a strong predictor of CaCO3 sediment dissolution and most reefs show a similar response to increasing average pCO2 (OA). However, every reef shows a different net sediment dissolution starting condition and the effect of end of century OA conditions on net sediment dissolution is different for every reef. The rate at which sediments are predicted to dissolve by the year 2100 has important implications on the net accretion of coral reefs and their future survival. Quantifying the global dissolution kinetics of CaCO3 sediments is clearly just as important as estimating calcification rates when predicting how OA will impact coral reef ecosystems.

PHOSPHORUS AS A KEY NUTRIENT FOR THE MAINTENANCE OF THE CORAL-DINOFLAGELLATE SYMBIOSIS DURING THERMAL STRESS (Abstract ID: 28332)

The current warming of the oceanic surface waters induces profound modifications of the biogeochemical cycles and of the diversity of marine ecosystems all over the world. In addition, massive bleaching events (symbiont/pigment loss) were observed in nutritional autotrophic symbioses, such as the coral-dinoflagellate one, that dominates tropical benthic ecosystems. As dinoflagellates provide the host with most of its daily energetic needs, their release during bleaching events induces host starvation. However, except for carbon, the nutritional impact of bleaching has poorly been investigated, especially regarding the needs in inorganic nutrients such as nitrogen and phosphorus. This study assessed the capabilities of four hard (clade C1) and one soft (clade D1) tropical coral species to acquire essential inorganic nutrients (NH4, NO3 and PO4) under normal (25°C) and thermal-stress (30°C) conditions. Results showed differences in thermal threshold and nutrient acquisition rates among coral holobionts. More, under thermal stress, all species bleached and most of them lost their ability to acquire nitrogen, closely linked to their photosynthetic capacities. However, phosphorus (P) demand largely increased for most of the holobionts at 30°C. This global response is linked to the beneficial effect of P in sustaining optimal rates of photosynthesis and carbon translocation as well as symbiont density. Broadly, this study highlights phosphorus as a key nutrient for the maintenance and resilience of the holobiont under thermal stress-inducing bleaching.

FISH, TRADE AND FOOD SECURITY: MOVING BEYOND THE 'AVAILABILITY' DISCOURSE IN MARINE CONSERVATION (Abstract ID: 27978)

The goal of food security increasingly serves as an objective and justification for marine conservation in the global south. In the marine conservation literature this potential link is seldom based upon detailed analysis of the socio-economic pathways between fish and food security, is often based on limited assumptions about increasing the availability of fish stocks, and downplays the role of trade. Yet, the relationship between fish and food security is multi-faceted and complex, with various local contextual factors that mediate between fish and food security. We use data from interviews and food security assessment methods to examine the relationship between fish and food security among fishing households in San Vicente, Palawan province, Philippines. We highlight the local role of income and trade, emphasising the sale of fish to purchase food not easily accessible for fishers, particularly staples. In particular, we show that because rice is the primary staple of food security for these households, fish must be traded with the intent of buying rice. Trade is therefore central to household food security. We argue that the relationship between fish and food security must be considered in greater depth if marine conservation is to engage with food security as an objective.

$CO_2$ SEEPS IN PAPUA NEW GUINEA AS A NATURAL LABORATORY TO INVESTIGATE THE EFFECTS OF OCEAN ACIDIFICATION ON CORAL RECRUITMENT (Abstract ID: 28827)

Predicting the ecological consequences of rising atmospheric $CO_2$ for marine communities remains a key knowledge gap. We have investigated coral recruitment processes at shallow volcanic $CO_2$seeps in Papua New Guinea, where nearly pure $CO_2$ gas is bubbling out of the sea floor. We studied (1) coral fecundity, spawning, larval settlement and recruitment success of in situ acclimatized *Acropora tenuis* corals on acclimatized settlement substrata, (2) recruit densities of all coral taxa along $CO_2$gradients on artificial settlement substrata after 5 and 13 months deployment, and (3) densities of coral juveniles at high $CO_2$ and control sites in the field. The experiments and surveys documented significant reductions in coral recruitment at high $CO_2$. Importantly, $CO_2$-acclimatised*A. tenuis* colonies showed the same level of reduction in recruitment success to non-acclimatised colonies. Our experiments in combination allowed us to identify some of the likely underlying mechanisms that were responsible for the observed reduction in recruitment success. They also show that major ecological changes, and not just physiological challenges, will strongly contribute to determining the resilience of shallow-water coral reefs in a future high-$CO_2$ world.

DEVELOPMENT OF A SUBTROPICAL, VOLCANIC GEOLOGY-SPECIFIC MODEL FOR SEDIMENT DELIVERY IN THE HAWAIIAN ISLANDS (Abstract ID: 29609)

Human induced accelerated erosion and transport of sediment to the coastal zone threatens coral reef systems. Sediment export data at the island scale would be useful to research efforts that distinguish between the effects of different land-based source pollutants on volcanic islands, but is typically not available. We used the InVEST sediment model, an open source, annual, RUSLE-based model based on the idea of the sediment delivery ratio, with modified cover and erodibility factors, custom stream delineation, and a new factor termed "terrain factor" to account for geologic differences. We calibrated the model based on annual sediment loads for 12 watersheds with daily USGS data, and validated the model with 42 additional watersheds. Using this model, we predicted sediment export for 817 watersheds that discharge to coastal waters. We found that annual sediment export ranged from 26 to 273 ton/km2/yr, by island, and the calculated SDR ranged between 1.1% and 10.4%. Understanding geologic differences between islands was critical. A correlation analysis showed watershed parameters slope, rainfall and elevation to be responsible for the majority of variability, while the SDR was correlated more directly to soil erodibility. Results from this model are the first state-wide estimates of sediment export. The parameterizations and calibration from this study will be useful for land-use managers looking to understand the spatial nature of sediment export and how land use changes might impact erosion and sediment that eventually is deposited in coastal waters.

CORAL COMMUNITY STRUCTURE OF CORAL REEFS IN SOUTH CHINA SEA AND TAIWAN: CURRENT STATUS AND CONSERVATION ACTIONS (Abstract ID: 27929)

Global coral reefs have been declined in the past several decades. It is critical to understand the current status of coral reefs and execute conservation actions. The benthic community structures were surveyed by phototransects at 38 sites in areas of Taiping (Spratly) island and Dongsha atoll in South China Sea as well as Hengchun peninsula, Hsiaoliuchiu and Penghu islands in Taiwan during March 2013 to April 2014. The mean cover of hard coral at all sites was 42.7% with that of hard coral at each site ranged from 12.3% to 74.1%. Six coral community types were characterized by dominant growth forms and genera. They are branching *Acropora*dominant, foliaceous *Montipora* dominant, foliaceous *Pavona* dominant,*Heliopora* dominant, foliaceous *Echinopora* – massive *Porites* dominant, and soft coral dominant communities. The major disturbances, conservation value and protection actions in the 5 areas were compared to enhance management effectiveness.

EFFECTS OF OIL DRILLING DISCHARGES ON NET OXYGEN AND NUTRIENT FLUXES OF THE ARCTIC-BOREAL SPONGE *GEODIA BARRETTI* (Abstract ID: 29750 | Poster ID: 324)

The arctic-boreal sponge *Geodia barretti* Bowerbank, 1858 is widely distributed on cold-water coral reefs, playing a key role in carbon and nutrient cycling. With expanding oil exploration in arctic-boreal regions, this study aimed to investigate the effects of barite and bentonite, which are commonly discharged during oil drilling operations, on the sponge. Explants of *G. barretti* were exposed to suspended barite and bentonite, as well as natural sediment, at a mean concentration of 10 mg $L^{-1}$ under a 12-hour daily exposure cycle for 33 days. On day 33, net uptake of oxygen by *G. barretti*explants from ambient seawater significantly decreased by at least 26% in the three treatments compared to the control. The reduced net oxygen uptake was accompanied by at least 28% decrease in relative oxygen content within *G. barretti* explants from all treatments, as measured by a needle-type oxygen microsensor. However, net uptake or release of silicate, ammonium, nitrate and nitrite by the explants were not significantly different among the control and treatments. The exposure period was followed by a recovery period of 33 days under control conditions. After the recovery period, parameters measured across all treatments were not significantly different from the control levels. Overall, this study demonstrated (1) the effects of barite, bentonite and natural sediment leading to less oxic conditions within *G. barretti* explants, and (2) the ability of *G. barretti* explants to recover from the effects. Our findings provide insight into ecological consequences of oil drilling activities in arctic-boreal regions.

CRYPTIC SPECIES AND PHYLOGEOGRAPHIC PATTERNS AMONG RED SEA AND WESTERN INDIAN OCEAN GIANT CLAMS (Abstract ID: 29297)

Most of the phylogeographic work on giant clams has been conducted in the Coral Triangle and adjacent regions. Much less attention has been paid on the four species from the western Indian Ocean (IO), Tridacna squamosina (endemic to the Red Sea), T. rosewateri (endemic to the Mascarene Plateau) and the Indo-Pacific distributed T. maxima and T. squamosa. We investigated the phylogeography of the two latter, sampled from Farasan islands (Red Sea), Glorieuses, Juan de Nova and Tulear (Mozambique channel), Reunion Island and Rodrigues (Mascarene Islands). A total of 430 clams were photographed, biopsied and genetically analysed using COI and 16S mitochondrial sequences, as well as 14 microsatellite loci for T. maxima. Preliminary results revealed a highly divergent lineage, distributed from Juan de Nova to Reunion Island. Phylogenetic analyses placed it as a sister clade of T. squamosina, pointing to cryptic speciation. Its morphological similarity with T. squamosina suggests that speciation originated by vicariance. A deep phylogeographic break was further found between Red Sea and the west IO populations of both T. maxima and T. squamosa. For T. maxima, the western IO population showed further division into two divergent clades with narrow latitudinal range overlapping in the Mozambique Channel. At the south west IO scale, T. maxima showed strong nuclear divergences among populations suggesting highly restricted dispersal rates, a surprising result considering its wide distribution range. Altogether, our results confirm that the western IO is a biodiversity-rich, yet neglected region of the Indo-West Pacific. Further phylogeographic work is warranted.

THE ROLE OF EARLY LIFE-HISTORY DYNAMICS IN THE RECOVERY OF A KEYSTONE HERBIVORE, DIADEMA ANTILLARUM, FOLLOWING RECURRENT DISEASE OUTBREAKS IN THE FLORIDA KEYS (Abstract ID: 28194)

Mass mortality due to disease of the abundant herbivorous sea urchin*Diadema antillarum* in the tropical western Atlantic and Caribbean in 1983–84 resulted in dramatic changes in coral reef ecosystem structure and functioning. Many shallow reefs shifted from a coral- to macroalgal-dominated ecosystem, due to the removal of this important grazer. Recovery of *Diadema* has led to localized shifts back towards coral-dominated reefs. However, in the Florida Keys, where a second disease outbreak in 1991 further depressed densities, *Diadema* remain relatively rare. It is possible that at early life-history stages, positive feedbacks for the algal-dominated state inhibit *Diadema* recovery. We test this by characterizing fertilization and settlement dynamics of Diadema across sites with variable habitat cover in the Middle Keys. We use a combination of field and modeling studies to identify factors limiting *Diadema* recovery and to determine the impacts of habitat type on recovery potential in the Florida Keys. Our results indicate that a severe depression of local fertilization rates (< 5%) occurred following disease and continue today. Despite this, we observed active settlement in summer 2015 suggestive of re-colonization from distant populations. Comparisons with habitat cover indicate selective settlement behavior, with a trend of higher settlement in algal- versus coral-dominated regions, which could destabilize the algal-dominated state. However, post-settlement processes, such as predation, may prevent settlers from reaching adulthood.

MONITORING AND CONSERVATION OF REEF FISH POPULATIONS IN SOUTH FLORIDA NATIONAL PARKS (Abstract ID: 29775)

The National Park Service (NPS) in collaboration with partner agencies and universities monitor reef fish populations in six ocean parks in Florida and the U.S. Virgin Islands. Fisheries independent monitoring protocols have been developed to provide spatially explicit population metrics such as abundance and size structure to evaluate the effectiveness of fishery managed protected areas. Streamlining the reporting process for regionally important species is in development so annual "quick look" reports can be used by parks to assess fisheries management strategies and direct management decisions. NPS units are generally not created to specifically conserve fish populations, yet can function as valuable management tools to sustain healthy population metrics and allow more fish to be available for capture in open fished areas. Reef fish population monitoring in the Dry Tortugas, Florida region with large no-take marine reserves, show enhanced reef fish populations. While in contrast, management by traditional length and bag limit regulations in the Biscayne National Park region show depleted and possibly unsustainable snapper and grouper populations, with a collapse of historical spawning aggregations. For example, mean length (35.5 cm +/- 5.2 se) and frequency of occurrence (0.09 +/- 0.03) of Biscayne*Lutjanis analis* were significantly below values for the Dry Tortugas (46.3 +/- 1.8 and 0.29 +/- 0.04 respectively). These factors have a significant effect on individual fecundity and the reproductive potential of the population.

METHODOLOGY TO SCREEN CHEMICALS FOR THEIR POTENTIAL BLEACHING EFFECTS ON CORALS: APPLICATION TO UV FILTERS (Abstract ID: 28739 | Poster ID: 495)

Some studies have reported that certain UV filters contained in sunscreen lotions and washed off by swimmers, could trigger coral bleaching. Suspicion has been extended to all organic UV filters present in sunscreens products. The present study aimed at investigating the potential effect that organic UV filters may have on different coral species. Two herbicides were used as positive reference compounds. A preliminary rapid screening test was developed to assess the potential adverse effect of short exposure (48h) to elevated UV filters concentrations (from 1 to 100 mg/L), on nubbins of the hard coral species Seriatopora caliendrum and Stylophora pistillata. As a sub-lethal endpoint predictive of coral bleaching, the photosynthetic efficiency of the photosystem II of the symbiotic microalgae (zooxanthellae) was monitored by continuous measurements using PAM (Pulse Amplitude Modulated) fluorimetry. Coral nubbins of Stylophora pistillata and Turbinaria reniformis were then exposed for 5 weeks at lower, but still higher concentrations than those reported for natural sea waters, in 15-liters aquariums. Nubbins were exposed in closed-circuit aquarium with weekly seawater renewal. A specific analytical methodology was developed, combining automated solid phase extraction with UPLC-UV detection, to monitor the water UV filters concentrations, all along the exposure period. Dose-responses curves generated with these organic UV filters will be presented and compared with the one generated with mineral sunscreens.

INFERRING SEDIMENT TRANSPORT USING LARGE BENTHIC FORAMINIFERA: COMPOSITION, TAPHONOMY AND GEOCHEMICAL PROXIES (Abstract ID: 28895 | Poster ID: 241)

Coral reef geomorphological processes are responsible for landform evolution, habitat change and sediment dynamics. Understanding reef sediment transport allows insight into antecedent processes and future landform responses. Large Benthic Foraminifera (LBF) live in the algal rim and deposit tests (shells) which are transported by hydrodynamics (eg. waves, currents). Due to well-defined source areas, LBF tests may act as a 'tracer' to infer sediment transport pathways. We analysed surficial (n=74) and down-core (n=97) samples from two sand aprons at One Tree Reef, in the southern Great Barrier Reef (Australia). LBF tests (*Baculogypsina sphaerulata* and *Calcarina* spp.) exhibited increased abrasion ($r_s$=0.60, p<0.001) with cross-reef lagoonward transport. Transport trends were consistent with wave direction and refraction. Down-core and surficial sediments were spatially consistent suggesting transport conditions have prevailed for the last 3 ka. While the effectiveness of LBF as tracers has been proved in this and other studies, low abundance remains a limitation. We propose elemental ratios using LBF tests as a novel proxy for determining sediment transport pathways. LBF test analysis (n=40) revealed decreased Mg/Ca and increased Sr/Ca with lagoonward transport. Mg/Ca ($R^2$=0.83, p<0.001) and Sr/Ca ($R^2$=0.32, p<0.001) ratios were significantly correlated against abrasion, suggesting a link with test alteration. This novel proxy is rapid, requires minimal materials and provides quantitative measures for LBF test alteration.

AN INTRODUCTORY COMPARISON OF THE IUCN RED LIST AND THE U.S. ENDANGERED SPECIES ACT (Abstract ID: 29923 | Poster ID: 694)

Coral reef scientists have not paid much attention to whether there may be endangered species on coral reefs until recently. It appears that knowledge of the differences between the IUCN Red List and the U.S. Endangered Species Act (ESA) is not widespread. There are a variety of basic differences, such as the IUCN Red List being international but only advisory, while the U.S. Endangered Species Act is a U.S. federal law which thus applies only in the U.S., but is an enforceable law. The IUCN Red List has extensive instructions and detailed, quantitative rules for applying a set of several terms indicating different levels of danger. The ESA however has only a few vague terms without any quantitative rules or extensive instructions, and even the basic terms have required judicial rulings to clarify. Also, the Red List rules explicitly encourage applying the precautionary principle, while the ESA forbids using it in making listings, but allows it for management actions. Some of the basic differences between these two systems will be explored in this presentation.

EVALUATION OF RETICULATE EVOLUTION IN CORAL REEF FISHES USING GENOME SEQUENCING (Abstract ID: 30115)

Coral reefs in the margins of biogeographic regions present unique conservation challenges and opportunities. Phylogeographic and biogeographic surveys of coral reef fishes have revealed the importance of peripheral locations in generating endemic species or lineages, and connectivity studies reveal that marginal coral reef may largely contribute to species persistence as sources of propagules in demographic feedbacks that connect populations over vast geographic distances. Furthermore at the edges of biogeographic regions, closely related species may come into secondary contact and interbreed. It has recently been well documented the presence of marine suture zones, where sister species of different faunal affinities overlap and hybrids with intermediate coloration are common. Although visual observations and preliminary genetic data suggest that the hybrids are fertile and interbreed, reticulate evolution in reef fishes and its evolutionary consequences are yet to be evaluated. To this aim, we investigated in various species complexes of Indo-Pacific reef fishes and applied a RADSeq approach to genotype individuals of parental individuals and hybrids from natural populations at thousands of Single Nucleotide Polymorphism (SNP) loci. Our results confirm the presence of hybrid individuals and suggests that ancient and ongoing introgression are substantial evolutionary forces shaping the evolution of coral reef fishes.

QUANTIFYING ANNUAL CORAL GROWTH AND EROSION USING 3D MODELS (Abstract ID: 29024)

Habitat structural complexity is the 3D structure of an ecosystem that underpins biodiversity and resilience to disturbance. In coral reefs scleractinian corals are the key habitat builders providing most structure. Corals have slow growth (a few mm – cm per year) and their growth follows a multidimensional trajectory. The capacity to detect change in the 3D structure of coral colonies relies on highly accurate and precise metrics capable of capturing the three-dimensionality of an object. This study used state-of-the-art 3D technologies to quantify annual coral growth and erosion of table corals in situ. We used photogrammetry to reconstruct 3D models of both dead and live colonies from underwater images in 2014 and 2015. We used the 3D models to measure change in both volume and surface area after 12 months. Live corals grew by 20.5 ± 10.5 % (mean ± SE) of their original volume and 21.7 ± 6.6 % of their original surface area, while dead colonies shrunk by 52.2 ± 7 % of their original volume and 47 ± 6.8 % of their original surface area. Measurements were precise to 1% coefficient of variation. This study highlights the utility of several off-the-shelf tools for quantification of coral colony growth and erosion in 3D, a metric relevant to ecologist and managers. The novel methodology used greatly improves existing techniques for measuring coral colony growth and erosion. This is the first study to quantify the change in volume and surface area of table coral colonies through time using 3D models, and could be applied to other coral morphologies to quantify change in 3D coral structure caused by disturbances.

SPATIAL DISTRIBUTION OF NOMINALLY HERBIVOROUS FISHES ACROSS A TEMPERATURE GRADIENT ON BRAZILIAN ROCKY REEFS (Abstract ID: 27962)

Herbivorous fishes are claimed to be an important functional group in tropical reef systems, however our knowledge of how the different functional groups respond to natural temperature gradients is still weak. Such info is clearly a baseline to understading how organisms will respond to possible warming events on the sea. We analysed patterns of herbivorous reef fishes density and biomass in a nearby (few kms) sites influenced (17oC) and not influenced (22oC) by upwelling currents in a subtropical rocky reef (23o S, 42o W). Assemblages of roving herbivores were consistently different between eastern, warmer, sheltered sites and western, colder, more wave-exposed sites. At eastern sites, detritivorous-herbivorous species dominated while omnivores had the highest biomass and were dominant at western sites. Macroalgivores did not show any trends related to location. These distributional patterns, at relatively small spatial scales of a few

kilometres, mirror large-scale latitudinal patterns observed for the studied species along the entire Brazilian coast, where cold water associated species are abundant on south-eastern rocky reefs (analogous to the western sites of this study), and tropical species are dominant on north-eastern coral reefs (analogous to the eastern sites). Species-level analyses demonstrated that depth was an important factor correlated with biomasses of Diplodus argenteus, Sparisoma axillare and Sparisoma tuiupiranga, probably due to resource availability and interspecific competition.

CHANGING LOCAL ECOLOGICAL KNOWLEDGE IN THE SOLOMON ISLANDS: APPLYING AN INDEX OF TAXONOMIC DISTINCTNESS TO FOLK TAXONOMY (Abstract ID: 28325 | Poster ID: 592)

The Western Pacific region is rich in biological and cultural diversity. Local livelihoods are closely linked to marine ecosystems, as reflected in a range of customs, fishing methods, and local ecological knowledge (LEK) specific to the marine realm. A rich folk taxonomy enables communities highly dependent on living natural resources to harvest and manage them more efficiently, but also to detect and react to environmental change. A loss of this LEK threatens the adaptive capacity of communities, increasing their vulnerability to local and global environmental change. Ongoing economic and societal changes have eroded LEK worldwide, including the Western Pacific. However, research on folk taxonomy in connection with environmental change is mostly limited to assessing the richness of terminology. Focusing on the number of terms alone fails to account for additional embedded information on locally-known attributes, such as behavior or habitat. Yet, this information is vital to understand and detect ecological processes and react to changes. Indicators accounting for this added layer of information are also more likely to detect subtle changes in LEK than those focusing only on the type and number of different names. We applied an index of taxonomic distinctness to folk taxonomy in a number of Solomon Island coastal communities, examining differences in folk taxonomic knowledge between age and gender groups and at different distances to market, and assessing whether the index of taxonomic distinctness performed better at detecting changes than an index of taxonomic diversity.

CORAL REEFS OF THE MAIN HAWAIIAN ISLANDS: A VANISHING RESOURCE? (Abstract ID: 28187 | Poster ID: 710)

The coral reefs of the Main Hawaiian Islands are a treasured resource for their cultural value, recreational use, food, coastal protection, and more. Seemingly robust and ubiquitous, they are in fact sparse, highly vulnerable, and currently imperiled. Reef accretion is severely limited by wave action, and in general modern reefs mostly consist of a thin live coral cover over ancestral reefs. Over-fishing, sediment pollution, and now climate change are threatening coral reef health and resiliency. The 2015 bleaching event was unprecedented in its severity and extent in Hawai`i, and more such events are projected to occur in coming decades. In view of the present and increasing stresses, reefs need effective, protective management to provide opportunities for survival. Specifically, nearshore regions of the four islands of Maui Nui contain nearly 15,000 acres of reefs having >50% live coral cover. Overall, these are the largest, most complex, and richest coral tracts within the Hawaiian Islands. Their extensive distribution, large size, connectivity, and natural wave sheltering make these reefs potentially resilient candidates for surviving regional-scale threats from climate change if other stresses are eliminated and they are properly managed. Currently, Hawaiian reefs are largely (<1%) unmanaged and unprotected, with few restrictions on fishing or pollution. These additional stressors make them highly vulnerable to bleaching induced by changing climate. Preliminary evidence indicates that widespread reef die-offs have triggered regime shifts that prevent reef recovery.

EMPOWERING CORAL REEF MANAGERS TO ENHANCE RESOURCE MANAGEMENT THROUGH CONSERVATION ACTION PLANNING (Abstract ID: 30016)

Conservation Action Planning (CAP)/Open Standards for the Practice of Conservation (OS) is a powerful tool to guide conservation teams to develop focused strategies and measures of success. A worldwide community of trained conservation practitioners from over 60 organizations and agencies use this process to coach conservation teams to their vision of success at both local and regional scales. The five steps of CAP/OS provide project focus and team unity, even for diverse groups of stakeholders. In Hawaii, as part of a 6-year NOAA Coral Reef Conservation Program-The Nature Conservancy partnership, ten coral reef areas have benefited from convening teams of scientists, community members, conservation practitioners, fishers, landowners, government agency staff, and other stakeholders to strategically address conservation needs. Case studies illustrate the customized use of CAP/OS methods at these coral reef sites in Hawaii, and how the process was specifically designed to meet their needs and address priority threats such as land based pollution, unsustainable fishing, and climate change. A comparative analysis across the plans will illustrate the similarities and differences among the sites for target species and habitats, viability, priority threats, strategies, measures and key outcomes.

ACCURACY AND PRECISION OF HABITAT STRUCTURAL COMPLEXITY METRICS DERIVED FROM UNDERWATER PHOTOGRAMMETRY (Abstract ID: 28126)

Photogrammetry together with application of structure from motion software is emerging as a leading technique to create three-dimensional (3D) models of corals and reefs from which biophysical properties of structural complexity can be quantified. It is essential to assess the accuracy and precision of photogrammetric measurements to support their application in research and monitoring. This study evaluated the precision (by repeated modeling) and accuracy (by comparison with laser reference models) of geometry and structural complexity metrics derived from photogrammetric 3D models of marine benthic habitat at two ecologically relevant spatial extents; individual coral colonies (of different morphologies) and patches of reef area of 100s of square metres. Surface rugosity measurements were generally precise across all morphologies and spatial extents with average differences in the geometry of replicate models of 1–6 mm for coral colonies and 25 mm for the reef area. Precision decreased with complexity of the coral morphology, with metrics for small massive corals being the most precise (1% coefficient of variation (CV) in surface rugosity) and metrics for bottlebrush corals being the least precise (10% CV in surface rugosity). The 3D geometry of coral models differed by only 1–3 mm from laser reference models however surface rugosity values for all morphs were underestimated by between 8% and 37%. This study provides important information on the accuracy and precision of models and metrics derived from off-the-shelf mapping systems which should allow for their targeted use by non-experts in computer vision within these contexts.

CORAL CONNECTIVITY IN THE GREAT BARRIER REEF: NEW INSIGHTS INTO CURRENT AND FUTURE DISPERSAL PATTERNS (Abstract ID: 29792)

Dispersal patterns shape species' distribution, abundance and persistence, their potential for genetic drift and adaptation, and ultimately determine rates of recovery following disturbances. Because the larval mortality and competency dynamics of most marine organism is altered under warmer conditions, it is fundamental to understand how climate change will alter current connectivity patterns. Here we used an experimentally calibrated high resolution unstructured-mesh, depth-integrated hydrodynamic model (SLIM) to project current and climate change-mediated dispersal and connectivity patterns of corals in the Great Barrier Reef (GBR). We show that as oceans warm, coral connectivity will decrease. Specifically, the average dispersal distance from origin to destination reef and the number of incoming connections to each reef decrease. Interestingly, the proportion of larvae that find a suitable place to settle increases because more larvae will settle in their natal reef. We also show that broadcast spawning species with greater egg sizes, such as *Acropora* spp., will experience greater changes in dispersal patterns than species with smaller eggs. We identified the reefs which contribute the most to the larval supply in the GBR and the reefs which recovery rates will be more af-

fected by the change in connectivity patterns. Improved predictions of coral connectivity are essential to design networks of protected areas that contribute more effectively to the long-term sustainability and resilience of tropical reef ecosystems.

LINKS BETWEEN COASTAL MARINE ECOSYSTEMS AND HUMAN WELLBEING IN JARDINES DE LA REINA NATIONAL PARK AND CAYOS DE ANA MARÍA FAUNA REFUGE, CUBA (Abstract ID: 28088 | Poster ID: 599)

This study shows the value of the economic benefits that Coastal Marine Ecosystems from Jardines de la Reina National Park and Cayos de Ana María Fauna Refuge provide to coastal communities. Values estimated for Jardines de la Reina National Park ($ 3.7 million of Cuban Pesos) are higher than the values of Cayos de Ana María Fauna Refuge (2.8 million of Cuban Pesos). In case of commercial fisheries, lobster is the main asset. It is important to continue the diversification of the fisheries activities such as mariculture. Besides, sustainable tourism, like diving should be increased moderately, giving priority for employment (such as dive masters, sailors, captains, cooks) to inhabitants of coastal communities. Sustainable economic activities increase income and conserve coastal and marine ecosystems at the same time, strengthening the perception of the link between human wellbeing and conservation of coastal and marine ecosystems.

MOVEMENTS OF APEX PREDATORS IN A SMALL, ISOLATED MARINE PROTECTED AREA WITH IMPLICATIONS FOR RESOURCE MANAGEMENT. (Abstract ID: 29867 | Poster ID: 517)

Apex predators play a critical role in maintaining the balance of marine ecosystems and are an important component of Hawaii's recreational and commercial fisheries. In light of the increasing pressures on these populations across the main Hawaiian Islands, the study of apex predator movements in marine protected areas has become a research priority. To this aim, we used passive acoustic telemetry to investigate the spatial and temporal movement patterns of five apex predators: bluefin trevally (Caranx melampygus), giant trevally (Caranx ignobilis), green jobfish (Aprion virscens), whitetip reef sharks (Triaenodon obesus) and grey reef sharks (Carcharhinus amblyrhynchos) at the 31 ha Molokini Marine Life Conservation District (MLCD) off Maui, Hawaii. Our results indicate that the predator assemblage in the MLCD was dominated by teleost fishes during the day and sharks at night. Residency was variable across species, with bluefin trevally exhibiting the highest residency in the MLCD and green jobfish the lowest. Long distance movements between the Molokini MLCD and the other islands of the Maui Nui Complex were common for grey reef sharks, giant trevally, and green jobfish. These results indicate that despite its small size, the Molokini MLCD provides a high level of protection to resident species such as bluefin trevally. While the more mobile species (giant trevally, grey reef sharks and green jobfish) are protected while resident at the MLCD but open to the fishery during these large scale movements away from the reserve.

THE IMPACT OF SPONGE FILTRATION ON THE CHEMICAL COMPOSITION OF CORAL REEF DISSOLVED ORGANIC MATTER (Abstract ID: 29994)

Sponges are efficient filter feeders, removing significant portions of particulates and dissolved organic matter (DOM) from the water column. Since sponges can process vast amount of water, they have the potential to shape the availability and composition of DOM where sponges are abundant. We applied untargeted and targeted metabolomics analytical techniques to seawater samples prior to entering the sponge (ambient reef water), samples released from the sponge (exhalent seawater), and to seawater collected just outside of the reef area (off reef seawater). Reef seawater samples were collected from two sponge species, *Ircinia campana*and *Spheciospongia vesparium*, on a near-shore hard bottom reef in the Florida Keys. Total organic carbon was not significantly different between samples, but was highest on average in the ambient seawater samples, followed by the exhalent samples, and lowest in the off reef samples. In contrast, metabolic profiles generated from the untargeted metabolomics analysis indicated that the concentration of many (n=430) metabolites was higher in the exhalent samples, while only some (n=52) metabolites were higher in the ambient reef samples. Finally, targeted metabolomics analysis revealed variation in the concentration of specific metabolites between seawater types. This work provides the first insight into the molecular-level impact that sponges have on DOM and provides a foundation for future experimental studies addressing the influence of sponge-derived DOM on chemical and ecological processes in coral reef ecosystems.

INCREASED LOCAL RETENTION OF CORAL LARVAE DUE TO OCEAN WARMING MAY BE OFFSET BY ACIDIFICATION (Abstract ID: 27956)

According to climate change projections, coral reef recovery in the near future will take place in a warmer, more acidic ocean. The recovery potential of reef metapopulations relies on an adequate supply of larvae coupled with their capability to successfully recruit and establish themselves in the destination habitat. This study investigates the recruitment potential of the threatened Caribbean scleractinian coral *Orbicella faveolata* exposed to elevated temperature and ocean acidification (OA) conditions by quantifying larval survivorship and settlement from 2-14 days post-spawn. Although mortality was greater at higher temperatures, an earlier onset of settlement competency resulted in greater total number of settlers than at lower temperatures (78% increase at ambient CO2). However, this earlier onset was not observed under combined high temperature and OA conditions, indicating a delay in the development of competency as a result of high CO2. This delay in settlement due to OA was also observed at lower temperature but to a lesser extent. Thus, while the recruitment potential of *O. faveolata*may increase with increasing temperatures, this effect will be diminished if CO2 levels reach those forecast for the end of the century. Using coupled bio-physical connectivity models, we show how the changes in timing and magnitude of settlement can alter larval dispersal patterns affecting both the spatial distribution and abundance of potential recruits to Caribbean reefs and recovery potential as a whole.

REEF FISH SPATIAL DISTRIBUTION AND BENTHIC HABITAT ASSOCIATIONS ON THE NORTHERN FLORIDA REEF TRACT (Abstract ID: 27957)

The Florida Reef Tract (FRT) extends from the tropical Caribbean up the southeast coast of Florida into a temperate environment where tropical reef assemblages diminish with increasing latitude. This study used data from a comprehensive fishery-independent survey to quantify reef fish spatial distribution along the FRT and define where the assemblage shifts from tropical to temperate. A total of 1,676 reef fish visual census surveys were conducted to assess the populations on randomly-selected sites of marine hardbottom habitats between the Miami River and St. Lucie inlet. Multivariate analyses were used to investigate differences in assemblages among sites. Depth (<12 m and 12-33 m), general habitat (reef or hardbottom), and slope (high or low) strata explained the dissimilarities between assemblages. A general trend of cold-tolerant temperate fish dominated the northern assemblages and more tropical species dominated further south. In shallow habitats the data clustered in three spatial regions: One south of Hillsboro inlet, one in Northern Palm Beach south of Lake Worth inlet, and one north of Lake Worth inlet. The assemblage in deep habitats mainly split in close proximity to the Bahamas Fracture Zone south of Lake Worth Inlet. Reef and hard-bottom assemblages did not differ significantly within regions but the reef habitat was significantly different than the hardbottom assemblages elsewhere. Substrate relief was significantly correlated with the differences in deep assemblages but did not appear to affect the shallow assemblages.

PREDICTORS OF CORAL STRESS AND MORTALITY DURING DREDGING (Abstract ID: 29023)

Over the last decade there has been a series of large scale dredging programs off Australia's North West Coast. These projects were large by global standards, in terms of the dredge volumes processed as well as the scale and quantity of associated water quality and biological data that were collected. The data collected during these programs provides an excellent opportunity to explore: what happens to water quality during dredging; how this impacts upon coral health; the spatial and temporal scale of dredging impacts; and may ultimately allow the development of water quality threshold values that can be used to manage other dredging programs in the future. Characterising water quality using turbidity and light data collected over minute time frames yet spanning time series of several years can be highly complex, and can differ greatly across temporal scales (hours versus month) and with the statistical metrics used (mean verus median). Here we explore a range of water quality metrics and examine how well these can predict coral stress and mortality.

DOES CHLOROPHYLL-A TURN UP THE VOLUME? EXPLORING THE RELATIONSHIP BETWEEN OCEANOGRAPHIC FACTORS AND CORAL REEF SOUNDSCAPES. (Abstract ID: 29623)

Remote coral reefs offer unique opportunities to explore how biological activities around coral reefs are influenced by oceanographic variables. Little is known about how oceanographic properties like chlorophyll-a, sea surface temperature, and wave energy flux influence acoustic biological signals. In this study, long-term passive acoustic monitoring methods were used to examine the soundscapes of three remote coral reef locations in the Pacific Ocean. Acoustic signals were separated into different frequency bands and the relationships between coral reef soundscapes and oceanographic variables were explored through generalized linear models and generalized additive models. Geophony is mostly observed in the lower octave bands, while biophony is reflected in the higher octave bands. Snapping shrimp are the dominant contributors to tropical and subtropical coral reef biophony. While our results confirmed the positive correlation between snapping shrimp signals and temperature, a negative relationship with chlorophyll-a was found; as chlorophyll-a increases, the overall soundscape decreases. The site with the highest levels of chl-a had the loudest soundscape, possibly suggesting that high nutrient coral reefs support increased snapping shrimp abundance and/or higher levels of acoustic activity. This study is an example of how an interdisciplinary approach to exploring relationships between soundscapes and oceanographic variables appears to be an effective method of further understanding remote coral reef environments.

FUNCTIONAL ASPECTS OF THE JELLYFISH CASSIOPEIA XAMACHANA - SYMBIODINIUM SYMBIOSES (Abstract ID: 28817 | Poster ID: 122)

Jellyfish of the genus Cassiopea rely on the establishment of a symbiosis with the dinoflagellate Symbiodinium in the asexual polyp portion of their life cycle. The polyp, or "scyphistomae," then strobilates a medusa (jellyfish). Many species of Symbiodinium are able to infect scyphistomae and induce strobilation, but in nature adult Cassiopea xamachana harbor Symbiodinium microadriaticum (= A1). While polyps may be found with various symbiont species, their displacement by S. microadriaticum occurs early during the ephyra stage. To examine functional differences among resident symbionts, net photosynthesis and respiration were measured on ephyra containing either Symbiodinium microadriaticum (A1), B1, B3, S. goreaui (C1), C2, or S. trenchii (D1a) at 26 and 30oC. While all Symbiodinium spp. photosynthesized at normal high rates when exposed to 26oC, only S. microadriaticum and S. trenchii maintained these rates at 30oC. All other species of Symbiodinium exhibited significant signs of photo-damage. These observations offer a physiological basis for selection of S. microadriaticum by C. xamachana. Larvae settle on the shady-side of mangrove leaves, and the scyphistomae strobilate medusae when temperatures are warm enough and they have acquired Symbiodinium. The medusae move to more sunny areas in mangrove habitats. However, some Symbiodinium are sensitive to the high temperatures/light that occurs in this habitat during the summer. Symbiodinium microadriaticum survives and has a high photosynthetic rate in the environment that Cassiopea xamachana thrives in today.

SO YOU'VE GOT SOME TECHNOLOGY, NOW WHAT? (Abstract ID: 29938)

Currently, a gap exists between the potential that technology can play in improving conservation management—especially increasing fisheries-relevant data collection in artisanal fisheries—and the reality of implementing that technology effectively on the ground. There are several drivers behind this short-coming, including: 1) efforts to promote technology uptake in emerging markets often focus solely on usability when, in reality, usability is only one of several critical factors that determine whether or not a specific technology is appropriate for a particular community and purpose; and 2) a disconnect between improved data collection on the water and robust data storage, sharing, and analytical capacity within fisheries management bodies and seafood supply chains. With the recent growth in the number of initiatives looking to deploy new on-the-water technologies for conservation gains, closing this gap becomes increasingly important. Through dynamic storytelling, this talk will share the experiences and insights around designing and implementing mobile applications for improved fisheries data collection and traceability in artisanal fisheries. Examples of both success and failure provide lessons for future efforts to promote technology uptake in similar fisheries around the world.

PHYLOGENETIC PERSPECTIVES ON THE EVOLUTION OF REEF FISH FUNCTIONAL DIVERSITY (Abstract ID: 27992)

Functional traits have been fundamental to the evolution and diversification of entire fish lineages on coral reefs. Yet their relationship with the processes promoting speciation, extinction, and the filtering of local species pools remains unclear. Using published and new data, we mapped functional traits on to phylogenetic trees to infer evolutionary patterns that have led to the current functional diversity of fishes on coral reefs. Diet and feeding mode were reconstructed on time-calibrated phylogenies for several reef fish families. We found examples of independent transitions to planktivory across different reef fish families that may represent cases in which ecological opportunity for the exploitation of different resources drives speciation and adaptation. The evolution of body sizes in the family Labridae shows no relationship with lineage age, with both large and small body sizes appearing multiple times within clades of mid-sized fishes. The reconstruction of range size revealed that ranges are constrained by the geography and size of ocean basins. Also, there were many cases of disparate range sizes among sister species. The diversity and evolution of traits within lineages is influenced by trait-environment interactions as well as by species and trait-trait interactions, where the presence of a given trait may trigger the development of related traits or behaviors. Our efforts to assess the evolution of functional diversity across reef fish clades add to the burgeoning research focusing on the evolutionary and ecological roles of functional traits.

DIMETHYL SULFIDE (DMS) IN MARINE ECOSYSTEMS. (Abstract ID: 27775 | Poster ID: 365)

DMS is a biogenic sulfur gas that is particularly abundant in marine ecosystems and that may influence climate regulation by contributing to the formation of clouds when oxidised into sulfate campounds in the atmosphere. Today, climate change is altering marine ecosystems, with these changes being expected to affect DMS production and emissions in the future. Changes in marine DMS production has been observed in a diversity of ecosystems such as coral reefs, upwelling ocean, mangrove, saltmarsh and seagrass environments. However, the extend and consequences of these changes still remain to be evaluated in order to make appropriate predictions for the fate of DMS in a changing ocean. Here, we provide a brief review of the prospective changes to DMS production across the various marine ecosystems.

DELIMITING REEF SPECIES USING HETEROZYGOSITY (Abstract ID: 29816)

Molecular taxonomists commonly turn a blind eye to heterozygosity by discarding loci that display intra-individual heterogeneity, by excluding heterozygotes from their analyses and/or by retaining only one of their allelic sequences. Indeed, the chromatograms of heterozygotes were long considered impossible to resolve without cloning since they contain double peaks. However, bioinformatic tools such as my programs Champuru and SeqPHASE are now available to unravel mixed chromatograms. Once the haplotypes of a collection of individuals have been determined accurately using Sanger or next-generation sequencing, knowing which alleles co-occur in heterozygotes makes it possible to delineate species in an accurate and sensitive fashion. Here I present a graphical method that relies on haplotype webs (in short, haplowebs) to delineate reef species. Haplowebs are trees or networks of haplotypes on which curves are added to connect haplotypes found co-occurring in heterozygous individuals, thereby providing an easy, intuitive way to delineate groups of individuals sharing a common gene pool. In contrast to other popular approaches such as ABGD and GMYC that are geared towards species-rich datasets, haplowebs are well-suited to detect species boundaries in species-poor systems, e.g. when the hypothesis that all the individuals sampled are conspecific cannot be rejected beforehand. Haplowebs do not assume species monophyly nor the existence of a barcoding gap. Besides, haplowebs can be used to detect introgression and hybridization.

MANAGEMENT RELEVANT INTERPRETATION OF REEF MONITORING DATA (Abstract ID: 29714)

Coral reef monitoring is expensive and time consuming, but the data collected is only infrequently used to guide management actions. One reason for this is that managers and conservation practitioners lack a simple guide for interpreting and understanding the ecological meaning of the monitoring data. Here we develop such a guide, using a medical "diagnosis" and "prognosis" approach. Based on evidence from the published literature we provide a guide to interpreting the temporal trends in the main coral reef monitoring attributes recorded by the seven largest coral reef monitoring programmes. Using select indicators from this guide, we propose a simple decision process for diagnosing the main stressor(s) that have impacted a reef. Finally, we integrate the diagnosis with further indicators to provide a prognosis for a reef; a measure of the recovery potential of the reef. Although previous studies have suggested the use of the medical examination approach for coral reefs, this is the first study to develop this method using commonly collected, or easy to collect, reef monitoring data. Our work offers reef managers a guide to what variables to focus monitoring on, and simple methods for interpreting monitoring data to guide management decisions.

EXTENSIVE PHENOTYPIC VARIATION IN CARIBBEAN ACROPORID HYBRIDS IS LIKELY A MECHANISM FOR ADAPTATION TO CHANGING ENVIRONMENTS (Abstract ID: 29469)

The merging of two genomes through hybridization produces a unique combination of traits and phenotypic variation in the hybrids. This phenotypic variation may promote hybrid adaptation to habitats not accessible to the parent species. While hybridization is common in corals, evidence for adaptation to new habitats due to morphological innovation in coral hybrids is missing. In the past, hybridization between Caribbean Acropora palmata (elkhorn) and A. cervicornis (staghorn) corals was rare and restricted to the F1 generation. New genetic data indicates that hybrids are now mating with each other and are capable of mating with A. palmata and A. cervicornis. In parallel, a variety of intermediate morphologies to the arborescent staghorn and elkhorn shaped parental species are now observed. Here, we conducted morphometric analyses using high-resolution 3D scans and scanning electron microscopy on Caribbean acroporid colonies representing the continuum of phenotypes between A. cervicornis and A. palmata and correlated the data with the genetic origin of the hybrid (i.e. F1, F2 or backcross). These data together with recent field observations of higher disease resistance, higher thermal tolerance, higher hybrid abundance, and hybrid habitat expansion suggests that the hybrids' ecological role and evolutionary potential is changing. Thus, coral hybrids are a possible and probable mechanism for coral adaptation to changing environmental conditions.

SIZE-MATURITY INDICATORS IN QUEEN CONCH OF PORT HONDURAS MARINE RESERVE, BELIZE; STRENGTHENING MANAGEMENT FOR IMPROVED FISHERIES SUSTAINABILITY (Abstract ID: 28736)

Queen conch (*Lobatus gigas*) is an important food source and economically important export product in Belize. Overfished in many parts of the Caribbean, international trade of *L. gigas* is regulated by CITES. This study compares relationships between gonad development and shell length, lip thickness (LT), lip width, meat weight, market-clean weight and operculum dimensions to determine the most reliable proxy indicator(s) of maturity in*L. gigas* specific to Port Honduras Marine Reserve (PHMR), south Belize. Until recently, PHMR enjoyed a relatively stable population, regulated by a 17.8cm national shell length limit or 85g market-clean meat weight, a 3-month closed season, and full protection in Replenishment Zones. However, TIDE fisheries-independent surveys indicate population decline with diminished reproduction since 2013. Fisheries-dependent catch surveys reveal the proportion of catch with LT <9mm (minimum maturity threshold in other studies) increased from 30% in 2009 to 90% in 2012. Other studies show LT is a more reliable indicator of maturity, but that maturity relationships vary on local and regional levels and therefore need to be determined locally. Phase 1 (late open season) LT: maturity relationships were stronger for males than females, with >80% probability that males >25mm LT are or have been spawning capable. Phase 2 results (closed reproductive season) are expected to yield stronger relationships for females. Recommendations are made for size limit revisions to achieve long-term sustainability of *L. gigas* in PHMR while meeting economic needs of fishers. http://www.tidebelize.org/project/marine

WHY ARE SOME EASTERN TROPICAL PACIFIC REEFS SO RESILIENT TO ENSO? BIOASSAYS REVEAL INCREASED HERBIVORY AND NUTRIENT LIMITATION DURING ENSO (Abstract ID: 28877)

Long term studies of reefs in the Eastern Tropical Pacific before, during and after 2 major ENSOs (82-83, 97-98) revealed that some reefs showed remarkable resilience through rapid recovery of coral cover. We hypothesized that increased herbivory and nutrient limitation during ENSO may limit algal proliferation during warming events and therefore facilitate coral recovery. We conducted short-term bioassays using dominant species of macroalgae to compare the relative strength of these top down and bottom up forces prior to and during ENSO-associated warming in 2 sites in Panama and 1 in the northern Galapagos. At both sites in Panama herbivory rates increased ~ 60% during warming conditions. While nutrient limitation was strong prior to warming in both sites, during warming algae was only able to maintain positive growth when nutrient limitation was reduced by added nutrients, even while protected from herbivores. In the Galapagos, herbivory was extremely strong regardless of warming. In contrast, nutrient limitation varied greatly across sampling times. Prior to warming, algal growth in ambient nutrients was vigorous (40-50% increase in 3 days) and increased up to 90% with added nutrients; however, even mild warming conditions in the Galapagos caused up to 75% loss of algal biomass, even while protected from herbivores, regardless of experimental nutrient addition. If intensification of the strength of these processes limiting algal proliferation is maintained, this may facilitate coral recovery. However, it is possible La Nina may reverse this process and facilitate algae.

THE MACROECOLOGY OF AGONISTIC INTERACTIONS IN REEF FISHES (Abstract ID: 29842)

Biotic interactions may influence species coexistence and act as an important selective pressure for evolution. In coral reefs, interspecific competition can alter spatial distribution of reef fishes and is mainly influenced by variation in habitat quality and species density. Only a few studies have addressed this issue over large spatial scales. Therefore we aimed to investigate the relationship between regional richness and the structure of agonistic interactions of reef fishes. Our dataset comprised seven tropical reefs across four biogeographic provinces (Brazil, Caribbean, Central Pacific and the Coral Triangle). Species richness and agonistic interactions data were collected through remote videos of shallow sheltered reefs, each sample consisting of a 2m 2 area during 10 min. We observed a higher species accumulation in regionally richer localities and a positive relationship between local and regional richness. For interactive species, we observed the same trend in species accumulation, but not the local and regional relationship. This pattern can be explained by the increasing species turnover towards richer regions. Moreover, the complexity of agonistic networks increased according to the regional richness gradient. Damselfishes, surgeonfishes and labrids mainly structured the networks in all regions and territorial herbivores performed a central role in all local communities. Our study identified key functional groups in agonistic networks and highlighted the increase in diversity of interspecific interactions towards increasing regional species richness. http://www.lbmm.ufsc.br

COMMUNITY-BASED SOCIAL MARKETING – THE CONSERVATION TOOL MOST OF US AREN'T USING BUT PROBABLY SHOULD BE (Abstract ID: 29020)

Community-Based Social Marketing (CBSM) aims to influence behavior in support of conservation objectives through a well-defined strategic process that is informed by social psychology and incorporates quantitative research and evaluation methods. CBSM is underutilized and often misunderstood, but has great potential to foster sustain-

able behavior and effect change. Several case studies and their accompanying media and communication strategies will be presented and critically examined, including the West Maui Kumuwai Campaign, an ongoing effort focused on reducing the land-based pollution that impacts coral reefs. ----- *I'm hoping to further edit this abstract later on if possible, when I don't have pneumonia...

INCONSISTENCIES BETWEEN TRADITIONAL AND NEW MONITORING TECHNIQUES FOR ASSESSING CORAL REEF RESILIENCE: AN EXAMPLE FROM FIJIAN LOCALLY MANAGED MARINE AREAS (Abstract ID: 29238)

Considering increasingly stressful conditions for coral reefs, it is critical to evaluate the effectiveness of varying management tools. In this context, it is essential to develop tools which identify ecosystem trajectories and provide early warnings of reef degradation. To achieve this, surveys should look beyond standard monitoring parameters (i.e. herbivore biomass, benthic cover), by quantifying system processes (i.e. herbivore grazing, algal turnover, coral recruitment), and complementing status parameters (i.e. turf algae length which could affect coral recruitment, state of coral-algal interactions that indicate competitiveness, damselfish movements which influence algal dynamics). A comprehensive review allowed us to develop a suite of informative parameters that were applied in Fiji, where locally managed marine areas (LMMAs) are well-established and allow an evaluation of community-based management. Surveys covered two depths inside and outside of three enforced inshore LMMAs. Location and water quality analyses confirmed that differences between paired reefs were driven by management. Tentative results highlight a decoupling between the findings of traditional monitoring and our parameters. For example, although benthic composition and fish biomass were similar inside and outside of LMMAs, the former displayed significantly shorter turf length and higher coral recruitment, implying that LMMAs can indeed enhance reef resilience. We propose a combination of process and status parameters that should be considered to improve evaluation of management effectiveness.

ISLAND GROWTH DURING RISING SEA LEVEL: JEH ISLAND, REPUBLIC OF THE MARSHALL ISLANDS (Abstract ID: 29552 | Poster ID: 401)

Low-lying reef islands are coral reef associated deposits of biogenic sediment considered highly vulnerable to the effects of sea level rise (SLR). One of the most frequently discussed impacts of continued SLR is the destabilisation and 'washing away' of reef islands. However, recent studies from throughout the Pacific have shown that reef islands have been predominantly stable or have accreted since the mid-20th century, a period coincident with accelerating rates of SLR. In order for shorelines to accrete and drive island growth there must be a supply and delivery of sediment to the island. The sediment contributing to island growth can either be generated under contemporary conditions, or relic sediments which have previously been stored within the reef framework, or within sub- and inter-tidal or island deposits. Establishing whether islands can accumulate modern sediment is critical to understanding future trajectories of reef island change. This study focusses on the island of Jeh on Ailinglaplap Atoll, where aerial photos from 1943 and satellite imagery from 2010 reveal pronounced island change and growth. Using radiocarbon dating of recently deposited sections of Jeh Island we are able to determine that island growth is on-going and largely driven by the accumulation of modern sediment. The growth of the island has occurred coincident with locally increasing sea level and these results highlight the importance of sediment supply in the response of islands to further SLR.

A COMPREHENSIVE MOLECULAR AND MORPHOLOGICAL STUDY OF CERIANTHARIA (ANTHOZOA,CNIDARIA) ACROSS SEAS (Abstract ID: 27771)

Cerianthids or tube-dwelling anemones (order Ceriantharia) are cryptic, solitary polyps that live buried in soft sediments in self-constructed tubes, which are made of a fibrous material made from secreted mucus and a kind of cnidocyst-like cells, known as ptychocysts, which are unique to this order. Recently cerianthids came to the attention of the scientific community because of their resilience and dominance in anthropogenic disturbed costal areas including coral reefs. To date little is know about cerianthid phylogeny and geographical distribution. Here we present a phylogenetic and morphological characterization of cerianthids collected at several locations: Mediterranean, Baltic Sea, Celebes Sea, Red Sea and Pacific Ocean. During this effort we identify few new species and shed lights on their, until now confusing, phylogeny. Furthermore we extensively characterized their elegant cnidocyst macromolecular structure at an unprecedented resolution. This work and the data presented here will help to better understand this order of marine invertebrates that are likely to become an important assessors of ecosystems perturbance.

LARVAL REEF FISH RESPOND TO DIMETHYL SULFIDE AND HOME TO ITS SOURCE (Abstract ID: 28203)

Transport of coral reef fish larvae is driven by advection in ocean currents and larval swimming. For swimming to be advantageous, larvae must use external stimuli as guides. A potential stimulus is "odor" emanating from coral reefs, which signals the upstream location of desirable habitat. However, specific chemicals and mechanisms for plume tracking have not yet been identified. Dimethyl sulfide (DMS) is produced in large quantities at coral reefs and may be an important cue. In this study, a choice-chamber (shuttle box) was used to assess preference of reef fish larvae for water with DMS and potential changes in swimming behavior. Video tracking of larval movement was used to compare swimming patterns in control and DMS seawater. We found a common response to the presence of DMS across taxa – a preference for water with DMS and a significant increase in turning frequency - reflecting a switch to "search behavior". Detailed patterns of movement when encountering a dyed DMS plume were monitored in a large flume tank to assess whether and how larvae were able to locate the source of DMS. Larvae quickly located the source of odorous plume injections in the flume but did not respond to plumes of non-odorous dye in seawater. Affinity for and swimming response to relevant concentrations of DMS allows a fish larva to locate its source and would enhance its ability to find settlement sites. Moreover, it may help them locate high concentrations of prey accumulating in fronts, eddies, and thin layers, where DMS is also produced.

PARSING METAGENOMIC LOCI FROM THE CORAL HOLOBIONT: NEW INSIGHT INTO UNRESOLVED SPECIES COMPLEXES IN PORITES, POCILLOPORA, AND MONTIPORA. (Abstract ID: 28090)

Genetic studies of non-model organisms have been restricted to a few markers that have limited resolution and utility, resulting in gaps in the understanding of the ecology, evolution, biodiversity, biogeography, extinction risk, and adaptive potential of organisms such as reef building corals. Next Generation Sequencing approaches such as RAD sequencing have shown promise for resolving both very recent and ancient divergence; however, the absence of reference sequences creates major challenges for the identification and comparison of loci particularly for metagenomic datasets such as the coral holobiont. Here, we discuss several strategies for identifying and parsing loci from components of the coral holobiont, including reconstruction of complete or nearly complete mitochondrial genome, the ribosomal array, histones and a diverse set of coral protein coding genes. The resulting data provides unprecedented resolution into unresolved species complexes. We present several examples of the application of these methods towards Porites, Pocillopora, and Montipora. We find surprising mitochondrial-nuclear discordance in Porites consistent with hybridization, supported by STRUCTURE analysis from thousands of SNPs. In contrast, Pocillopora and Montipora have strong concordance among nuclear and mtDNA datasets, allowing us to examine within species variability for these genera, including M. dilatata, one of the rarest known corals. The ability to extract and compare known loci from these metagenomic datasets will further improve as more reference sequences become available, providing additional insights into the ecology, evolution, and conservation of reef building corals.

GROWTH AND LONGEVITY OF ICONIC REEF FISHES IN VERDE ISLAND PASSAGE, PHILIPPINES (Abstract ID: 28588 | Poster ID: 260)

Scarus niger and Acanthurus pyroferus are important iconic grazers in the Northern part of the Verde Island Passage, Philippines. Hence, important life history characteristics must be established for purposes of managing their population. The study focuses on the age and size relationship of these reef fish species using the von Bertalanffy growth function. Fish sample size for S. niger (n=146) ranged from 143.6 to 268.2 mm with age estimates ranging from 3 to 12 years. For the collected A. pyroferus samples (n=38), standard length ranged from 119.5 to 159.5 mm with age estimated between 5 to 9 years. Morphometric characters of otoliths (i.e., size and shape) were also examined to determine any relationships that would help verify the validity of the age estimates. The results showed that the size (SL) of both species had strong and linear relationship with their wet body weight (g) establishing an isometric growth pattern (b≈3.0) for both species. Furthermore, linearity between otolith width (mm) and otolith weight (mg) was observed in females only and strong linear relationship between otolith index, fish size (SL) and body weight (g) for both species. In general samples collected for both species were at their rapid growth stage and reflected strong linear relationship between their age and body size. The initial batch of samples collected was at their mid- to large body size range. Thus, collection in the next two months will now target smaller and much younger fish to complete the growth history curve for both species.

A COMPARISON OF SYMBIOTIC DINOFLAGELLATE (SYMBIODINIUM) COMMUNITIES IN HEALTHY SIDERASTREA SIDEREA CORALS AND THOSE AFFECTED BY DARK SPOT SYNDROME (Abstract ID: 28909 | Poster ID: 160)

Dark Spot Syndrome (DSS) is an indicator disease prevalent in coral reefs throughout the Caribbean. Often DSS is non-fatal though it can lead to more aggressive diseases such as Black Band Disease (BB) and Yellow Band Disease (YB). Although ubiquitous, little is known about the cause and spread of DSS. This study aims to further characterize the symbiotic dinoflagellate community and potential factors leading to DSS in Siderastrea siderea corals by microbial comparison of healthy and DSS affected corals from one time point. To study this syndrome, Symbiodinium communities were collected from coral mucus samples and were identified using high-throughput techniques to elucidate potential factors of disease progression. In both healthy and DSS affected samples, no significant differences were found in the relative abundance of mucus associated Symbiodinium communities, implicating that DSS is a multi-faceted syndrome that does not directly impact the photosynthetic Symbiodinium of afflicted corals.

HAWAII'S ENVIRONMENTAL COURT - BRIDGING SCIENCE TO POLICY THROUGH IMPROVED ADJUDICATION OF RESOURCE VIOLATIONS (Abstract ID: 28244)

This paper will examine Hawaii's Environmental Court, established in 2014. Although environmental courts exist in other states, Hawaii's Environmental Court is the first in the nation with a strong emphasis on natural resource management and enforcement. The Court was established largely in response to the State's difficulties enforcing and adjudicating its laws pertaining to aquatic and terrestrial resources. In addition to other challenges, the State Department of Land and Natural Resources was having difficulty achieving positive outcomes for cases involving legally or scientifically nuanced violations. In response to this problem, the Hawaii State Legislature established the Environmental Court. The legislation provided the Court with exclusive jurisdiction over nearly all of the state's natural resource statutes. Under the Court's structure, the judiciary trains designated judges to hear resource violation cases. Many of the training materials are developed in collaboration with scientists and resource managers working in corresponding subject matter areas for the State of Hawaii. This results in enhanced judicial awareness about the impact of resource violations on ecosystems and the communities that reside therein. Establishment of the Court represents a meaningful and collaborative effort by policymakers, resource managers and members of the judiciary to ensure that resource violations receive the attention they deserve by persons with specialized knowledge regarding environmental issues.

CONSERVING HAWAIIAN COMMERCIAL HARBOR CORAL REEF RESOURCES IN A S.M.A.R.T. WORLD BY KEVIN B. FOSTER (Abstract ID: 28913)

Large plate corals, seagrass meadows, green sea turtles, marine plants, non-coral invertebrates, and reef fish make their home in Hawaiian commercial harbors. The U.S. Army Corps of Engineers (USACE) is responsible for maintaining or expanding federal limits within commercial harbors; conducting maintenance or new dredging to meet safety considerations, or expanding the turning basins to accommodate larger cruise ships and cargo vessels. The USACE coordinates project planning activities with the U.S. Fish and Wildlife Service, National Marine Fisheries Service and State of Hawaii's Division of Aquatic Resources. Recent surveys document extensive resources that have adapted to commercial harbors despite altered water quality conditions, such as exposure to fresh water, sediments and pollution. These hardy individuals may present clues towards the future survival of coral reefs in a changing climate. The USACE's adoption of the SMART planning process, nationally, is intended to streamline feasibility studies and expedite project completion, potentially at the expense of adequate mitigation for Hawaiian coral reef resources. The USACE's Honolulu District Civil Works Division has the lead for implementing the SMART process locally and therefore, a new paradigm should be developed and standardized when coordinating the evaluation of project alternatives and recommendations for mitigating project impacts to coral resources with state and federal resource agencies.

OCEAN ACIDIFICATION CAUSES STRUCTURAL DEFORMITIES IN JUVENILE CORAL SKELETONS (Abstract ID: 28010)

Rising atmospheric CO2 is causing the oceans to both warm and acidify, which could reduce calcification rates of corals globally. Successful coral recruitment and high rates of juvenile calcification are critical to the replenishment and ultimate viability of coral reef ecosystems. While elevated pCO2 has been shown to reduce the skeletal weight of coral recruits, the structural changes caused by acidification during initial skeletal deposition are poorly known. Here we show, using high resolution 3-dimensional X-ray microscopy, that ocean acidification (pCO2 ~ 900 uatm, pH ~7.7) causes not only reduced overall mineral deposition, but also a deformed and porous skeletal structure in newly settled coral recruits. In contrast, elevated temperature (+3°C) had little effect on skeletal formation except to partially mitigate the effects of elevated pCO2. The striking structural deformities we observed show that new recruits are at significant risk, being unable to effectively build their skeletons in the pCO2 conditions predicted to occur for ocean surface water under a 'business-as-usual' emissions scenario (RCP 8.5) by the year 2100.

NATURAL VS. ANTHROPOGENIC SEDIMENTATION: DOES REDUCING A LOCAL STRESSOR INCREASE CORAL RESILIENCE TO CLIMATE CHANGE? (Abstract ID: 28236)

Corals face worldwide population declines due to global climate change and local anthropogenic impacts. Global climate change effects are hard to tackle but recent studies show some coral species can better handle climate change stress when provided with additional energy resources. The local stress that most undermines energy acquisition is sedimentation because it impedes coral feeding and their ability to photosynthesize. To investigate if reducing local sedimentation will enable corals to better endure global climate change, we quantitatively assessed the synergistic effects of increased temperature, sediment concentration, and sediment composition on the survival and growth of juvenile *Porites astreoides*. We used sediment from a reef and a boat basin to mimic natural sediment (more coarse) and anthropogenic sediment (finer grain sizes, more common in dredging operations). The most detrimental effects were observed with anthropogenic sediment. We found that corals' capacity to deal with higher temperatures is improved when anthropogenic sedimentation is maintained at minimal levels. Our study suggests that a reduction of allowable NTU's from 29 to 7 near coral reefs should facilitate coral juvenile survival under higher temperatures. Additionally, dredging operations should be conducted in Winter to minimize synergistic effects of temperature and sedimentation.

STRENGTHENING SCIENCE AND CAPACITY FOR CORAL REEF CONSERVATION (Abstract ID: 29898)

Effective coral reef conservation relies on ecological and social monitoring and evaluation to inform adaptive management. With potentially high costs of monitoring and most coral reefs in developing countries, strategies to ensure a good return on investment are critical. These include investing in aspects of monitoring beyond data collection (e.g., study design, data management, communication); and strengthening local scientific capacity for this full cycle of monitoring. We highlight initiatives in the Coral Triangle and beyond that aim to increase scientific value of monitoring without significantly increasing costs. 1) In the Bird's Head Seascape of Indonesia, long-term investments were made to build capacity of local staff to manage, analyze, interpret and communicate data. 2) In five countries with high marine biodiversity and community dependency on fisheries (Belize, Brazil, Mozambique, Indonesia, and the Philippines), a monitoring program was designed to evaluate the outcomes of TURF-reserves (territorial use rights for fisheries and no-take reserves) coupled with community engagement. Both efforts seek to support site-level adaptive management as well as multi-scale analyses to inform marine conservation policy, and both required increased attention to study design and data management. This has spurred innovative tools to enhance collaborative analysis and communication, offering tremendous opportunity for advancing science and laying the foundation for scaling effective and efficient approaches to place-based marine conservation and fisheries management.

REGIONAL-SCALE OCEANOGRAPHY INFLUENCES BENTHIC CORAL REEF COMMUNITY STRUCTURE IN THE REMOTE CENTRAL PACIFIC (Abstract ID: 29881)

Increased inorganic nutrient concentrations are often associated with changes in community structure on coral reefs, particularly shifts from coral to macroalgal-dominated states. Yet experimental manipulations of nutrients have often been conducted over limited temporal scales and do not examine ecosystem-scale responses. Using five uninhabited islands that span a natural gradient of nutrient availability in the remote central Pacific, we examined how distinct nutrient regimes relate to the structure of benthic coral reef communities in the absence of local human impacts. Specifically, we tested how this natural gradient influenced the relative abundance of key benthic taxa and the proportion of autotrophy to heterotrophy in common coral species across depth (5-30 m). We hypothesized that corals on more nutrient-limited reefs would exhibit higher dependence on autotrophy at shallower depths while corals on more nutrient-replete reefs would exploit heterotrophic resources at all depths. Ambient inorganic nitrogen concentrations ranged from 0.46-4.45 μ mol · $L^{-1}$and we observed diverse patterns in coral and algal cover across this gradient. Coral cover varied from 5-87% and 0-78% at 5 and 30 m, respectively. Heterotrophy in corals correlated positively with nutrient availability and did not exhibit clear depth zonation at more nutrient-rich islands. These results suggest that natural nutrient delivery can have dynamic impacts on benthic coral reef communities that are more complicated than direct shifts towards macroalgal-dominance.

DIFFERENCE IN SUBSTRATE COVERAGE BETWEEN A DISTURBED AND AN UNDISTURBED CORAL REEF SITE AND THE IMPLICATIONS FOR FISHERIES MANAGEMENT (Abstract ID: 28854 | Poster ID: 410)

This study was conducted in the Dampier Straight, Raja Ampat, Indonesia, one of the most biodiverse coral reef regions in the world. Two sites were chosen, a disturbed reef that was in very close proximity to a fish farm, as well as the presence of boating detritus and an undisturbed reef site that had no such anthropogenic influences present. Comparison of visual differences in substrate coverage were examined at each reef. Six, 20 meter transects were completed at each site. A photograph was taken every two meters on the transect and were later examined to determine percent cover. Four different categories were created for substrates to determine percent cover: hard coral, soft coral, algae and other/ unknown, such as sand or live rock. Prominent species of coral and algae were also noted for each of the photos. After analyzing the data using an independent samples t-Test, results showed significantly more algae cover at the disturbed site compared to the undisturbed site. Significantly more soft coral and unknown coverage was measured in the undisturbed site compared to the disturbed site. There was no significant difference between sites in terms of hard coral coverage. Understanding the conditions necessary for the support of diverse reef ecosystems, and the possible threats that could cause them to deteriorate is critical for the effective management of fisheries and development of marine sanctuaries.

DISTANCE DECAY IN SIMILARITY OF CORAL REEF COMMUNITIES (Abstract ID: 29073)

Distance decay of community similarity is a fundamental concept in ecology, where near things are more related than distant things, and was once known as the "First Law of Geography". Nevertheless, despite the fundamental importance of distance decay for understanding the processes that structure assemblages of species, almost all our understanding of this phenomenon comes from studies of tropical plant communities. In this study we quantify distance decay in a marine invertebrate community by comparing scleractinian coral assemblages along an 1100km latitudinal gradient on the Great Barrier Reef. We also compare the rates of distance decay between three distinct habitats; outer shelf, lagoonal and mid-shelf reefs. Despite the general view that marine systems are more 'open' than terrestrial systems, we find overall distance decay to be as strong in marine benthic assemblages as in terrestrial assemblages. We use the novel method of beta-diversity partitioning to look further into the processes that cause this distance decay, and find that differences in taxonomic β–diversity between reefs are governed by species replacements rather than a net change in diversity (species loss or gain). Furthermore, the replacement of species appears to be by species from within the same functional group, as no distance decay of functional β–diversity was found. These analyses indicate that species replacement is not a random process, and our results therefore provide insight into the environmental and biological processes that structure coral reef assemblages.

PUTTING MARINE POLICY INTO PRACTICE: THE USE OF POLICY IN MARINE PROTECTED AREA MANAGEMENT (Abstract ID: 27869)

An ever-growing range of environmental, legal and policy initiatives, such as international agreements, laws and conventions aim to protect biodiversity, and improve management of human activities which impact on marine environments. Along with policies at the international level, complexity is added by a range of national and state policies. For effective management to occur, the intent and goals of these policies at various jurisdictional levels need to be harmonised and integrated. Fragmented sector-based marine management is likely to be a major contributor to the decline in health of oceans, where problems created by a patchwork of policy constrain achievement of management goals. We analyse how the management of Australian marine protected areas (MPAs) is undertaken when applying a range of policy, agreements and legislation, and how the policy implementation process is actually achieved. The implementation of complex marine environmental protection policy requires cooperation and communication amongst key institutions and actors, and necessitates establishment of clear hierarchies, detailed objectives, and specific roles and responsibilities of those implementing policy. We conducted semi-structured interviews with MPA managers, practitioners and policy makers across several Australian jurisdictions. Qualitative data from interviewee responses were categorised, and themes identified. Our results provide evidence for future improvement of policy development, implementation processes, and MPA outcomes in Australia and beyond.

IMPACTS OF INVASIVE LIONFISH ON NATIVE FISHES FOUND ON CONTIGUOUS CORAL REEFS SURROUNDING LITTLE CAYMAN ISLAND, BVI (Abstract ID: 29631)

Indo-Pacific lionfishes in the western Atlantic Ocean and broader Caribbean region generate concerns about reduced abundances of native fishes, increased competition with native piscivores and disrupted trophic interactions. Many hypotheses regarding potential consequences of the invasion arise from studies of patch reefs, but studies of larger, contiguous reefs should yield broader insights that will improve management. On such reefs off Little Cayman Island, BVI, lionfish were culled from 3 experimental sites in each quarter for 3 years. In conjunction, lionfish and potential prey fishes were counted along 50 m x 2 m transects at each of the culled sites and at 3 nearby control sites. Culls maintained reduced numbers of lionfish, and analyses indicated a broad diet and a shift to piscivory for 1-4 year-old lionfish. Counts of 89 potential prey species did not indicate ecologically important variation in presence/absence, diversity or evenness between culled and control sites. Twenty-seven species exhibited ecologically important differences in abundance, with multiple species commonly found in lionfish stomachs being more abundant at culled sites (e.g., blue chromis, Creole wrasse, masked goby, fairy basslet and blackcap basslet). The remaining 62 species were more abundant at sites with lionfish, or they exhibited variable abundances. Thus, this study provides insight into the feeding habits of lionfish, a valuable documentation of "realized" impacts from lionfish predation and reason to believe that detrimental impacts can be managed effectively using culling.

IMPACT OF GROWTH ANOMALY ON GENE EXPRESSION IN THE CORAL *MONTIPORA CAPITATA* (Abstract ID: 30008 | Poster ID: 27)

Growth anomaly (GA) is a coral disease of unknown etiology that affects corals around the world. GA exhibits high prevalence in a common Hawaiian coral, *Montipora capitata*, at the study site in Waiopae, Hawaii. We used RNA-seq to analyze coral tissue from healthy colonies, GA lesions, and apparently healthy regions of GA-affected colonies to explore the molecular pathology of GA. To isolate the transcriptional patterns of coral holobiont constituents, our *de novo* transcriptome assembly was filtered into putative coral (15,585) and *Symbiodinium spp.* (21,265) transcript subsets. Both coral and *Symbiodinium* transcriptomic patterns were most highly correlated with the *Symbiodinium* clade harbored by the host, with 1,767 and 7,804 differentially expressed genes, respectively (FDR>0.001, FC>2). Despite such strong influence of *Symbiodinium* clade on host transcription (detailed in another presentation), we identified 121 coral genes that were differentially expressed among tissue types (FDR>0.05, FC>1.4), while no *Symbiodinium* genes showed differential expression among tissue types. Pair-wise comparisons of coral gene expression among tissue types revealed the greatest difference between GA lesions and healthy colonies. The functions of these genes are consistent with reported physiological impacts of GA on coral, and may provide hints to understanding the etiology of this disease. This study shows the utility of RNA-seq to understanding molecular pathology, as well as the interactions among coral host and symbiont.

SOFT CORALS AS QUORUM SENSING MIMICS? NEW PERSPECTIVES ON WELL-KNOWN COMPOUNDS (Abstract ID: 30168 | Poster ID: 152)

Quorum Sensing (QS), a mechanism coordinating gene expression across bacterial populations, is a potential pathway of interaction between a host organism and its associated microbial community. QS signal molecules are extracellular, allowing their interference and mimicry. The active site of, acyl homoserine lactones, well-known QS signal molecules, includes an oxygenated ring. Many Alcyonacean soft corals contain cembranoid diterpene metabolites that possess similar structural features. Bioactivity in cembranoid diterpenes have been heavily studied but no consensus has yet been reached on their *in situ* ecological roles. This study investigated the potential for QS to mediate interactions between soft corals and their associated bacteria with four questions. 1) Do soft coral extracts demonstrate QS activity; 2) Do bacteria associated with soft coral surfaces utilise QS systems; 3) Is any QS activity due to cembranoid diterpenes; and 4) Is there QS activity in the absence of cembranoid diterpenes? Bacterial biosensors in combination with chromatography, structure elucidation and molecular biology techniques were used to address these questions. QS activity, both induction and inhibition, was prevalent amongst soft corals extracts and bacterial isolates tested. Variations in the oxygen ring of cembranoid diterpenes resulted in a change from QS induction to QS inhibition. Finally, the presence of a non-cembranoid diterpene QS mimic was established in the soft coral *Nephthea brassica*. Results suggest QS interference may help mediate bacterial communities.

DIVERSITY IN SPONGE HOLOBIONT FUNCTIONING: THE ROLE OF MICROBIAL ABUNDANCE, HOST SPONGE IDENTITY, AND GEOGRAPHY (Abstract ID: 29719)

Although marine sponges are frequently placed into functional categories based on their overall microbial abundance (High and Low Microbial Abundance [HMA and LMA]), recent research has shown that these communities and overall interactions are highly variable across individual species. To elucidate the role that overall microbial abundance, photosymbiont abundance, host sponge identity, and geography play in holobiont C and N cycling, we used a stable isotope approach in conjunction with multivariate and ellipse-based analyses. This allowed us to evaluate the core isotopic niche of a species or group and investigate factors driving the placement of individuals within isotopic space. Up to 14 sponge species were collected from three Caribbean sites (Panama, Honduras, and Belize), the Florida Keys, and a temperate reef off Georgia, USA. Some variation was attributed to geographic location, but this effect was greatly minimized when data from the temperate reef were excluded. Within individual sites, HMA and LMA groups filled unique niche space. However, host identity accounted for at least 70 percent of the variation in isotope values within a site, while photosymbiont and overall microbial abundance accounted for a much lower proportion of this variation. Together these data suggest that microbial symbionts may allow sponges to expand into novel niche space on tropical reefs, but species placement within isotopic space is relatively stable and is likely structured more by host-specific microbial community composition than by overall microbial or photosymbiont abundance.

ON THE DISTRIBUTION OF REMOTELY SENSED CORAL REEF REFLECTANCE WITHIN THE HAWAIIAN ISLANDS AND PAPAHĀNAUMOKUĀKEA MARINE NATIONAL MONUMENT (Abstract ID: 28396)

Coral reefs are among the most diverse, productive ecosystems worldwide & provide economically important services to many coastal nations. Within the state waters of Hawai'i the net economic contribution of coral reefs is approximately $360 million/year & the overall value is estimated at nearly $10 billion. Coral reef health, diversity, & cover are thought to be declining globally in response to pressures from human activity & climate, resulting in the need for more efficient & accurate monitoring methods. Thus, remote sensing from aircraft & satellites is viewed as a potentially important tool for reef ecosystem scientists & resource managers alike. As a test of potential remote sensing application, spatial & temporal gradients in remotely sensed coral reef reflectance are investigated for reef systems within the Hawaiian Islands & adjacent waters of the Papahānaumokuākea Marine National Monument. Spectral reflectance is used to estimate coral reef ecological state, expressed as combinations of three spectrally unique regimes: 1) healthy calcifying corals, 2) turf and coral rubble-dominated, & 3) fleshy macroalgae. Remotely measured coral reef reflectance is verified with reflectance models using in situ measurements of benthic reflectance. Coral reef regime is derived as a function of location & time from remotely sensed imagery collected via aircraft & satellites. Computed spatial & temporal gradients in regime coverage is explored as possible functions of direct human impact, e.g., proximity to population centers, & climate, e.g., water temperature.

ASSOCIATIONS BETWEEN CORAL REEF SOUNDSCAPES AND TROPHIC GROUPS IN THE HAWAIIAN ISLANDS (Abstract ID: 27902)

Passive acoustic evaluation and monitoring of coral reefs may offer a fast, quantitative technique that reveals aspects of ecological function important for resource management. Here we report associations between visually observed nocturnal and diurnal reef

ecology, and spectral aspects of reef soundscapes from 23 sites throughout the Hawaiian archipelago. Results integrated over all field sites suggest that larger, highly mobile predatory fishes were correlated with low frequency (< 2 kHz) daytime and evening sound levels. The presence of small benthic fish and herbivorous fishes were also correlated with sound levels in this band. Reef-based predatory fishes were correlated with higher frequency (1-20 kHz) evening sound levels. The nocturnal presence of benthic crustaceans was also associated with evening sound levels in bands up to 20 kHz. In addition to an association with sound level magnitudes, variability in observed numbers of crustaceans, herbivorous fishes, and echinoderms was correlated with the temporal variability of the soundscape components with which their presence was associated. These results suggest that sound levels in certain frequency bands are associated with unique groups of organisms, and that predators may use these sounds as cues to seek areas where appropriate prey are more abundant. Cost-effective and more accurate coral reef monitoring techniques are urgently required. Using associations such as these, remote and autonomous passive acoustic recording devices may be used to identify reef areas where ecological functionality is more robust.

EVIDENCE FOR FINE-SCALE NICHE PARTITIONING OF *PARACIRRHITES*-SPECIES AT FLINT ATOLL (SOUTHERN LINE ISLANDS) VIA METAGENOMIC ANALYSIS OF GUT CONTENTS (Abstract ID: 30051)

Niche partitioning and trophic/functional versatility are known to influence patterns of speciation among coral reef fishes. Current trophic designations of reef fishes are coarse, however, suggesting dietary overlaps which seemingly conflict with Gause's law of competitive exclusion. Fine-scale differences in diet beyond that of traditional designations are likely, but perhaps undescribed. Hawkfishes in the genus *Paracirrhites* are an apt model system with respect to speciation and ecological niche differentiation, exhibiting striking differences in coloration in addition to described differences in habitat and potential foraging preferences. Fish from four*Paracirrhites* species were collected from Flint Atoll in the Southern Line Islands of the Republic of Kiribati. Analysis of the metagenomic data from hindgut samples revealed differences in taxonomic composition of microbiomes. Two species (*P.arcatus* and *P.xanthus*) showed non-significant separation of microbiome taxonomy (including comparability of two color morphs of *P.arcatus*), while *P.nisus* and *P.bicolor* revealed distinct gut flora. Intriguingly, an analysis of overall metagenomic data, including presumed prey abundance, revealed further evidence of partitioning among species. This included separate clustering of the two color morphs of *P.arcatus*, potentially reflecting an example of incipient speciation driven in part by foraging preferences. In all, diets of related reef fishes hold potential to be much more complex than previously described.

LARGE-SCALE CORAL REEF RESTORATION IN SEYCHELLES ADAPTED TO CLIMATE CHANGE (Abstract ID: 29566)

We completed large-scale coral reef restoration at Cousin Island Special Reserve, Republic of Seychelles, to recover coral loss due to the 1998 El Nino-Indian Ocean Dipole and 2004 Indian Ocean tsunami. Using "coral gardening", first, we harvested fragments from donor colonies or corals of opportunity and reared them in mid-water rope nurseries for 1-2 years. Second, we transplanted the nursery corals to a degraded reef site. Nine nurseries built with recycled materials had 40,000 coral fragments of 9 species: Acropora hyacinthus, A. cytherea, A. abrotanoides, A. sarmentosa, A. muricata, A. lamarcki, A. appressa, Pocillopora verrucosa and P. grandis. After hurricane and invasive sponge losses, we transplanted 24,431 corals to a degraded reef site during December 2012-April 2013 and November 2013-April 2014. Mean coral survival from nursery to transplantation was 86.5 %. The restored area was 5,225 m2. We scaled-up experimental-sized restoration techniques. We developed time-saving "cleaning stations", so fish conditioned corals prior to transplantation. Animal-assisted cleaning at nurseries reduced person-hours 2.75 times. The restoration enhanced coral settlement and recruitment, increased fish biomass, and had lower bleaching rates than natural reefs. The use of cement and natural substrate to transplant corals, big nursery-reared colonies (10-20 cm wide), high transplant density (4-8 corals/m2) and a species composition similar to a healthy coral reef were critical for success. Large-scale coral reef restoration is feasible, affordable, and restores ecosystem function

HUMAN-INDUCED GRADIENTS OF REEF FISH DECLINE IN THE HAWAIIAN ARCHIPELAGO VIEWED THROUGH THE LENS OF TRADITIONAL MANAGEMENT (Abstract ID: 29077)

Large declines in reef fishes in Hawaii over the past century have raised concerns about the sustainability of these resources and the ecosystem as a whole. To help elucidate the reasons behind these declines, we conducted a comprehensive examination of reef fishes across the entire Hawaiian Archipelago by synthesizing all available visual survey data since 2000 into a single database representing > 25,000 surveys. The moku or district was the basic unit of marine resource management in pre-contact Hawaii and was used as a unit of spatial stratification. Biomass of resource species was negatively correlated with human population density among moku, however we found no such relationship for species not targeted by fishing. A number of remote areas with small human populations still support high fish standing stocks, and are likely important refugia for maintaining fisheries production and biodiversity functioning. Marine protected areas (MPAs) were effective in conserving fish populations, with size, age, and habitat quality important determinants of MPA success. Current centralized, top-down management is incongruent with traditional place-based management that was developed at the community level. There is increasing interest among communities and coastal stakeholders in integrating aspects of customary Hawaiian knowledge into contemporary co-management. A marine spatial planning framework should be applied that incorporates existing MPAs to create a multi-use zoning plan engaging stakeholders at all levels in order to maximize resilience of ecosystems and communities.

ONLINE FRAMEWORK FOR COLLABORATIVE ANNOTATION OF UNDERWATER IMAGERY & VIDEO (Abstract ID: 29134)

Ecologists and biologists have increasingly relied on digital video & imagery to examine and monitor coral reefs and other marine habitats. Gathering these large data streams is becoming routine, but transforming them into quantitative information for science and policy decisions, requires substantial effort by human experts. Data syntheses between and within different groups is limited by inconsistent workflows and non-standard analysis, which pose barriers to data reuse and limit collaboration. Furthermore the lack of standardised workflows often results in significant lags between data collection and scientific discovery. We present an online framework for annotating georeferenced underwater imagery & video that enables speedy access to survey data through interfacing pre-existing, decentralised online storage facilities. This new framework provides consistent, customisable annotation schemes and data management capability through map-based tools enabling the exploration, querying, analysis and synthesis of annotated visual data. A centralised repository of georeferenced annotation data catalogued in a consistent format opens up the possibility of answering 'big picture' questions and provides opportunities to access large data sets for training machine learning algorithms. These algorithms ultimately have the potential to provide a scalable, cost-effective and collaborative environment for dealing with huge volumes of seafloor image & video data that can continuously improve and adapt through input from ecologists, biologists, experts and even citizen scientists.

GENOMIC EVIDENCE FOR ECOLOGICAL SPECIATION IN CORAL ASSOCIATED NUDIBRANCHS (Abstract ID: 29757)

Many marine species have highly dispersive larvae that can travel long distances via ocean currents. As such, there appear to be insufficient dispersal barriers in marine ecosystems to attribute the great diversity of species solely to vicariance. Corals often host other invertebrates and fishes in mutualistic or parasitic relationships. Symbiotic

relationships are known to promote ecological speciation in insect-plant systems, but this process is relatively unexamined on coral reefs. Nudibranchs in the genus *Phestilla* live and feed upon specific coral hosts. Previous work demonstrates that host shifts have occurred and may be the mechanism for speciation. We examine the roles of geography and coral host in ongoing population divergence within *Phestilla minor*. We sequenced and genotyped genome-wide single nucleotide polymorphisms (SNPs) using restriction-associated DNA from nudibranch specimens collected across Indonesia. Population structure analyses reveal strong divergence across the Sunda Shelf regardless of coral host, but on the Pacific side, populations from different coral hosts have diverged despite close proximity. These results imply that coral host acts as a stronger barrier to gene flow than purported geographic barriers in the Pacific Ocean. The existence of extremely differentiated SNPs (outlier loci) between host-separated populations reveals the important role of natural selection in this ecological divergence.

SEDIMENT REMOVAL INCREASES TURF ALGAE GRAZING AND ALTERS ALGAL COMMUNITY COMPOSITION ON CORAL REEFS (Abstract ID: 29141)

Many abiotic factors threaten coral reefs, including sedimentation from terrestrial runoff and storm activity. Sedimentation has known negative effects on corals, reducing coral growth and reproduction and damaging live tissue. Corals also compete with turf algae growing on the reef, and herbivorous fishes can facilitate coral growth by grazing on these algae. Studies in the Pacific have shown that sedimentation can decrease herbivory by grazing parrotfishes and surgeonfishes. Herbivorous fishes on Caribbean reefs also adjust their feeding behavior across small scales, but effects of sediment cover on algal grazing are not well-studied. To test how sediments influence the behavior of herbivorous fishes on Caribbean reefs we conducted a sediment removal experiment on three reefs in the upper Florida Keys. We compared short-term changes in grazing pressure and algal cover and height on plots where we experimentally removed sediments with control plots. We found that grazers significantly reduced algal cover and length in experimental plots but not in controls. However, herbivore responses were species-specific, with grazing by some species (e.g., Sparisoma viride, Sparisoma aurofrenatum, and Acanthurus coeruleus) increasing significantly in experimental plots, while others (e.g., Acanthurus bahianus) did not change. This suggests sedimentation could indirectly harm corals by decreasing algal removal by common herbivorous fishes, but the effect may depend on the grazing species present.

NO FREE LUNCH: IMPLICATIONS OF SYMBIOTIC RELATIONSHIPS ON THE CORAL IMMUNE RESPONSE VIA THE TRANSFORMING GROWTH FACTOR-BETA SIGNALING PATHWAY (Abstract ID: 28200)

The transforming growth factor-beta (TGF-beta) pathway is often used by parasites to promote tolerance on the part of the host. Similarly, so as to not be destroyed by the immune system, coral symbionts may suppress host immunity through this pathway. Corals are dependent upon symbiotic dinoflagellates of the genus *Symbiodinium* for their nutritional needs. However, *Symbiodinium* may upregulate host TGF-beta expression to allow for the establishment and maintenance of symbiosis. We investigated this hypothesis using a previously generated immune challenge data set. Five colonies of *Orbicella faveolata* were exposed to bacterial lipopolysaccharides. RNA was extracted from each replicate of the five colonies and analyzed using RNAseq. Differential expression analyses identified 17 differentially expressed transcripts which had potential immune function. Inexplicably, several of these immune transcripts, termed 'dysfunctional', decreased in expression following immune challenge. Bioinformatic techniques were then used to identify components of the TGF-beta signaling pathway in our resultant transcriptomes. Expression of candidate TGF-beta transcripts was correlated to expression of immune transcripts, revealing insight into the mechanisms contributing to 'dysfunctional' patterns of gene expression. The findings of this study provide new insight into the importance of symbiont modulation of host immunity in contributing to variation in coral disease susceptibility. http://www.twitter.com/laurenfuess

PHYLOGENETIC RELATIONSHIPS BETWEEN THE ORDERS ZOANTHARIA AND ACTINIARIA (CNIDARIA: ANTHOZOA: HEXACORALLIA) UTILIZING NEWLY OBTAINED SPECIMENS FROM JAPAN (Abstract ID: 28135)

As molecular phylogenetic analytical techniques have developed, more and more knowledge about the diversity of the order Zoantharia (Hexacorallia) has been obtained over the last two decades. Order Zoantharia, characterized by the encrustation of granules into the body, had been one of the least examined orders within Anthozoa because of the few useful concrete morphological features for taxonomy. Thus, only a few zoantharians species have been used for the phylogenetic studies on higher taxa, and the phylogenetic relationships between Zoantharia and the other orders in subclass Hexacorallia remain unclear. Although in general topologies of Hexacorallia are different among various studies, most show order Actiniaria is closest to Zoantharia. Here we show results from a phylogeny constructed with mitochondrial cytochrome oxidase subunit I (COI), the most common marker for DNA barcoding, and compare with a 16S ribosomal DNA phylogeny. Until now COI has not been used much with Actiniaria. The COI phylogeny also includes newly acquired specimens from Japan (e.g. Edwardsiidae, Halcuriidae Actinerniidae Microzoanthidae, Nanozoanthidae), and the resulting phylogenetic tree shows Zoantharia and Actinaria are more closely related and less distinct than previously assumed. While the tree also shows the monophyly of Zoantharia, there is the possibility of paraphyly of Actinaria.

VARIABILITY OF TEMPERATURE-INDUCED BLEACHING WITHIN AND AMONG CORAL COLONIES (Abstract ID: 28291)

Many studies have shown that seawater temperature anomalies can cause bleaching of anthozoans, and some studies have demonstrated that bleaching susceptibility varies among species. However, spatial variability of bleaching within the same species has not been well investigated, although it is often observed. In laboratory experiments, colonies of *Palythoa caribaeorum* were exposed to water flow at controlled temperatures. In a high-flow, high-temperature regime, upstream sides of large colonies bleached less than downstream sides, and small colonies bleached less than large colonies. The results support the hypothesis that bleaching is mitigated by high flow rates (i.e., enhanced efflux of toxic reactive oxygen species from coral tissues). Cold temperatures also cause bleaching. Colonies of *Acropora sp.* are being monitored at approximately 20 m depth off the coast of Okinawa, Japan, where bleaching has been observed during the coldest months. However, not all colonies equally bleached at low temperature, and degrees of bleaching were not uniform within a given colony. This may be due mainly to variability of local water currents, as shown in laboratory experiments or to genetic susceptibility of corals and/or symbiotic algae. Other possible factors as well as bleaching mechanisms in general, understanding of which will eventually help coral reef management and conservation efforts, are also discussed.

NEWLY DEVELOPED "TRIGONOMETRIC METHOD" FOR AN ESTIMATION OF REEF PRIMARY PRODUCTION (Abstract ID: 29248)

Coral reef metabolism of primary production is an important indicator to assess the reef condition under various threats of environmental changes. Traditionally, measurements of reef metabolism have been carried out using a slack water method or a flow respirometry. These methods need a lot of labor for field measurement to monitor reef condition. Recently, eddy correlation study has been introduced to derive reef oxygen metabolism in the same manner as CO2 flux study on land. However, applying the land study to water environment still has some problems and it is off from practical use. We have newly developed "Trigonometric Method" (hereafter abbreviated as TriM) based on the flow respirometory to derive reef primary production. This method saves a human energy and enables to monitor the primary production for long term without frequent sensor maintenance. Three dissolved oxygen loggers were deployed to coral reef at vertex of a triangle in which a targeted reef community was included. The difference of dissolved oxygen in the water mass across the triangle was calculated to estimate oxygen flux between water column and benthic community. Light-photosynthesis curve was produced to derive community metabolisms. We applied this method to two different reef community in Okinawa, Japan (Site A and B). Higher respiration rate was obtained at Site B, which is home to coral at high coverage but also more heterotrophic organisms than Site A. This newly developed "TriM" can be a useful tool for quantitative evaluation of reef condition with respect to community primary production.

SYMBIODINIUM CELL CYCLE CONTROL BY CORAL HOSTS (Abstract ID: 28965)

Dinoflagellates of the genus Symbiodinium are tied to an endosymbiotic life style with marine invertebrates such as reef forming corals, but via a transient free-living phase. In symbiosis, the host controls Symbiodinium populations pre-mitotically by limiting division to maintain optimum cell densities; however, this fundamental process has not been detailed at the cellular level. Using flow cytometry, we analysed the cell cycle of a broad range of Symbiodinium ITS2 types (n=15 spanning clades A-D, F) in culture. All types exhibited typical eukaryotic cell cycle progression: G1-phase (preparation for DNA replication) through S-phase (DNA synthesis) during the day, and S-phase to G2/M-phase (pre-mitotic gap and mitosis) during night. However, the proportion of proliferating (S and G2/M phase) cells differed between ITS2 types, which in part reflected differences in type-specific growth rate. Upon exposure to heat stress for select types (n=5), cells were generally arrested in S-phase, possibly reflecting enhanced DNA repair and at a cost to division. We subsequently repeated our analysis for Symbiodinium spp. in hospite of three key coral species from the Great Barrier Reef; here, Symbiodinium populations exhibited similar levels of G1-S-G2/M cells but weak phased division compared to cultures, and with little further response to subsequent sub-lethal heat stress. We discuss how, together these new observations challenge our current assumptions of cell cycle control of Symbiodinium populations, and questions current practices used for monitoring these populations in nature.

BACK-REEF DEVELOPMENTS DURING MIS2 SEA-LEVEL FALLS: IODP EXPEDITION 325, GREAT BARRIER REEF (Abstract ID: 28898 | Poster ID: 387)

Sediment cores recovered from the shelf edge of the Great Barrier Reef during the IODP Expedition 325 record the course of sea-level changes as well as the history of coral-reef developments during the last glacial cycle. Although extensive studies have been conducted on reef growth patterns during interglacial highstands, reef growth patterns during glacial lowstands have not yet been fully understood. Here we show that back reef flats were formed after sea-level fall during Marine Isotope Stage (MIS) 2 based on fossil foraminiferal data. Unconsolidated carbonate sands found in depths from 120 to 140 mbsl at the Hydrographer's passage contained abundant large benthic foraminifers (LBFs). The taxonomic composition of LBF assemblages indicated a shallowing upward sequence in these intervals, with changing from fore-reef assemblage dominated by Amphistegina and Operculina to back-reef assemblage dominated by Baculogypsina and Calcarina. Radiocarbon ages of foraminiferal tests were consistent with the timing of lowering sea levels during MIS2 revealed from radiometric ages and paleo-water depths of coralgal assemblages. Relative abundance of well-preserved Baculogypsina tests in these intervals indicates that depositional environments were closer to reef margins. These foraminiferal evidences suggest that remnants of biologically constructed barriers such as coralgal reef crests existed offshore associated with sea-level falls, possibly causing moating effects. Our results would also imply paleo-intertidal water levels during the Last Glacial Maximum.

CHANGES IN MESOPHOTIC REEF FISH ASSEMBLAGES IN THE NORTHWESTERN HAWAIIAN ISLANDS ALONG A LATITUDINAL AND LONGITUDINAL GRADIENT (Abstract ID: 28439 | Poster ID: 341)

Mesophotic coral ecosystems (MCEs) are characterized by the presence of light-dependent corals and associated fauna at depths below 30 m and support a diversity of marine organisms. We investigated changes in the structure of mesophotic reef fish assemblages in the Northwestern Hawaiian Islands (NWHI) along a latitudinal and longitudinal gradient, using survey data from 27 - 92 m depths. There was a clear gradient in the assemblage structure from the southeastern end to the northwestern end of the NWHI. The three atolls at the northwestern end of the NWHI (Pearl and Hermes, Midway and Kure) had higher abundances of two endemic planktivores, *Genicanthus personatus* and *Pseudanthias thompsoni*, and a temperate species, *Centropyge interrupta*, than all other locations. An endemic invertivore, *Bodianus sanguineus*, was also relatively abundant on deeper mesophotic reefs of these three locations. The two locations at the southeastern end of the NWHI (Nihoa and French Frigate Shoals) were characterized by high abundances of the introduced invasive species,*Lutjanus kasmira*; this species was only recorded at these two locations with an exception of one individual at Lisianski Island. This study indicates that MCEs in the NWHI can be treated as three regions for monitoring and management purposes: southeastern and mid regions characterized by the presence/absence of the invasive fish *L. kasmira*, and a northwestern region where fish assemblages, largely composed of endemic species, can be influenced by cooler temperate climate.

FROM FISHING FISH TO FISHING DATA: CITIZEN SCIENCE, CONSERVATION AND MANAGEMENT IN FISHING COMMUNITIES. (Abstract ID: 28259)

The participation of artisanal fishers in conservation and management rarely goes beyond providing traditional ecological knowledge to visiting scientists and managers. Communities are often excluded from monitoring, evaluation and decision-making, despite potential impacts on livelihoods. For 15 years, we have implemented a citizen science-monitoring program in three key marine ecosystems in Mexico: the coral reefs of the Mesoamerican Reef, the kelp forests of Baja California and the rocky-reefs of the Gulf of California. We have designed, tested and implemented the community-monitoring model in collaboration with local fishers, achieving science-based conservation and management decisions and improving livelihoods. Through collaborative research fishers have collected data to calculate quotas, biologically evaluate 11 MPAs, propose the establishment of 22 no-take zones, contribute to scientific publications and implement conservation and fishery management tools for over 620,000 hectares of coastal waters. Over 400 community members have participated in the marine reserve program, of these, 174, including 30 women, have been trained to conduct underwater censuses, completing over 12,000 transects with internationally recognized methodologies. Both civil society and government in Mexico and neighbouring countries are now adopting this successful model. Empowering community members to collect scientific data creates responsibility, pride and a deeper understanding of the ecosystem in which they live and work, providing both social and ecological benefits to the community.

SURVIVAL OF THE SMALLEST: CRYPTIC CELLS LIVING IN DEAD CORAL SKELETON (Abstract ID: 29855)

Corals are modular organisms with the surprising ability to survive and regrow after breaking into pieces. How small is too small to survive? Coral reefs have maintained life through natural global changes for thousands of years but are currently faced with the most dramatic change yet. Corals can recover from stress by regrowing from cryptic tissues. Cryptic tissues are made of coral cells that survive in recessed or shaded areas of the reef, often not visible by standard coral surveys. These tissues are known to give corals the ability to return to life from apparent death. For some species, survival at a small scale can lead to a population-scale recovery. This study tests the boundaries of coral life and death. By microscopically exploring apparently dead coral skeleton, we used hyperspectral mapping microscopy and genetic approaches to search for living coral cells hidden inside the skeletal matrix. Within the skeletal matrix of recently 'dead' coral colonies, we found live, fluorescing, coral cells. Like most cnidarians, coral cells are effectively stem cells with the capacity for cellular differentiation and colonial development. The cryptic coral cells were found well beneath the coral skeletal surface, suggesting that individual cells can survive away from surface stressors, and perhaps re-grow, once external conditions have improved. This study changes what constitutes a "dead" reef and could have lasting impacts on coral reef conservation.

DEVELOPMENT OF A SIMPLE AND EASY-TO-USE MULTI-WAVELENGTH EXCITATION *IN-SITU* FLUORESCENCE IMAGING APPARATUS (Abstract ID: 28694 | Poster ID: 500)

Numerous marine organisms, including corals, have fluorescent substances such as green fluorescent proteins. Coral fluorescence has been shown to vary with coral health and environmental factors, making it a possible non-destructive proxy for coral health. However, due to the lack of adequate system for *in-situ* observation, available data are rather limited. We developed a system which simplifies the fluorescence imaging of corals in night and day conditions in the field, using excitation light of 470nm and a cut filter of 470nm to emphasize green-red fluorescence. The system was tested by monitoring coral fluorescence *in-situ*, along with environmental data, for an extended period of time, showing the effectiveness of the system. In addition to green fluorescence, red and blue fluorescence, due to photosynthetic pigments and other fluorescent proteins, can be observed. Based on the measurement of the fluorescent spectra of several coral species and marine organisms, we then made a "handy multi-fluorescence imaging apparatus" with six excitation lights (470, 530, 591, 617, 655 nm, and white (5650k)) and five cut filters (<390, <480, <540, <620, <640nm). This system allows the imaging of not only the conventional blue to red wavelength but also longer wavelength such as deep red fluorescence. In the future, such method will make it possible to understand the relation between corals' fluorescence and their physiology, and to provide an useful monitoring tool for more effective marine ecosystems managements and environmental impact assessments.

THE EFFECT OF SYMBIONT DIVERSITY ON INFECTION PATTERN, SYMBIONT CELL PROLIFERATION AND PHYSIOLOGICAL STATUS IN A MODEL CNIDARIAN-DINOFLAGELLATE SYMBIOSIS (Abstract ID: 29318)

Warming ocean temperatures increase the frequency of mass coral bleaching events, which might lead to changes in coral symbiont communities that would not necessarily be beneficial to the host. The genus Symbiodinium is characterized by a high degree of genetic and physiological diversity, therefore it is an important driver that can influence the symbiosis. This study examined for the first time the functional diversity of a wide range of Symbiodinium phylotypes on cnidarian host, by infecting aposymbiotic individuals of the model sea anemone Aiptasia sp. with one of five types of dinoflagellates (Symbiodinium A1, B1, C3, D1.A, E) over a period of eight weeks. The spatial pattern of infection and physiological parameters were monitored. Infection began in the oral disc and progressed to the tentacles. After the tentacles were heavily infected, the infection continued to the column and pedal disc. No differences were found in the infection pattern between different Symbiodinium types, however symbiont proliferation rate was different between the types. The homologous type B1 colonized the anemone the fastest, while A1 and D1.A were slower to fully infect and reached lower densities than B1. C3 and E showed few signs of infection. There were also differences in physiological parameters tested between anemones infected with different symbiont types. For example, anemones infected with B1 were much bigger and had more buds compared with the other types. These findings suggest that cnidarian hosts might be able to survive with heterologous types that are considered opportunistic; however, there may be physiological costs, such as lower growth and reproductive rates

BALANCING INTROGRESSION AND SPECIES INTEGRITY ACROSS A MOSAIC HYBRID ZONE (Abstract ID: 28467)

Hybridization among coral reef taxa has been well documented, particularly in corals and more recently in fishes. Hybrid zones offer rare opportunities to study interspecific gene exchange in nature and may provide valuable insight into the evolution of species, where tension between gene flow and selection can result in mosaic ecological and genetic patterns. In this way, hybridization may act to fuse parental populations and remove species, or lead to new species through reinforcement in time. The natural hybrid zone of the anemonefish Amphiprion leucokranos presents an ideal study system to investigate regional differentiation among species involved in an ongoing hybridization. We examined phenotypic variation, ecological resource use, mate preference, and gene exchange across parent species and hybrid populations at three sites within the hybrid zone. Historical and contemporary estimates of gene exchange were derived from mitochondrial cytochrome b and 21 polymorphic microsatellite loci. We found that evolutionary outcomes for species involved in this hybridization event vary regionally, and are potentially driven by the availability of conspecifics. Our results also reveal the persistence of the hybrid group within all regions, appearing both phenotypically and genetically (using nuclear microsatellite loci) distinct from parent species despite the ongoing backcrossing and introgression occurring. Our data suggests that over time this hybridization event may lead to speciation of the white-bonnet anemonefish, highlighting the balance between hybrid persistence and maintaining parent species integrity in a dynamic hybrid zone.

FISHES THAT RULE THE WORLD: CIRCUMTROPICAL DISTRIBUTIONS REVISITED (Abstract ID: 28023)

Briggs (1960) published the first annotated checklist of circumtropical fishes with 107 species. This work served for a half century as the most comprehensive checklist of globally distributed fishes, but the intervening years witnessed many discoveries and molecular data have changed the way we evaluate species. Here we update the list guided by taxonomic revisions, phylogenies, phylogeographic data and DNA barcodes. The resulting list now includes 284 species. The dramatic increase is primarily due to continued exploration of the seas leading to species discoveries and public databases make range data more accessible. Five species were removed from the list as closer scrutiny revealed multiple taxa, 14 were removed due to updated range information, and 35 more are suspected to be species complexes. The species listed here are mostly pelagic and bathypelagic fishes. Euryhaline, anadromous, catadromous, freshwater, and with few exceptions, reef fishes do not achieve global distributions. The most species-rich family of marine fishes (gobies) is absent. The fishes with the longest pelagic larval stage (eels) are absent. In contrast, requiem sharks, tunas, jacks, remoras and especially lanternfishes have multiple representatives. The combined evidence indicates that high mobility as an adult is a key requirement to achieve global distribution. Many others are members of monotypic genera or families, indicating old lineages that did not diversify. We conclude that global ranges may promote persistence over evolutionary timescales, but also reduce opportunities for speciation.

RELATIONSHIPS BETWEEN HABITAT, SOCIAL BEHAVIOUR AND DIET: A CASE STUDY IN DAMSELFISHES FROM MOOREA (Abstract ID: 28446)

Models for vertebrate adaptive radiations predict that diversification occurs in the form of temporal stages. Generally, adaptive radiation happens first along the axis of habitat features and then follows a divergence related to trophic specializations. Here, we aim to test this hypothesis by investigating the relationships among habitat, social behaviour and diet in damselfishes (Pomacentridae) from coral reefs at Moorea, French Polynesia. Stable isotope ratios of carbon and nitrogen in combination with stomach contents delineated three trophic groups, as observed in other regions: pelagic feeders consuming zooplankton, benthic foragers mainly grazing on algae, and a group called intermediate that feeds on zooplankton and benthic preys in equal proportions. Stable isotope ratios of sulphur revealed a segregation between species of the outer reef, which are mostly dependent on oceanic food input, and the other species from the lagoon, which rely more on autochthonous local productivity or even on terrestrial supply. Without phylogenetic corrections, the diet of damselfishes defined with stomach contents was correlated with habitat and social behaviour, and it was also correlated based upon stable isotopes. Furthermore, with phylogenetic corrections, significant relationships were found for either dietary proxy. Overall we demonstrate a dependence between habitat and trophic diversification during the evolutionary history of damselfishes, providing no support for a model of adaptive radiation in stages.

USING BIO-OPTICAL MODELS OF CORAL CALCIFICATION TO EVALUATE THE EFFECTS OF GLOBAL CHANGE (Abstract ID: 29700)

Coral calcification is strongly correlated to the photosynthetic activity of the endo-symbiotic dinoflagellate Symbiodinium, but other environmental factors (temperature, seawater chemistry) can also alter calcification, through the disruption of photosynthesis. In the present study, using physiological differences caused by environmental changes in light and water temperature, a bio-optical model was created, and its predictive capabilities on Porites astreoides calcification were evaluated. We described photophysiology and calcification rates between two different populations of P. astreoides. The first population was grown under optimum conditions (Back Reef, BR), while the second was grown under a natural ocean acidification (OA) scenario (subterraneous water spring, SWS). Both locations also differed in light availability and diurnal variations in water temperature, mainly due to SWS having decreased light availability and higher variations in temperature. Our results indicated differences in calcification between both coral populations as estimated by buoyant weight and densitometry analyses. Despite previous reports attributing a 35% decrease in calcification rates to OA in SWS corals relative to BR corals, our bio-optical model indicates that differences in water temperature, not OA, explains the majority of this decrease.

AN INTEGRATIVE APPROACH TO ENVIRONMENT AND HUMAN GEOGRAPHY, THE CASE STUDY OF MAGOODHOO ISLAND-MALDIVES (Abstract ID: 28692)

Several regions around the world are currently undergoing rapid, wide-ranging changes in land use and land cover. Conversion of rural areas through development is occurring at a rate unprecedented in recent human history and is having a marked effect on natural ecosystem functioning. Pronounced climate change and land-use/land-cover change represent the two primary challenges that most ecosystems will face this century. Land-use/land-cover deeply influences biotic diversity through natural habitat fragmentation and biodiversity loss. Land-use/land-cover also has an important and extensive influence on climate by altering the distribution of ecosystems and their associated energy fluxes. In tropical coastal regions, fragile marine coral reef ecosystems, already threatened by increasing carbon dioxide, are exposed to an increased load of terrestrial sediment, nutrients, and other pollutants. It has been proved that increased sedimentation and poor water quality compromise the resistance of corals to thermal stress and their potential to recover from bleaching events. This work offers an integrative perspective on the political and ecological processes shaping landscapes and resource used in Magoodhoo, Faafu Atoll, Republic of Maldives as case study. Our research has demonstrated how union of environmental and human geography studies can contribute to understanding key environment-and-development issues and working toward effective policies.

PILOT PROGRAM: DIVERSIFYING FISHERMEN INCOME GENERATION ACTIVITIES TO REDUCE LOCAL IMPACTS ON PUNTA CANA´S CORAL REEF COMMUNITIES, DOMINICAN REPUBLIC. (Abstract ID: 29751 | Poster ID: 559)

Coral reefs worldwide provide various social-economic services for bordering nations. However, these ecosystem services are threatened by a continued decline in reef health. In the Dominican Republic reef health is threatened the disappearance of the important reef building Acropora corals, the lionfish invasion, overfishing of herbivorous fish, an overabundance of coral predators, and tourism associated activities. Here, we present potential options for alternative income generation and to reduce local reef impacts. To combat the decline of Acropora corals and the overfishing of herbivorous fish, fishermen were hired to work 1 week/month on Puntacana Ecological Foundation´s (PCEF) coral restoration program. These same fishermen land on average 16.60kg of fish/day/ind. of which 49% is parrotfish. This restoration work week saves approximately 56.8kg of parrotfish/ind. and earnings for 4 weeks of work is equivalent to 88% of their fishing income. Similarly, fishermen family members are helping with invasive species by commercializing lionfish-based products, supplementing their monthly family income by 18.4%. Tour operators and PCEF are developing new excursions in which tourists are involved in coral restoration and work with fishermen to reduce the overabundance of fireworms using traps as a new income source. These income generation activities can be easily replicated and as new projects are added that fund these activities, will continue to be attractive for fishermen, allowing local stakeholders to reduce reef impacts without excluding local community participation.

COLOMBIAN CITIZEN SCIENCE TO IMPROVE CORAL REEF CONSERVATION (Abstract ID: 27854)

The Foundation ICRI Colombia through its Observatory in Pro of Coral Reefs and its National Network of Volunteer Observers of the Coral Reefs (RENOVO) worked in a Coalition under the principles for conservation effectiveness: 1) Environmental Management is about people 2) The local knowledge should be taken into account when decisions are made 3) Monitoring is relevant for adaptive management. Scientific results are based on eight years of data collection in collaboration with the community of artisanal fishermen and diving operators. The daily observations were reported in a systematic way to monitor fishing and dive sites in coral reef areas in Colombia. Qualitative reports based on underwater videos and photos, served to study the progression of the invasion of Lionfish Pterois volitans in the Colombian Caribbean and to identify species to be protected in the new coral reef Varadero, Cartagena. The quantitative data gathered as Catches Per Effort Unit (CPEU) also was useful to monitor since 2009 the changes in artisanal fisheries composition in Capurganá-Cabo Tiburon after the appearance in 2010 of the invasive lionfish. The RENOVO´s citizen science successfully contributed to provide environmental education to the community that became the best guardian of the coral reefs improving the conservation effectiveness and provided information to the national, regional and local authorities to guide better conservation decisions, such as implementing the route for the declaration of the new coral reef protected area Capurganá-Cabo Tiburón and help avoiding Varadero destruction

REEF-SCALE STUDIES OF BOUNDARY LAYER FLOWS AT DIFFERENT BOTTOM TYPES (Abstract ID: 29355 | Poster ID: 522)

The boundary layer is a layer that is affected by the shear stress produced near the bottom boundary in which large velocity gradients exist. The thickness of bottom boundary layers (BBL) is characterized by water velocity, shear stress and roughness element. Flows over spatially varying bottom topography of the coral reef have been known to influence settlement, retention and dispersal of particles and can be linked to frictional forces imparted by the complexity of the boundary. This study focused on understanding the hydrodynamic processes at the boundary layer over a coral reef area to provide valuable insights on the ecological functions of the reef ecosystem. The flow structure and thickness of the BBL were estimated through time-series measurement of a high-resolution velocity profile over a tidal cycle at three different bottom types at fringing reef systems of Miniloc and Shimizu Island, El Nido, Palawan. Field velocity measurements were analyzed to provide estimates of shear stresses and roughness length over different bottom types using logarithmic fit. The study showed that flow structures, thickness of boundary layer and velocity profile changes over different bottom types due to frictional effects. From these observations, implications for particle settlement and advection are discussed. In conjunction with this reef scale study, 2D (X-Z) hydrodynamic simulation was developed to describe the dynamics and structure of boundary layer flows for different bottom types. Results from actual measurements and exploratory model simulations are compared and discussed.

ENVIRONMENTAL DRIVERS OF BROAD-SCALE DISTRIBUTION OF SPONGE COMMUNITIES ON THE MESOAMERICAN BARRIER REEF (Abstract ID: 29375 | Poster ID: 506)

Sponge communities play a vital ecological role on coral reefs. Despite the general agreement that environmental regimes influence the distribution of sponges, key mechanisms that explain patterns of sponge assemblages are not yet fully understood. We studied the spatial patterns of sponge abundance and morphological traits along the Belize Barrier Reef System against hurricanes, wave exposure and depth (5-20 m) as key drivers of their distribution, using video transect surveys. We expected that the role of these drivers would result in effects based on sponge structural robustness or morphological adaptation to hydrodynamic processes. Our analyses supported this, as under high mechanical stress (wave exposure and hurricane incidence), sponge communities were dominated by low-profile morphologies, namely large encrusting individuals that were adapted to such hydrodynamic regimes. Depth provided refuge to structurally complex, slow growing sponges, such as vase and barrel sponges. As wave exposure decreased, the depth range of certain sponge morphotypes expanded to include shallower areas. At a species level, morphological plasticity also allowed for certain sponge species to occur over a wide range of exposures and depths. Our results showcase mechanical stress as a key driver of benthic assemblages and highlight a strong morphological response of sponge species. Knowledge of these morphological trends in sponges, related to mechanical stress, provides insight into expected sponge community assemblages in other locations with similar environmental conditions.

CALCIFICATION IN CORALLIUM RUBRUM: DISSECTING THE PROCESS USING GENOMICS AND TRANSCRIPTOMICS TOGETHER WITH SCALPELS AND SCISSORS (Abstract ID: 29459)

The Mediterranean red coral, *Corallium rubrum*, famous in jewelry for its red colored skeleton, elaborates two biominerals (high magnesian calcite) structures which differ in size, shape and organic fraction composition: 1) the axial skeleton, produced by the skelotogenic epithelial layer which surrounds the axial skeleton and 2) the sclerites, produced by the scleroblasts which are isolated cells in the mesoglea. Within the class of Anthozoa, *C. rubrum* belongs to Octocorallia, the sister group to Hexacorallia which includes sea anemones and reefs building corals. *C. rubrum* thus represents a model of choice to understand some of the evolutionary processes that govern calcification in corals: 1) what mechanistic processes control the formation of the two different skeletal structures; 2) to which extended is the calcification toolkit used by octocorallians and by hexacorallians comparable? We chose to answer these questions using genomic and transcriptomic approaches. We are currently establishing a reference genome sequence for the red coral, which size is about 500 Mb. On the other hand, we have produced transcriptomes representing different sub-compartments of the red coral: microdissection using scalpels and scissors enabled the physical separation of different tissues, enriched in or devoid of calcifying cells, for differential expression analyses. These combination of approaches shed light on some of the processes linked with calcification in *C. rubrum* for both the organic and the mineral part.

ATMOSPHERIC CORRECTION OF PRISM AIRBORNE IMAGING SPECTROMETER DATA FOR SUPPORTING CORAL REEF RESEARCH (Abstract ID: 28081)

The COral Reef Airborne Laboratory (CORAL) is a recently funded NASA project. The goal of CORAL is to provide critical data and new models that are needed to analyze the present status of coral reefs and to predict their future. The NASA JPL Portable Remote Imaging Spectrometer (PRISM) will be mounted on a small plane and deployed over a number of coral reef sites in the coming years. Atmospheric correction is necessary in order to obtain water leaving reflectance spectra over coral reefs. During past few years, we have developed techniques that involved theoretical radiative transfer modeling and empirical removing of sunglint effects for atmospheric correction of PRISM data. In early 2014, PRISM already acquired hyperspectral imaging data over coral reefs southwest to Florida during a different airborne field campaign. We will further develop the atmospheric correction algorithm, and apply the algorithm to the PRISM Florida data set. We will describe the algorithm and present results from application of the algorithm to the PRISM data during the symposium.

TRANSBOUNDARY MANAGEMENT OF CORAL REEF COMMERCIAL FISHERIES USING LARVAL CONNECTIVITY. (Abstract ID: 28701)

Coral reef commercial fisheries represent one of the main economic resources in the Caribbean region. Each Caribbean nation manages its own fishery stocks, typically at the national scale. However, targeted populations are structured in metapopulations that are connected through larval dispersal across national boundaries. One of the main challenges for an effective management applied to these metapopulations is the need of partnering between countries that share the same resource. In this study, we focus on the highly valuable commercial fishery of the spiny lobster Panulirus argus. The broad-scale larval dispersal patterns of this species have been assessed in the Caribbean region but no transboundary management has been proposed for this important resource. We coupled a biophysical larval dispersal model and a metapopulation dynamic model at reef scales to obtain a finer-grained representation of connectivity and dynamics of spiny lobster across the Caribbean. We analyzed the spatial heterogeneity in patterns of the species dispersal both within and across national boundaries and evaluated the scales of larval exchange and self-seeding in the Caribbean region. Based on these results we propose trans-national neighborhoods for spiny lobster management scale that are adapted to the scale dynamics of spiny lobster metapopulation dynamics.

GENOMIC ANALYSIS OF DISJUNCT PACIFIC AND SEA OF CORTEZ POPULATIONS OF A REEF FISH (GENUS: *ANISOTREMUS*) (Abstract ID: 29954)

Disjunct populations are formed after a physical barrier separates the populations of a species, which then has the potential to remain the same species or diverge depending on how effectively the barrier impedes gene flow. Disjunct populations provide an excellent opportunity to study the evolutionary processes of allopatric speciation. The sargo, *Anisotremus davidsonii*, has a disjunct distribution with populations in the Pacific coast of California and northern Baja California and isolated populations in the upper half of the Sea of Cortez. These disjunct sargo populations have been suggested to be at the initial phases of allopatric speciation. This project utilizes restriction site associated DNA (RADSeq) to produce a highly confident connectivity analysis of populations sampled across the Pacific and Sea of Cortez ranges of the sargo. The goals of this project are to (1) characterize the genetic structure of these populations and assess divergence levels across the Baja California peninsula, (2) determine the connectivity within each region and (3) explore the molecular signatures of incipient allopatric speciation. This study sheds light into the processes in the speciation continuum in this species and provides a deeper understanding of how populations are connected and how biodiversity might be shaped in these regions.

EXPLORING THE ISSUE OF BOTTOM REFLECTANCE PARAMETERISATION IN SHALLOW WATER INVERSION MODELS (Abstract ID: 29261)

A key processing step in the optical classification of benthic substrates from hyperspectral imagery of coral reef environments is correcting for the radiometric effects of the water column to derive bottom reflectance. Shallow water inversion models are a proven methodology able to simultaneously retrieve the water column's inherent optical properties (IOPs), geometric depth and bottom reflectance from remote sensing reflectance with little or no in situ data. However the accuracy of the retrieved IOPs and depth is influenced partly by the spectral shape of the benthic endmember(s) that are input to

the inversion model. Current inversion schemes parameterise the bottom reflectance as a single or a linear mixture of two or three benthic endmembers. However, the efficacy of these parameterisations remains untested given the narrow water column penetrating bands and the exponential attenuation of light with depth. Here, we analyse three parameterisations of bottom reflectance previously published: (1) a single endmember scaled by its brightness; (2) the fractional coverage of two endmembers, and; (3) a linear mixture of three endmembers. Here each parameterisation utilises the same IOP model and optimisation algorithm allowing for more readily comparable results. Issues such as over-parameterisation and the ability to detect benthic mixtures from above water reflectance will also be addressed. We evaluate these approaches using both in situ radiometry and airborne imagery from NASA's Portable Remote Imaging SpectroMeter (PRISM) of coral reefs.

IMPORTANCE OF THE THREATENED ACROPORA CORALS FOR THE CONSERVATION OF REEF FISHES (Abstract ID: 29398 | Poster ID: 259)

A high proportion of reef fish species use branching scleractinian corals as shelter, breeding, and feeding sites. In the Caribbean, coral reefs have suffered a drastic decline, which has been found to affect economic activities such as fishing, tourism, and conservation. Branching corals of the genus Acropora have been widely decimated with mortalities reaching in some places over 90%. This study surveyed and evaluated visually the fish community associated to the two Caribbean species of Acropora at five localities along the continental Colombian Caribbean reefs. The best conserved A. palmata patches were found in Tayrona Natural Park, while Gulf of Uraba shelters the best conserved A. cervicornis reefs. 61 fish species of 25 families were associated to A. palmata; the families better represented in those habitats were Labridae, Haemulidae, Pomacentridae, and Serranidae. Thalassoma bifasciatum, Microspathodon chrysurus, and Stegastes adustus were common to all reef localities; San Bernardo Islands presented the largest number of species (44). 33 species included in 11 families were seen in A. cervicornis patches. Labridae, Pomacentridae, and Haemulidae were the most abundant. Stegastes planifrons was common at all localities; the greatest number of species was found in Uraba Gulf (29). Although topography provided by A. palmata was relevant to the abundance of fish, high coverage of A. cervicornis was a significant factor that allowed for greater complexity for the associated fish community.

MESOPHOTIC REEF SPONGES (PORIFERA) FROM PUERTO RICO AND THE US VIRGIN ISLANDS (Abstract ID: 27802)

The marine sponges collected during three research cruises conducted by the University of Puerto Rico at Mayagüez Caribbean Coral Reef Institute and Department of Marine Sciences are described and discussed. Over twenty sites were surveyed by scientific divers using closed circuit rebreathers at depths ranging from 50 to 80 m. The goals of the expeditions were to characterize mesophotic coral ecosystems starting from Isla Mona (West coast Puerto Rico) along the south coast of Puerto Rico heading towards the US Virgin Islands and concluding at Lang Bank off the eastern end of St. Croix. A total of 84 specimens were analyzed and incorporated in the collections of the Naturalis Biodiversity Center (Leiden, Netherlands). Sponges belonging to the classes Homoscleromorpha and Demospongiae were analyzed. A total of 7 sponge species belonging to the class Homoscleromorpha were analyzed, all belonging to the Family Plakinidae. The remainder 68 sponge specimens belonged to the class Demospongiae. In total, eight Orders were identified during our preliminary analysis: Haplosclerida (19 species), Agelasida (7 species), Dictyoceratida (7 species), Poecilosclerida (5 species), Verongiida (5 species), Suberitida (5 species), Axinellida (3 species), and Tetractinellida (3 species). Based on our preliminary taxonomic analysis, we report four new sponge species from this region. This is the first systematic study of mesophotic reef sponges from Puerto Rico and the US Virgin Islands, and will serve as the foundation for future studies regarding this understudied group at these depths.

IMPROVING RESILIENCE THROUGH CORAL RESTORATION IN NO TAKE AREAS (Abstract ID: 29857)

Coral reefs are being affected by a combination of human and natural perturbations, accentuated by global climate change. Although climate change related events are not readily controllable with local management interventions, we are able to influence to a certain extent opportunities for coral reefs to resist or recover enhancing natural resilience through active restoration. Oceanus and its partners are working to strengthen resilience and adaptation potential of coral reefs and to promote recovery of associated species of fish and invertebrates by implementing a Coral Restoration Program with special emphasis on recovering no-take areas as a part of the Kanan Kay Alliance and similar initiatives in neighboring countries. Restoration techniques developed by Oceanus involve the construction of PVC pipe nurseries planted with key coral fragments at selected sites along the Mesoamerican Reef and the Gulf of Mexico, and transplantation of thousands of colonies every year. The program includes identification and selection of genetic material from healthy donor populations that are naturally resistant to climate change and local stressors. It also seeks to engage local communities and reef managers as a part of a Restoration Network to achieve greater impact over a larger area. With strategic selection of the restoration sites and increasing the number of healthy live coral colonies genetically diverse, effects of restoration through sexual reproduction and larval dispersal is expected to result in a multiplier effect of reef rehabilitation in a larger area. http://www.oceanus.org.mx

THE STATUS OF REEF FISH ASSEMBLAGES AROUND THE URBANIZED, SMALL ISLANDS AT THE CENTER OF THE CORAL TRIANGLE (SPERMONDE ARCHIPELAGO, SE SULAWESI, INDONESIA) (Abstract ID: 28966 | Poster ID: 659)

Reefs in Indonesia are arguably the world's most important reefal communities in terms of biological diversity and because of the populace they provide for. For the thousands of small island communities throughout Indonesia, fisheries production and livelihoods are dependent on the condition of their reefs. Yet so often little is known about the ecological 'state' of these reefs and importantly the dynamics of the fish assemblage upon them. The reefs of the Spermonde archipelago provide a valuable case study for other urbanized, island based communities throughout the Indo-Pacific. We assessed the status and trends of reef fish assemblages across the archipelago and compare associations with the benthic conditions and the socio-economic context of local communities. We found 'healthier' reef fish communities around well inhabited islands where some habitat structure is still intact. Outer and uninhabited islands are less endowed presumably because illegal fishing practices are easier to undertake on un-watched reefs. Reefs within 5km of the heavily populated mainland and major industrial cities are highly sedimented and have quite variable benthic and fish communities. Despite the relatively poor condition at present, the Spermonde reefs have a long extraction history and have sustained large human populations. Priority areas for management actions in the area include: major enhancements in targeted enforcement against destructive fishing; prioritization of sewage treatment on densely inhabited islands; and soil management practices in adjacent, mainland agricultural areas.

THE ANTIOXIDANT ROLE OF DIMETHYLSULFONIOPROPIONATE (DMSP): CAN SULFUR HELP CORALS IN A CHANGING CLIMATE? (Abstract ID: 28865)

Corals, with their symbiotic dinoflagellates, are among the largest producers of dimethylsulfoniopropionate (DMSP) and are known to increase the production of this compound under stressful conditions. DMSP is a key molecule in the global sulphur cycle and it has been hypothesised that DMSP and its breakdown products can act as a highly effective antioxidant system in phytoplankton; however its exact function(s) in corals remains unknown. Here we investigate antioxidant mechanisms of DMSP, superoxide dismutase (SOD), glutathione (GSx) and catalase (CAT) in the host and symbionts of Acropora millepora and Stylophora pistillata under increasing temperature (27oC - 32oC). Corals exposed to increased temperatures showed a strong decline in photosynthetic efficiency, indicative of stress. This stress response correlated to an up-regulation of host SOD, GSx and CAT in both species, an increase in symbiont CAT for A. millepora and GSx and CAT for S. pistillata. Once normalised to per Symbiodinium cell, there was significant increases in symbiont SOD, GSx and CAT for S. pistillata and GSx and CAT for A. millepora. There was a significant increase in intracellular DMSP and DMSO per symbiont for both A. millepora and S. pistillata, highlighting a potential antioxidant function of DMSP under thermal stress. These findings highlight how the different responses of two common Indo-Pacific corals may be used to explain their abundance and distributions in the future under a warming climate.

CORAL REEF STRUCTURE INDEX: A SPATIALLY EXPLICIT TOOL FOR MANAGEMENT DECISION SUPPORT IN THE WESTERN CARIBBEAN. (Abstract ID: 28062)

We present a synoptic management tool for decision support: the Coral Reef Structure Index (CoRSI) for the Western Atlantic. It is a three-pronged approach based on the coral community composition (density of colonies by species), coral cover and rugosity. It offers a common currency to objectively compare the reef structure in reef sites, zones and tracts temporally and spatially. This index can be used as stand-alone values for comparison, or can be mapped using high-resolution satellite imagery and spatial prediction techniques. Our study case, Akumal, is a very well developed fringing reef in Quintana Roo México, part of the Mesoamerican Reef, which has experienced a boom in coastal development and tourism in the last two decades, with the highest average hotel occupancy in Quintana Roo. Since 2001 it has been assessed as in critical condition with changes in the coral community composition as well as a complete phase shift with macroalgae coverage averaging 65% vs. 7% of average coral cover. Historical data from a network of monitoring stations since 2000, and archival imagery (Ikonos, WV-2, WV-3), allow, in the one hand, the calculation of CoRSI, and in the other hand, allow the mapping of CoRSI to estimate the loss of reef structure. These spatial estimates using CoRSI reflect 66% of reef structure loss in a 15 years span (2000-2015) for Akumal Reef. This result is in accordance with the historical analysis of shifts in coral community composition, the decrease in coral cover and rugosity estimates in the area.

CRESCYNT: CORAL REEF SCIENCE AND CYBERINFRASTRUCTURE NETWORK – BUILDING DATA TOOLS AND RESOURCES FOR CORAL REEF RESEARCHERS WITH EARTHCUBE (Abstract ID: 30049)

EarthCube envisions a community-driven dynamic cyberinfrastructure intended to increase and democratize access to advanced technological and computational capabilities for geosciences research. As an EarthCube research coordination network, CRESCYNT is working to match the data sources, data structures, and analysis needs of the coral reef community with current advances in data science, visualization, and image processing from multiple disciplines to advance coral reef research and meet the increasing challenges of conservation. CRESCYNT is structured as a network of networks, including both disciplinary nodes (e.g., microbial diversity, symbiosis, disease, physiology & fitness, reef ecology, fish & fisheries, conservation & management, biogeochemistry & oceanography, paleontology, climate change) and technological nodes (e.g., visualization, geospatial analysis & mapping, image analysis, legacy & dark data, data management). Participation remains open at http://crescynt.org. CRESCYNT offers the community an opportunity to collaborate and share resources, tools, training, and solutions to current problems in the near term, as well as the chance to identify needs and influence priorities for cyberinfrastructure development for geosciences over the long term. Collaborative efforts of participants and node coordinators, identification of applicable technologies developed in other disciplines, and partnership with a broad set of valued partners particularly in other sections of EarthCube have been essential to progress so far. “Hypotheses come and go but data remain” (Cajal).

FINE-SCALE POPULATION STRUCTURE OF TWO HOST SEA ANEMONE SPECIES IN KIMBE BAY, PAPUA NEW GUINEA (Abstract ID: 30007 | Poster ID: 521)

Anemonefishes are one of the main groups that have been used over the last decade to empirically measure larval dispersal and connectivity in coral reef populations. Ten species of sea anemone are integral to the life history of these fish, yet the biology and population structure of these anemones remains poorly understood. Furthermore, host anemones are heavily targeted for the aquarium trade and are susceptible to bleaching, so understanding their biology is crucial for developing better management strategies. This study measured the genetic structure of host anemones within and between two nearby reefs to elucidate their reproductive mode and dispersal potential. We sampled two species (*Stichodactyla gigantea* and*Heteractis magnifica*) almost exhaustively at Tuare and Kimbe Island in Kimbe Bay, Papua New Guinea, which are separated by approximately 25 km. Panels of microsatellite markers were used to study the reproductive mode and population structure of these species. Surprisingly, genetic analyses confirmed six pairs of clones for *S. gigantea* (n=350), indicating the first record of asexual reproduction for this species; while no clones were found for *H. magnifica* (n=128), which is known to use longitudinal fission as a reproductive mode in other locations. Our results show the first genetic evidence of their reproductive characteristics, high levels of connectivity among islands and significant levels of genetic relatedness among individuals within islands.

CORAL REEF HEALTH MONITORING BY COMMUNITY VOLUNTEERS AT WAR IN THE PACIFIC NATIONAL HISTORICAL PARK, GUAM (Abstract ID: 28279 | Poster ID: 729)

As a way of bridging the gap between policy makers, scientists, and stakeholders, the War in the Pacific National Historical Park on Guam is undertaking several reef-related citizen science projects. Citizen science is a remarkably successful tool; it fulfills the needs of policy makers, it helps stakeholder participants learn about the organisms and environment they are monitoring, and it develops strong partnerships between the parties involved. At the National Park citizen scientists are taking to the ocean to conduct quarterly coral reef and giant clam (Tridacna spp.) monitoring. By using standardized methods (Coral Watch, http://www.coralwatch.org) to collect large quantities of data from multiple habitats and locations over long periods of time, these citizen science programs will supply much needed information to Guam’s policy makers, scientists, and coral reef stakeholders. With the basic – but integrally important – data, these parties can make educated decisions on how to regulate, recover, and protect some of the island’s most valuable resources.

NO REEF LEFT BEHIND: USING AND INTERPRETING NOAA CORAL REEF WATCH’S 5-KM REGIONAL VIRTUAL STATIONS FOR MONITORING BLEACHING STRESS (Abstract ID: 28366 | Poster ID: 615)

The National Oceanic and Atmospheric Administration’s (NOAA) Coral Reef Watch (CRW) program has developed a set of Regional Virtual Stations (RVS) that provide comprehensive, localized summaries of bleaching thermal stress conditions for all reef locations worldwide. The RVS bring together CRW’s daily 5-km satellite-monitored and 50-km climate-model projected sea surface temperature products to track environmental conditions in near-real-time and provide bleaching outlooks up to 12 weeks out. There are currently 211 RVS, each of which provides regionally representative statistics based on all satellite data pixels contained within the defined area. RVS locations were created based on political/jurisdictional boundaries; they use global coral reef locations from sources including the Millennium Coral Reef Mapping Project, the World Atlas of Coral Reefs, and other in-house sources. Reef-containing 5-km satellite pixels were identified and augmented with a 20-km buffer around each pixel to define the extent for each RVS. The RVS are used in a series of products including Regional Bleaching Thermal Stress Gauges; the new Satellite Bleaching Alert email system; time series graphs; interactive Google Maps and Google Earth interfaces; and associated data files. These products are

designed to alert reef managers and other stakeholders to changes and potential environmental threats to reefs of interest and help facilitate effective management actions in preparation for and response to mass coral bleaching. This poster details each product's methods and how to interpret the data.

SPECIES DELIMITATION AND CLUSTERING METHODS HELP IN REVEALING CRYPTIC DIVERSITY IN THE POCILLOPORA CORAL GENUS (Abstract ID: 29285)

The South Western Indian Ocean (SWIO) and the South Western Pacific Ocean (SWPO) are striking marine biodiversity hotspots, showing high levels of cryptic diversity. We focused on one of the major constituents of the Indo-Pacific reefs, the coral genus Pocillopora, using genetic tools to assess species diversity. To do so, 840 colonies from different morphospecies (P. eydouxi, P. verrucosa, P. meandrina and P. damicornis complex) were sampled in both regions. Using species delimitation methods (ABGD, GMYC and PTP) on sequence datasets (ORF, Dloop and ITS2) together with clustering methods (Structure and DAPC) on 10 microsatellites data allowed us unrevealing high cryptic diversity. Indeed, combining the different markers and methods allowed us identifying several putative species: (1) P. meandrina-like colonies from West Madagascar and New Caledonia similar to P. sp. type 8 (sensu Pinzon et al 2013) from Pacific, (2) P. verrucosa-like colonies from SWIO similar to P. sp. type 7a from Indian Ocean (sensu Pinzon et al 2013), and (3) P. eydouxi-like colonies with small, neat, uniform and tight verrucae and present in both regions which have not been described yet. Additionally, P. fungiformis-like colonies sequences from SWIO formed a robust clade with P. effusus sequences from Tropical Eastern Pacific , suggesting these two species being synonyms.

PLASTICITY IN THERMAL TOLERANCE WINDOWS OF EARLY LIFE HISTORY STAGES (Abstract ID: 30066 | Poster ID: 47)

Temperature is a key factor determining the physiology and distribution of marine species. As the rate of global climate change increases, the influence of temperature becomes more relevant; however, its effects can vary across different life-history stages. Benthic marine species with planktonic larvae may experience different thermal environments during development than as adults and, therefore may also exhibit stage-dependent tolerance to thermal stress. Thermal tolerance of early life stages may also differ in its acclimatory capacity. This research aims to compare thermal tolerances of the sea urchin *Tripneustes gratilla*, an ecologically important grazer present on Hawaiian coral reefs, reared at 20C, 25C and 29C. In order to more accurately predict the ecological consequences of climate change, sublethal and lethal effects of temperature will be investigated, including LT50, oxygen consumption, and swimming/clearance rates of larvae. Results from LT50 measurements demonstrate that early life- history stages of this species do not exhibit a difference in their temperature dependent mortality when reared at different temperatures and that they may lack plasticity in this response to thermal stress. These findings provide a method of comparing and highlighting vulnerabilities of *Tripneustes gratilla* larvae by estimating their capacity for acclimation and potential for adaption to future climate change scenarios.

CORAL REEF GEOMETRY WARS: USING CORAL GEOMETRY TO UNDERSTAND CORAL-ALGAL INTERACTIONS (Abstract ID: 28869)

Corals must defend their perimeters against algae and other benthic organisms. We hypothesized that resources available to defend a coral's perimeter or attack a competitor depends on the surface area of a colony available for nutrient uptake and photosynthesis. To test this hypothesis, two variable chain-link methods were used to measure the perimeter of six coral colonies from the Caribbean island of Curacao. Surface area was calculated using a 3D, overlapping photo method. These values were used to calculate the perimeter to surface area ratio. Visual scoring was then used to determine the percentage of coral perimeter losing to another benthic organisms (i.e. algae overgrowing coral tissue). The perimeter to surface area ratio positively correlated with the percentage of perimeter along which the coral was losing a competitive interaction, suggesting that a large perimeter:area is energetically expensive and may allow algal overgrowth. Coral geometry serves as a visual representation of all factors impacting a coral colony and may have implications for better understanding coral-algal interactions.

PH HOMEOSTASIS DURING CORAL CALCIFICATION IN A FREE OCEAN $CO_2$ ENRICHMENT (FOCE) EXPERIMENT, HERON ISLAND REEF FLAT, GREAT BARRIER REEF (Abstract ID: 28269)

Understanding the ability of corals to regulate their internal chemistry at the site of calcification is central to predicting how coral reefs will respond to ocean acidification (OA) as atmospheric $pCO_2$ continues to increase. A major concern is how corals will calcify as seawater pH and carbonate saturation levels decline. Some laboratory studies have suggested corals may cease to calcify as $pCO_2$ levels approach ~600ppm. Yet some corals in their natural habitat are exposed to relatively low pH levels on daily to seasonal time scales. Boron isotope analysis, used as a proxy for pH of the calcifying fluid ($pH_{cf}$) during calcification, suggest corals increase $pH_{cf}$ relative to the surrounding seawater. We present boron isotope data from corals (*Porities cylindrica*) grown in situ at Heron Island Reef flat. These corals were subject to the natural pH regime (control) of the reef and an additional lowering of pH (treatment) relative to this natural regime through $CO_2$ injection. This experiment was performed over 6 months using Free Ocean Carbon Enrichment (FOCE) flumes to allow for the natural variability in ambient seawater chemistry. Our findings suggest pH regulation within these corals is stronger than previously thought. These corals appear to maintain elevated $pH_{cf}$ (~8.6) regardless of seawater pH (range ~7.7–8.3) to facilitate calcification. Furthermore, we expand on how our measurements can resolve some of the ambiguity surrounding the interactions of dissolved inorganic carbon (DIC) during the calcification process.

A NEW IMAGE CLASSIFICATION APPROACH FOR MAPPING CORAL DENSITY IN KUWAIT USING HIGH RESOLUTION SATELLITE IMAGES (Abstract ID: 27845)

This research study,explores the capability of high spatial resolution multispectral (MS) satellite sensors (WorldView-2 (WV-2) and Pleiades-1B) in quantitatively mapping coral density of Kubbar coral reef ecosystem, located in Kuwait's southern waters. The MS imagery of WV-2 and Pleiades-1B were,after geometric and radiometric corrections, subjected to a number of different classification methodologies and approaches; supervised Maximum Likelihood (ML), unsupervised K-mean, Object-Based Image Analysis (OBIA), and a Multiple Linear Regression (MLR) coral density model.The MLR analysis used the dependent variable of coral density percentage from ground truth and independent variables of spectral reflectance in bands 1 through 6 (WV-2) and bands 1 through 3 (Pleiades-1B),depth (as estimated from a surface derived from bathymetric charts) and distance to land or reef unit center. The results showed that coral density maps developed using the MLR coral density model proved to be the most reliable and accurate (overall accuracy of 67% and Kappa statistic of 0.5 for raw WV-2 and overall accuracy of 70% and Kappa statistic of 0.4 for raw Pleiades-1B) amongst all other image classification methodologies and approaches.In addition,the results highlighted some issues attached to implementation of image classification processes when mapping coral density such as: errors attached to geometrical accuracy of collected data from the field, reef heterogeneity,number of classes being used in image classification and the effects of image pre-processing (radiometric corrections) on image data

WAVELENGTH-SPECIFIC FORWARD MIE SCATTERING BY BRAGG-REFLECTIVE IRIDOCYTES CONTROLS THE INTERNAL PHOTIC ENVIRONMENT IN GIANT CLAMS (Abstract ID: 27848)

A surprising discovery from our lab revealed that brightly reflective iridocytes in the mantles of Tridacnid giant clams scatter solar photons forward more deeply into the

tissue. While intracellular Bragg reflectors produce these cells' colorful back-reflection, forward Mie-scattering actually enhances illumination of the endosymbiotic, microalgae. We used microspectrophotometry to measure the refractive indices and thicknesses of the Bragg lamellae in live iridocytes in situ, and used these parameters to model the optical behavior of the iridocytes with electromagnetic finite difference time domain (FDTD) simulations. The results offer potentially significant new insights for our growing understanding of the physiological, ecological and evolutionary complexities of the symbiotic relationship between giant clams and their endosymbiotic microalgae. Our results confirm that ca. 90% of wavelength-specific solar photons incident on the iridocytes are propagated deeper into the tissue by forward Mie scattering, and quantitatively show how variations in iridocyte ultrastructure generate variations in the internal photic environment in the animal host that might establish optimal habitats for different clades of algae that preferentially utilize different regions of the solar spectrum for photosynthesis. If this should prove to be the case, reflection of a particular color from the mantle iridocytes might provide a convenient diagnostic for recognition of the light environment within a giant clam, and consequently, for the subtype of alga it might harbor and rely upon.

NUTRITIONAL INTERACTIONS IN LONG-TERM REDUCED PH SUGGEST ACCLIMATION OF ANEMONIA VIRIDIS? (Abstract ID: 28346)

Growing evidence suggests that symbiotic sea anemones will flourish in an acidified ocean. $CO_2$-enrichment has a fertilizing effect on photosynthesis, increasing the passive diffusion of carbon across membranes and thus reducing an organism's reliance on energetically-costly carbon concentrating mechanisms. Here, we used pulse-chase $^{13}C$ labeling in conjunction with TEM and NanoSIMS imaging to examine how long-term acclimation to reduced pH influences carbon uptake, fixation and turnover in both the symbiont and its host. *Anemonia viridis* were collected from two sites (pH 8.1 and 7.4) situated along a naturally-occurring $CO_2$ gradient in Vulcano Island, Italy. The samples were transferred from their respective sites to tanks with $^{13}C$-bicarbonate labeled seawater. After 5 h, some animals were collected while others were transplanted back to their native sites for a chase period, during which samples were collected at 12 and 36 h, respectively. NanoSIMS images of dinoflagellate symbionts from the 5 h timepoint revealed strong $^{13}C$-labeling of the starch sheath surrounding the pyrenoid, starch granules and lipids present in the symbiont. No significant difference in $\delta^{13}C$ was detected in symbionts and the host gastroderm between sites. The rate of carbon turnover however, did differ, with turnover ca. 23 % faster in symbiont and ca. 40 % faster in the host gastroderm in anemones from the low pH site. We will discuss the long-term acclimation in defining an organism's response to ocean acidification.

FUNCTIONAL MORPHOLOGY OF PARROTFISHES AND BIOEROSION AT THE ABROLHOS BANK (Abstract ID: 27859 | Poster ID: 263)

Parrotfishes (Labridae: Scarini) play key roles in a number of ecological processes in tropical reefs. Species within this group may differ in their feeding morphology and behavior, which directly shape their impact in a given system. The Abrolhos Bank, northeastern Brazil, encompasses the largest coral reef in the South Atlantic, but little is known on parrotfish feeding ecology in this region. We compared the feeding morphology of three abundant parrotfishes and assessed bite and bioerosion rates of the largest species, Scarus trispinosus, which has suffered severe population declines during the last decade. We found marked differences in the premaxilla, dentary and mouth configuration among the studied species, and between life phases of S. trispinosus. Scarus zelindae has the weakest and most mobile jaws and, as juveniles of the other studied species, was classified as a scraper. In contrast, adults of S. trispinosus and S. amplum are excavators, as they possess robust jaws with simple joints. For S. trispinosus, body size and feeding rates were positively related to volume of substratum removed. Large adults of this species removed about 207 cm3 of substratum per day, with bioerosion rates of 75,500 cm3 per year. This study shows clear differences in feeding morphology among parrotfishes in Abrolhos and indicates that, because of its robust jaws and large size, S. trispinosus plays unique roles in this system. Our results are relevant considering the overfishing in these reefs, especially of large herbivore species, which may directly alter the dynamics of Abrolhos.

A SYNCRETIC VIEW OF TIME; ASSESSING CORAL-REEF ECOSYSTEM TRAJECTORIES TO SUPPORT SOCIAL-ECOLOGICAL RESILIENCE AND ADAPTIVE CAPACITY INTO THE FUTURE (Abstract ID: 28297)

Coral reefs and human communities are tightly coupled, especially in Pacific Islands where human beings have depended on these resources for millennia. Historical reconstructions of marine ecosystems in Hawaii show steep declines in living marine resources since Western contact. Despite this overall downward trend, integrated social and biological data reveal past periods of local recovery in some resources such as reef fish. We examined marine eco-state trajectories of two communities in Hawaii (Haena and Kaupulehu) that are initiating management plans consistent with traditional knowledge. Based on historical reconstructions, current ecological assessments, and vulnerability to projected climate pressures, we present a syncretic (combining many perspectives) approach to support coral reef ecosystem management. Past recovery periods were associated with increased resource protection, and resurgence in traditional management practices. Present resource fish biomass was significantly lower at Kaupulehu (75 %) and Haena (57%) compared to a virtually unfished reference area. To assess fisheries vulnerability to projected climate change, we constructed a reef fish susceptibility index based on fish size and feeding specialization, which indicated that a small percentage (<1%) of adult resource fish biomass was highly vulnerable to habitat loss due to coral mortality. However a much higher proportion (>75%) of the fish assemblages consisted of fishes <20 cm, indicating vulnerability during early life stages and the need for increased fisheries management and habitat protection.

TRANSCRIPTOME RESPONSE OF SYMBIODINIUM TO PROLONGED THERMAL STRESS (Abstract ID: 27941 | Poster ID: 19)

Endosymbioses between dinoflagellate algae (Symbiodinium sp.) and scleractinian coral species form the foundation of coral reef ecosystems. Coral symbioses are highly susceptible to elevated temperatures, resulting in coral bleaching, where the algal symbiont is released from host cells. This experiment determined the transcriptional response of Symbiodinium to prolonged thermal stress. Cultures were exposed to elevated temperatures (average 31°C) or control conditions (24.5°C) for twenty-eight days. Thermally treated cultures exhibited reduced cell density from day four onwards ($p < 0.001$). Imaging pulse-amplitude modulated fluorometry determined that photosynthetic efficiency was affected in thermally stressed cells with decreased dark-adapted yield of photosystem II on days 14 ($p < 0.05$), 19 ($p < 0.001$) and 28 ($p < 0.001$). Whole transcriptome sequencing of Symbiodinium cells on days 4, 19 and 28 was used to identify differentially expressed genes. A large number of genes (~23,654 genes, FDR < 0.05) with differential expression were detected, further, fold changes across the transcriptome were low with 92.49% at less than 2-fold. Though a large portion of the transcriptome was differentially expressed, only 2,978 (4.3%) transcripts detected were differentially expressed at all three time points. Analysis identified differentially expressed genes involved in metabolism, growth and stress responses. Interestingly, 56 genes encoding light-harvesting proteins were identified. These genes are hypothesised as critical in the cellular response of Symbiodinium to stress events.

IMPACTS OF BAPTISM DIVING ON A TROPICAL REEF IN SOUTHEASTERN BRAZIL (Abstract ID: 29991 | Poster ID: 452)

Tropical reefs are a popular destination for scuba diving and one of the world's fastest growing recreational sports. Along the year, millions of people practice their first experience with scuba diving through diving baptism, where a professional conduct a non-certified diver. In Brazil, one of the main sites for diving baptism is the Arraial do Cabo Marine Extractive Reserve (ACMER). Approximately 10,000 people practice diving baptism per year. The diving behavior of the instructor and baptized divers were observed inconspicuously in situ during March and April 2015. We classified the interactions according type of interaction (damage or contact) and organism. Eighty-one diving baptisms were observed, with an average duration of 25 minutes. We verified an interaction overall rate of 0.61 ±0.04 (±SE) touches and 0.15 ±0.02 damages per minute of baptized diver and benthic organisms, mainly gorgonians. The highest rates of touches (1.4 ±0.09) and damages (0.33 ±0.02) occurred when the instructor positioned the baptized diver closely the benthic organisms to take a photo. In this moment, several contacts with benthic organism occurred, but were ignored by instructors. This is a prob-

lem because the high rates of baptism diving in the ACMER can represent a high rate of impacts to benthic organisms. ACMER managers urgently need to implement strategies to eliminate interactions with benthic organisms during baptisms, such as specific sites to take photos, with no occurrence of fragile benthic organisms.

QUANTIFYING AND OPTIMISING MANAGEMENT OUTCOMES FOR INSHORE REEFS (Abstract ID: 28227)

Prioritising interventions for both land (e.g. sedimentation) and sea-based (e.g. overharvesting) impacts is vital for coastal systems, as the capacity for management authorities to fully address all impacts is often limited. However, prioritisation steps are yet to be completed for many ecosystems, especially those that experience a higher influence of land-based impacts. We use a Bayesian belief network to determine the influence of key management actions for the health of inshore reefs in Moreton Bay, Australia (c. 27°18'S; 153°17'E), a system under threat from multiple anthropogenic influences. Increasing coverage of no-take MPAs by between 50 and 100% and reducing sedimentation by between 25 and 50% were the most important management targets for optimising health of Moreton Bay's reefs. Addressing individual impacts through separate management actions mostly resulted in additive effects for ecosystem health. Importantly, synergistic increases in ecosystem health were not found until the highest actions on sedimentation and no-take MPAs were implemented. Our results show that addressing key impacts from both land and sea are critical for increasing ecosystem health in nearshore marine environments, meaning that dialogue surrounding focus on either is not appropriate and should rather focus on which impacts are most significant for individual systems. Finally, managers should aim to address key impacts first and should not expect synergistic increases in ecosystem health through multiple, but separate management actions until major impacts are substantially reduced.

HERMIT CRAB-OCTOPUS INTERACTIONS IN DISTRIBUTING RESOURCES BETWEEN REEF AND TERRESTRIAL SYSTEMS (Abstract ID: 28120 | Poster ID: 295)

Terrestrial hermit crabs using shells get this resource primarily from the marine environment. While it is easy to understand how smaller shells commonly found in the shallow back reef might be transported to the terrestrial environment through storm and wave movement, it is unclear how larger shells from gastropods found in deeper reef areas might be obtained in the terrestrial environment. Earlier studies documented that octopuses are important in providing shells for hermit crabs in shallow reef environments of Cayos Cochinos, Honduras. Octopuses range from the shallow intertidal to the outer reef when foraging. Though they consume prey while foraging, they also return to dens with prey, discarding remains into nearby middens. Cumulative data over a ten year study period show that shells of large gastropods are discarded by octopuses near dens in shallow intertidal areas. Distribution of such shells among terrestrial and marine hermit crabs suggests that octopuses are important in moving these resources across the reef. Some shells become incorporated into the reef structure and encrusted by organisms such as poriferans, cnidarians, crustaceans, and algae or may be buried by sediment. Hermit crabs attracted to middens by visual or chemical signals may remove shells from middens as well. Larger shells in shallow middens were exposed at very low tides or during storms, making them accessible to terrestrial hermit crabs. The octopuses are critical intermediaries in this transport system. This research was made possible through permission of the Honduran government.

LINKING GOVERNANCE TO ECOLOGICAL OUTCOMES IN CORAL REEF MPAS GLOBALLY (Abstract ID: 29787)

Marine Protected Areas (MPAs) are increasingly being employed as a tool to promote biodiversity conservation and maintain flows of ecosystem goods and services to coastal communities; however, their implementation has had varying levels of success. Results from numerous case studies suggest that protected area governance is a major factor in explaining the variation in ecological outcomes, but few studies have been able to examine the linkages between MPA governance and reef fish impacts at a regional or global scale. As part of a global study, we compiled ecological data from over 13,000 underwater reef surveys and governance data from approximately 350 management assessments to explore the relationship between MPA governance and ecological outcomes in reef fish populations. Using an impact evaluation approach to control for potentially confounding factors, preliminary analyses demonstrate (on average) increases in fish population metrics (e.g. total biomass) within MPA boundaries, particularly within no-take zones. Detailed governance data were available in approximately 50 coral reef MPAs, and preliminary results show significant relationships between responses of fish populations to protection and the presence of specific governance and management attributes (e.g. clearly defined boundaries). This research will provide evidence-based insights into how the ecological impacts of coral reef MPAs are shaped by governance and management conditions, contributing to more informed coral reef management and policy.

IMAGE MOSAICS BEFORE, DURING, AND AFTER THE 2014 MASS CORAL BLEACHING AT CHEECA ROCKS, FLORIDA KEYS REVEAL HIGH RESILIENCE OF A CARIBBEAN CORAL REEF (Abstract ID: 29758)

Warm-water coral bleaching has been a main driver of reef decline in recent decades. However, little is known about how coral community composition will change with annual bleaching. Underwater photomosaic imaging technology is a rapid in-water survey technology that provides accurate information on coral community composition, coral cover, and individual colony health that can be used over time to answer questions on species susceptibility and mortality due to coral bleaching. In 2012 a long-term monitoring program, part of NOAA's National Coral Reef Monitoring Program (NCRMP), was established at Cheeca Rocks, Florida Keys using photomosaics to map and document the health of 5227 coral colonies representing 21 Caribbean species. Mosaics were collected annually from 2012-2015, with additional sampling in September 2014 and March 2015 to document peak bleaching in 2014 and recovery, respectively. We evaluated coral species' bleaching susceptibility and mortality as a result of the 2014 event. Bleaching incidence was low for *Porites astreoides* and *Siderastrea siderea*, but nearly 100% for *Porites porites* and the threatened coral species*Orbicella annularis*. Despite 2014 being the warmest on record, the coral community at Cheeca Rocks was highly resilient with low partial and total coral mortality. Continued mosaic monitoring during and after the repeat bleaching in 2015 will lead to information on species resistance and resilience under consecutive heat-stress events; a scenario predicted to occur as early as 2020 in the Florida Keys.

THE ROLE OF SULFATE ON GROWTH RATES AND SKELETAL COMPOSITION OF *POCILLOPORA DAMICORNIS*: INSIGHTS INTO BIOMINERALIZATON IN ANCIENT OCEANS (Abstract ID: 29451 | Poster ID: 98)

The rise and fall of scleractinian coral dominated reefs throughout the Mesozoic and Cenozoic is strongly linked to changes in the chemistry of seawater (calcite vs aragonite seas). Changes in the ion chemistry of seawater have profound effects on the dominant

reef builders in ancient oceans and the biomineralization process. Calcite is precipitated in low Mg/Ca seawater, while aragonite is precipitated in high Mg/Ca seawater but other ions (ie. sulfate) may inhibit the precipitation of these minerals. In order to understand the combined effect of both seawater Mg/Ca ratios and sulfate concentrations on coral growth and skeletal composition, we conducted a series of experiments, with *Pocillopora damicornis*, to manipulate the Mg/Ca ratio and sulfate concentration of seawater. Element ratios were quantified to understand the coral calcification under ancient ocean conditions. All coral fragments produced a substantial amount of new growth over the 8 weeks of our experiment; calcification rates increased with increasing seawater Mg/Ca ratios, while treatments with reduced sulfate concentrations grew slower than our control treatments. Preliminary data indicate that skeletal S/Ca ratios are inversely related to seawater Mg/Ca. Skeletal S/Ca ratios also increase with additions of Ca, suggesting that S is not incorporated into skeletons relative to Ca and rather the sulfate anion may be substituted for carbonate in the crystal lattice. Similar mechanisms may also operate on other anions present in coral skeletons and these processes may be rate dependent.

RISING SEA LEVEL AND REEF RESPONSE IN BORA BORA, SOCIETY ISLANDS, SOUTH PACIFIC (FRENCH POLYNESIA) (Abstract ID: 28050)

Sea-level rise was crucial for Holocene fringing and barrier reef development in Bora Bora, because it created accommodation space and controlled reef architecture. Based on 35 new U-series ages from corals obtained from six rotary cores, early-mid Holocene sea level rose with rates of ca. 5 m/kyr and reached modern level some 6 kyr BP. This level was subsequently exceeded by at least 1 m and eventually approached present level. Occurrence and distribution of coral assemblages indicate an upcore increase in wave energy. Age-depth plots further suggest that fringing and barrier reefs have prograded during the mid-late Holocene. The Holocene fringing reef is up to 20 m thick and comprises coralgal and microbial reef sections, and abundant loose sediment, overlying Pleistocene basalt and soil. An Acropora-Montipora assemblage transitions upcore into a Pocillopora assemblage. Fringing reef growth started 8.78±0.05 kyr BP; accretion rates average 6.54 m/kyr. The barrier reef consists of >30 m thick Holocene coralgal and microbial successions, characterized by an upcore transition from an agaricid-rich to a robust-branching Acropora assemblage. Holocene barrier reef growth began 10.03±0.05 kyr BP; accretion rates average 6.15 m/kyr. An underlying Pleistocene barrier reef contains laminar Montipora and agaricids, and formed 116.93±1.1 kyr BP, i.e., at the end of marine isotope stage 5e, in water at least 20 m deep.

SHORT-TERM EXPOSURE AT $CO_2$ VENT AFFECT SPERMATOGENESIS IN A TEMPERATE NON-ZOOXANTHELLATE CORAL (Abstract ID: 29470)

Ocean acidification is expected to significantly affect calcifying marine organisms, such as corals. While ocean acidification effects on coral calcification have been widely investigated, the effects on coral gametogenesis are almost unknown. A volcanic vent at Panarea Island (Mediterranean Sea, Italy) characterized by continuous and localized $CO_2$ emission, generates a stable $pCO_2$ gradient from the centre to its periphery, providing a unique natural laboratory for ocean acidification studies. Here we assessed the effects of ocean acidification on gametogenesis and embryogenesis of the Mediterranean non-zooxanthellate coral *Leptopsammia pruvoti* transplanted along this natural $pCO_2$ gradient. After 3 months under experimental conditions, increasing $pCO_2$ seemed to negatively influence spermary production and development. In the control Site, all spermaries showed the latest (most advanced) maturation stage while in the most acidic Sites they also displayed earlier stages, indicating a delay in spermatogenesis and consequently of fertilization and planulation processes. Considering the negative response showed by this species after a short-term exposure, an even stronger negative effect on sexual reproduction is hypothesized under a long-term exposure.

COMPARISON OF PRESENT DAY CORAL REEF DISTRIBUTION WITH THE EXPOSED HOLOCENE REEF IN RAMESHWARAM ISLAND, GULF OF MANNAR, INDIA – INFERENCE FOR PALEOECOLOGY (Abstract ID: 29236 | Poster ID: 231)

The Rameswaram Island in Gulf of Mannar forms the southernmost extension of the Cauvery basin, India. Carbonate and clastic rocks of Holocene were observed exposed as cliff/terraces along the shores of northeast to northwest and central part of this Island. The uplifted terraces display well preserved coral reef and associated facies indicating the paleoecology and sea level. Totally 25 rock samples collected from eight locations were studied for petrographic, geochemical and isotropic characters. Three types of facies such as lithified beach rock (older), constructed reef facies and lithified beach rock (younger) facies were identified in the exposed cliff. Few regions are dominated by branching and table growth forms (Acropora), which indicate the shallow facies with low energy, whereas most of the region is dominated by boulders (Porites and Favites), which indicate deeper facies with high energy than branching type. The exposed reef shows a complex diagenetic history, which certainly implies the flooding and exposure phases the reef system went through as well as climate changes. Current distribution of corals was assessed with line intercept transects in the near-shore region of the exposed reefs and it is understood that the study region is dominated by boulders and very few patches of acroporids. The study provides evidence that there is a change in ecology from Holocene to present day. The assemblage of corals, algae, bryozoans, echinoids and benthic foraminifera point towards an inner neritic depositional environment for the raised reef during deposition.

BIGGER IS BETTER: UNDERWATER IMAGE MOSAICS OF LARGE AREAS FOR IMPROVED CORAL REEF MONITORING AND ASSESSMENT (Abstract ID: 29771)

An underwater image mosaic is a high-resolution single-image map of an area of interest created through the alignment and blending of downward-looking component images. Underwater image mosaic surveys retain the speed, detail, and measurement accuracy associated with diver-based coral reef surveys while providing a superior archival tool for documenting benthic changes over time. As a result, underwater image mosaics have become a valuable tool for documenting marine resources as part of both traditional monitoring programs and damage assessments intended for mitigation. Recent technological advances, such as inexpensive high-resolution underwater cameras and low-cost computing have increased both the speed and size of benthic surveys that can be imaged without the use of complex underwater robotics. As a result, underwater image mosaics have recently been used to survey over 50,000 m2 of reef around a ship grounding, rapidly acquire 500 m2 of imagery in a single dive, and document large-scale reef restoration success. The ability to rapidly obtain high-resolution benthic information over large areas makes image mosaics a powerful tool for monitoring and assessing damage when both biological information and accurate size estimates are essential for assessing and restoring reef resources.

VARIABILITY IN CORAL RECRUITMENT ALONG THE FLORIDA REEF TRACT (Abstract ID: 29685)

Reef resilience to global climate change is enhanced when coral recruitment rates exceed mortality rates. Along the Florida Reef Tract (FRT), USA, there is consensus that recruitment failure is impeding coral recovery, but the temporal and spatial variability in this parameter is unknown. We are quantifying interannual variation in scleractinian and octocoral recruitment to 15x15 cm terracotta tiles and natural substrata across much of the FRT. A total of 30 long-term stations (18 in Florida Keys, 12 in southeast Florida) employed by the Coral Reef Evaluation and Monitoring Project were selected, thus allowing comparative analysis of the role that extant biological communities and water temperatures play in coral recruitment processes. Young coral recruits (<3 months old) are often difficult to identify to the species level, so a further transformative aspect of this project is development of a PCR-based system that incorporates species-specific molecular markers to identify recruits. To date we have deployed 32 tile pairs at each site, a total

of 1,920 tiles. A preliminary analysis of a subset of tiles indicates low recruitment rates, 0.2 recruits per tile, consisting exclusively of brooding coral species. Development of the molecular markers is well underway for 16 coral species and shows promise as a tool for verifying recruit identity. In sum, this study is informing management efforts within the FRT by identifying recruitment hotspots, as well as those sites and species having limited ability to counter climate change stressors through natural recruitment processes.

BEYOND ECOSYSTEM SERVICES: EMPIRICAL EVIDENCE OF THE CAUSAL MECHANISMS LINKING MARINE PROTECTED AREAS AND HUMAN WELL-BEING FROM PAPUA, INDONESIA (Abstract ID: 29711)

Recent conservation policy and practice has emphasized the central role of ecosystem services in shaping human well-being. For example, marine protected area (MPA) narratives are dominated by the role of protection in enhancing food security and incomes through increased fish biomass. But, ecosystem services do not represent the only pathway linking conservation and human well-being. Scholars have long recognized the potential for impacts to emerge from the restructuring of resource rights and the infrastructure linked to conservation interventions, as alternative pathways by which conservation efforts may affect local communities. We present empirical evidence of the multiple pathways linking the establishment of MPAs to human well-being in coral reef ecosytems. Drawing on a quasi-experimental impact evaluation of six MPAs in the Bird's Head Seascape, Indonesia, we examine five distinct pathways by which MPAs affect human well-being, including ecosystem services, property rights reallocation, MPA management infrastructure and ancillary opportunities. Structural equation modeling reveals the existence of multiple pathways, initiated by MPA establishment that generate an array of short-term social impacts. We examine the synergies and trade-offs among pathways, as well as the relative importance of unintended pathways. In so doing, we illustrate the incentives, and constraints to the long-term sustainability of MPAs, highlighting the need for a more nuanced understanding of conservation-poverty relationships as the basis for more effective policy and practice.

INSIGHTS ON THE PERSISTENCE OF THE WELLINGTON REEF IN THE NORTHERN GALAPAGOS ISLANDS: A MODELING PERSPECTIVE (Abstract ID: 27832)

Wellington Reef is the largest known structural reef in the Galápagos Islands. This study explores the recovery potential of the Wellington Reef using a stochastic simulation that employs empirical data on coral growth, bioerosion, fecundity, recruitment, bleaching and mortality from the Wellington Reef and nearby sites. A probabilistic model was developed to estimate $CaCO_3$ erosion of individual coral colonies by the sea urchin *Eucidaris galapagensis*. The daily mobility behavior of *Eucidaris* was approximated using empirical observations obtained from other sea urchin species demonstrating similar foraging behavior. A non-central chi-squared distribution provided the foundation for modeling the expected number of *Eucidaris* visits a coral colony may experience. Numerous projections 50 years into the future were performed utilizing sea urchin density distributions ranging from very low to very high obtained from local surveys. We subjected each projection to El Niño event schedules that offer plausible future oceanographic disturbances based on recent historical event frequencies. We evaluated the survivability of the Wellington reef by analyzing the net $CaCO_3$ production on an annual basis over a 50-year projection period. Moderate levels of sea urchin densities above current very low densities may significantly increase the likelihood of collapse of the Wellington Reef.

CORAL REEF ECHIURANS: AN UNDERSTUDIED CRYPTIC FAUNA (Abstract ID: 27821)

Recent sampling of the cryptic fauna of a pocilloporid patch reef in Panama has revealed high abundances of an undescribed species of the echiuran *Analassorhynchus* sp. This species is relatively small (2-4 cm) and secretive, inhabiting fine sand/silt sediments beneath coral rubble and simulated frameworks. The guts of all examined specimens were packed with sand grains, shell fragments, and particulate organic matter, evidence of deposit feeding and a potentially important contribution to nutrient recycling. The occurrence of *Analassorhynchus* sp. in the deep recesses of carbonate structures would allow it access to entrapped fine sediments not easily reached by large deposit feeders. Quantitative sampling along the Uva Island forereef, from 3 to 6 m depth, revealed median population densities of 1.2 to 7.2 ind per 20 liters of sediment sampled over a four year (2002-2006) period. In terms of reef area sampled, this is equivalent to 4.8 to 28.8 ind per m. These abundances held steady through the wet and dry seasons. Echiurans are presently known to inhabit coral reefs in Australia, Hawaii, and at upwelling and non-upwelling sites in the eastern Pacific. An important role in nutrient recycling is likely to be recognized as studies of this taxon proceed.

SMALL FISH REVEAL THE BIG PICTURE ON CORAL REEFS (Abstract ID: 28285)

Although Glenn may be better remembered for his work on connectivity and marine reserves, he made great advances in studying the settlement and predation of small fishes on coral reefs. Small fishes play critically important roles in coral reef ecosystems, yet unfortunately for them, reefs represent high risk habitats. Upon settlement, many small fishes face extremely high mortality rates, which can range from 6% to almost 70% per day. Given the danger of being small on a coral reef, it is surprising that such a large number of fishes such as gobies and blennies stay small throughout their lives. In this presentation I will consider small fishes, whether juveniles or adults; introduce what is currently known about their important functional roles on coral reefs, then present results from a series of recent studies that offer insights into the dynamic nature of small fish communities. I will demonstrate how the short lifespans, fine niche-partitioning and high mortality rates of small fishes result in diverse and highly structured assemblages that anchor many trophic pathways and may prove to be sensitive indicators of environmental change. I will also highlight a previously overlooked role of small fishes as predators on coral reefs. These recent findings suggest that the high mortality rates observed in small fishes may be a result of feeding by overlooked cryptic predators. Indeed, some of these small fishes may be the most important predators on coral reefs.

BIOCHEMICAL AND BACTERIAL COMMUNITY CHANGES DURING THE COURSE OF PATHOGENESIS IN THE SPONGE DISEASE APLYSINA RED BAND SYNDROME (Abstract ID: 28441)

Sponges are essential ecological components of coral reefs, and like corals, sponge diseases have been reported with increasing frequency worldwide. Aplysina Red Band Syndrome (ARBS) is widespread across the Caribbean basin, affecting up to 10% of Aplysina cauliformis, one of the most common members of the Caribbean sponge community. ARBS significantly impacts sponge physiology and, ultimately, sponge growth, survival and population dynamics. ARBS is highly transmissible via sponge-to-sponge contact, enabling us to identify biochemical and bacterial community changes in sponges over the course of pathogenesis. We performed 9-day contact experiments with healthy-diseased and healthy-healthy control treatments in the Bahamas in January and July. We compared individual sponges sampled initially and at successive time points to characterize short-term temporal changes in concentrations of chlorophyll a (associated with the loss of cyanobacterial symbionts), total protein, secondary metabolites, and heat shock protein, as well as bacterial assemblages. All healthy sponges in contact with diseased sponges developed ARBS by day 9 and observed changes correspond with the timing of ARBS development. Several biochemical markers, and bacterial assemblages, of initially healthy sponges that developed ARBS during the experiment shifted towards those of naturally diseased sponges over this time period. This represents one of few studies to evaluate temporal changes over the course of pathogenesis in a marine invertebrate.

CHARACTERIZING PARTICIPATION IN NON-COMMERCIAL FISHING AND OTHER SHORE-BASED RECREATIONAL ACTIVITIES ON ST. CROIX, USVI (Abstract ID: 29572 | Poster ID: 598)

Fishing is part of the culture and heritage of the U.S. Virgin Islands (USVI). Residents of USVI fish for enjoyment, to gather food, to bond with others, as well as for gifting and other traditional activities. From December 2013 - October 2014, researchers walked the shores of St. Croix to gather information on shore-based fishing and other recreational activities. A primary goal for this study was to assess fishing effort for non-commercial fishing conducted from shore, as well as to document levels of participation in other

shore-based activities. The study found that the number of fishers using the shoreline at any given time during the study was relatively low compared with people engaged in other recreational activities. However, findings indicate that particular areas, times of day, and days of the week were more popular with shore-based fishers than others. Observing, walking, swimming, sunbathing, camping and snorkeling were the most common non-fishing activities documented during the study period. Shoreline areas near population centers exhibited higher numbers of people engaged in recreational activities than more remote areas of the island. The study found that shore-based, non-commercial fishing on St. Croix was not as commonplace as expected, but that the shoreline is important to the community for a variety of other recreational activities.

A COMPARISON OF DISEASE PREVALENCE IN WILD AND OUTPLANTED*ACROPORA CERVICORNIS* COLONIES ALONG THE FLORIDA REEF TRACT (Abstract ID: 29027)

As coral restoration projects become more common there are important ecological questions to be addressed, such as the health of outplanted corals in relation to the natural reef community. Here we examined data from multiple projects to make preliminary comparisons of disease prevalence in wild and outplanted *Acropora cervicornis* colonies. Data were gathered from a large *A. cervicornis* demographic monitoring project covering three Florida regions: Broward County (BWD), Middle Keys (MDK) and Dry Tortugas (DRTO) and multiple outplanting projects within BWD. Prevalence of disease was calculated for every monitoring event (annual to monthly) between 2010 and 2015 for each region and all outplant projects. The overall mean colony prevalence of disease per event, all projects combined, was 3.4%. Disease was most prevalent during summer months for wild and outplanted populations. MDK wild colonies had the highest mean prevalence of disease per monitoring event, whereas outplanted colonies had the lowest mean prevalence of disease per event. The highest prevalence of disease for any one event was recorded on wild colonies in BWD during the Summer 2015 at 18.5%. These data indicate that the prevalence of disease in outplanted corals across multiple years and during outbreak events is similar to, if not less than, that recorded across the entire Florida Reef Tract for wild colonies. These data also provide further evidence that outplanted corals respond to stressors similar to wild colonies and currently are not a significant health risk to wild coral populations.

OPTIMIZING OUTPLANT SUCCESS FOR *ACROPORA CERVICORNIS*: AN ASSESSMENT OF VARYING COLONY DENSITY, SIZE AND ATTACHMENT TECHNIQUES (Abstract ID: 28404)

The most widely used coral species in the greater Caribbean for reef restoration is Acropora cervicornis. However, best outplant methodologies in terms of colony density, size and attachment technique have not yet been adequately evaluated. Two studies were developed to evaluate A. cervicornis outplanting methodologies in southeast Florida. In the first study, colonies 10-15 cm total linear extension(TLE) were outplanted using a nail, epoxy and cable tie at densities of 1, 4 or 25 corals per 2 $m^2$ plot, each density was replicated 12 times. Colonies outplanted in the second study were of small (5-10 cm TLE), medium (11-30) or large (31-50) size class and outplanted using nail and cable tie, epoxy or cement puck. Each size class was replicated 45 times per attachment technique. In the first study, survival after 2 years was highest for corals outplanted at 1 coral per 2 $m^2$ and lowest for corals outplanted at 25 corals per 2 $m^2$. The number of colonies missing and overall prevalence of disease and predation was greatest in high density plots. In the second study (9 months), corals attached using a nail and cable tie, regardless of size, was the most successful in terms of survival. Large corals had the highest rate of survival over small and medium corals. A majority of coral loss was attributed to missing corals, which was highest for the puck technique and also small epoxied corals. These results indicate that greatest outplant success may be achieved by using a nail and cable tie to attach larger colonies at a minimum spacing of 2 m.

PERIODICALLY HARVESTED CLOSURES PROVIDE SHORT-TERM FISHERIES BENEFITS (Abstract ID: 28424)

Periodically harvested closures (PHCs) are small fisheries closures that range from being mostly closed to mostly open to fishing. We provide the first comprehensive assessment of PHCs to provide short-term fisheries benefits across Fiji and the broader Western Pacific. PHCs in Fiji consistently decreased the wariness of larger targeted fish species, but were less likely to increase abundance or biomass. PHCs in the Western Pacific had a 48% greater abundance and 92% greater biomass of targeted species when compared with areas open to fishing, suggesting they are capable of providing short-term protection benefits. Harvesting PHCs results in a rapid increase in wariness and decrease in the abundance and biomass of targeted fishes. Factors affecting the ability of PHCs to provide short-term protection and harvest benefits included size, duration of closure and compliance. Strict controls are needed during openings to optimize future benefits. One year of PHC closure was insufficient for the recovery of pre-harvest protection benefits, which were principally observed for species with low and moderate vulnerabilities to fishing. Despite the ability of PHCs to provide some short-term fisheries benefits, a broader range of fisheries management and conservation strategies are needed for the long term sustainability of small-scale fisheries in the Western Pacific.

CLIMATE CHANGE, THE GREAT BARRIER REEF, AND THE RESPONSE OF AUSTRALIANS (Abstract ID: 30151 | Poster ID: 600)

Inspiration, aspirations, attitudes, and perception of threats play a pivotal role in the way that individuals associate themselves with natural environments. These sentiments affect how people connect to natural places, including their behaviours, perceived responsibility, and management interventions they support. World Heritage Areas hold an important place in the lives of people who visit, aspire to visit, or derive a sense of security and wellbeing from their existence. Yet, the connection between people and special places is rarely quantified and policymakers find it difficult to incorporate these human dimensions into decision-making processes. Here we describe the personal concern and connection that Australians have with the Great Barrier Reef and discuss how the results may help with management. We utilise a statistically representative sample of Australian residents (n= 2,002) and show empirically that climate change is perceived to be the biggest threat to the Great Barrier Reef, and that the Great Barrier Reef inspires Australians, promotes pride, and instills a sense of individual identity and collective responsibility to protect it. An increased understanding of the high levels of personal connection to iconic natural resources may help managers to enhance public support for protecting climate-sensitive systems within Australia and around the world.

DETECTING HOURLY TO DAILY VARIABILITY IN SUBMARINE GROUNDWATER PLUMES, NUTRIENTS AND FLUORESCENT DISSOLVED ORGANIC MATTER AT A CORAL REEF IN MAUNALUA BAY, HI (Abstract ID: 29707 | Poster ID: 461)

Submarine groundwater discharge (SGD) can deliver high concentrations of dissolved inorganic nutrients (DIN; N, P, Silicate) to Maunalua Bay, Oahu, Hawaii. Our previous research has demonstrated that fluorescent dissolved organic matter (fDOM) is a useful biogeochemical tracer of SGD, but we know little of how hourly to daily variation in SGD may alter dissolved nutrient distributions across reefs. Here, we present data tracking the temporal and spatial variation in SGD, fDOM and dissolved nutrient distributions over a 9-day period at Black Point, Maunalua Bay. Four coastal ocean sites were sampled over an onshore to offshore spatial gradient: the submarine spring, 2 sites in the transition zone, and a near-reef crest "marine-like" site. Samples were collected for fDOM, radon, temperature, salinity, DIN, dissolved organic carbon and nitrogen (DOC and DON), chlorophyll a, and microbial abundance and diversity. Our results reveal that Black Point SGD has cooler temperatures, lower salinity, and higher radon and dissolved inorganic nutrient concentrations than that of "marine-like" waters. We also observed clear temporal and spatial patterns in the enrichment and decline of SGD and DIN at each site, and were able to resolve significant enrichment at the "marine-like" site. Patterns in fDOM will be discussed as they relate to tracing SGD at each site. These results provide new information on the effects of SGD on coastal coral reef nutrient dynamics over hourly to weekly timescales and as a function of tides and land hydrology.

REFUGIA AND RESILIENCE: VARIABLE POPULATION DEMOGRAPHICS AND REPRODUCTION OF A CORAL REEF FISH ACROSS VERTICAL SPATIAL SCALES (Abstract ID: 29782)

With the decline of coral reef ecosystems, reef organisms may become dependent upon habitats at the periphery of their distributions for population persistence. Mesophotic coral reefs (30-150 m), near the depth boundary of most reef fishes, may be natural refuges that can supply larvae to degraded reefs, and are buffered from anthropogenic and natural disturbances. However, depth-driven habitat variability can mediate the refuge function of mesophotic reefs by affecting demographic parameters that influence population resilience and connectivity. We compared population density and structure, size, growth, and reproduction of a model reef fish (bicolor damselfish: *Stegastes partitus*) across shallow shelf (<10 m) and deep shelf (20-30 m) reefs in the Florida Keys, and mesophotic reefs (60-70 m) at Pulley Ridge to assess the refuge function of peripheral habitats. As depth increased, populations were comprised of older and larger individuals, and density decreased, suggesting that mesophotic populations are limited by replenishment of young fish. Otolith-derived ages, measurements of oocyte area, and batch fecundity indicated that mesophotic fish reach larger asymptotic sizes, and have longer lifespans and higher reproductive investment than fish in shallower habitats. Reliance on long-lived individuals for population persistence may decrease ecosystem resilience, however, by supporting populations of large, long-lived individuals, mesophotic reefs may be important sources of larvae for shallow fish populations and may function as valuable refuges for future populations.

BLUE THE DIVE: AN INNOVATIVE PARTNERSHIP BETWEEN THE OCEAN CONSERVATION COMMUNITY AND THE SCUBA INDUSTRY (Abstract ID: 30166 | Poster ID: 637)

SCUBA professionals, scientists, and recreational divers are first-hand witnesses to the destruction of marine and coral habitats, which includes potential adverse impacts from divers themselves. The SCUBA industry is in a position to promote and advance responsible stewardship of the ocean by both changing the way that people interact with their underwater environment and inspiring them to advocate for marine conservation. However, there has been no substantive, effort to organize the dive community. NOAA's National Marine Sanctuary Program began a campaign in 2007 but shelved it because they did not have the backing of the SCUBA industry. In 2013, a new initiative called Blue the Dive (BTD) originated in Boulder, Colorado that aims to create partnerships between the conservation community and the dive industry. The mission of BTD is to promote a strong and unified voice for ocean protection driven by the dive community, improve SCUBA industry sustainability practices, create a more informed and educated consumer, support scientific research, and promote actions that protect the ocean. So far, BTD has organized 3 well-attended symposia at Diving Equipment & Marketing Association (DEMA) meetings (the dive industry's largest trade show), created a BTD social media presence, developed guidelines on "How to be a Blue Diver and Blue Dive Shop", sponsored a BTD Pledge with 2000 signatures, partnered with Blue Certified (an eco-certification program), and filmed messages of support from over 20 industry leaders.

USE OF ANCIENT DNA TO UNDERSTAND CORAL-MACROALGAE INTERACTIONS AT MILLENNIAL SCALES (Abstract ID: 28969)

Phase shifts and the declining ability of ecosystems to recover from disturbances are now commonplace in marine environments. On the inshore Great Barrier Reef (GBR), coral dominance has shifted from*Acropora* to weedier coral species reducing ecosystem resilience. Phase shifts have also resulted in the replacement of corals by fleshy macro-algae. We conducted a coring program of inner shelf reef sediments along the GBR. Through study of the fossil record within the cores, we found recent unprecedented disruption of millennia-scale dominance of *Acropora*. The timing of these shifts is consistent with degrading water quality associated with European colonization of the adjacent coastline. Using ancient DNA (aDNA), here we test whether shifts in coral community composition were associated with changes in macro-algae abundance. All of the sediment samples studied yielded aDNA across the past 750 years. Multivariate analysis of 12 functional groups showed significant temporal variation in the aDNA community structure of one of the two sites studied. The abundance of brown algae from aDNA was negatively related to the abundance of the most dominant corals for both sites. Our results demonstrate the ability for reef sediments to record environmental aDNA, providing a valuable archive for understanding past distributions and relative abundance of important reef dwellers that do not fossilize. This information can be used to detect temporal trends in the frequency and magnitude of past coral to macro-algae phase shifts over decadal to millennial time scales.

GENETIC DIVERSITY RELATED TO HABITAT IN THE REEF BUILDING CORAL ACROPORA PALMATA (Abstract ID: 28426)

The critically endangered Acropora palmata plays a unique role throughout the Caribbean region. It has a life history strategy that combines sexual (genet recruitment) and asexual (ramet recruitment) reproduction. The spatial distribution of genets and ramets are expected to change as a function of the frequency with which this species recruits different types of offspring. In this study, 12 A. palmata stands (322 colonies) were randomly sampled on 7 reefs along the Caribbean coast of Mexico. Habitats were identified as high (HWZ) and low (LWZ) wave action zones. Application of microsatellite markers resulted in 297 multilocus genotypes. Estimates of allelic and clonal diversity were calculated, and fine-scale spatial genetic structure (SGS) characterized. Estimates of clonal diversity (richness, diversity and evenness) were significantly higher in HWZ. No SGS was detected when considering each genet once. However, positive SGS was detected in both HWZ and LWZ at the ramet-level, with an estimated clonal range of 27 m and 58 m, respectively. A statistical difference in SGS between habitats was also identified. Estimates of allelic diversity were significantly higher in HWZ, providing further evidence that A. palmata stands from the two habitats are distinct in terms of genetic diversity. We suggest that clonal range is mainly determined by wave action along the Mexican Reef Tract, perhaps due to differential rates of fragmentation and/or due to lower rates of fragment survivorship in high-energy habitats. When restoring reefs with nursery-reared fragments, existing habitat differences in genotypic and genetic diversity should be considered.

THE 2014-2016 GLOBAL CORAL BLEACHING EVENT: PRELIMINARY COMPARISONS BETWEEN THERMAL STRESS AND BLEACHING TIMING AND INTENSITY (Abstract ID: 28759 | Poster ID: 343)

Rising ocean temperatures have increased the frequency of coral bleaching events. The extremely strong El Niño in 1997/98 triggered bleaching that killed about 16% of the world's coral. In 2010, during a mild El Niño year, elevated ocean temperatures resulted in mass bleaching events in many parts of the world. Currently during another record-strength El Niño event, another global bleaching event has been underway since mid-2014. The National Oceanic and Atmospheric Administration's (NOAA) Coral Reef Watch (CRW) is undertaking an effort to collect and document reports of the severity and extent of the ongoing bleaching event. CRW is collating bleaching data (including reports of no bleaching) from collaborators for the period 2014 through at least 2016. In situ bleaching observations are compared with CRW's satellite measurements of bleaching thermal stress to test CRW's thermal stress monitoring products, including the Coral Bleaching HotSpot and Degree Heating Week products. This presentation explores the timeline of record thermal stress and bleaching occurring globally from 2014-2016 based on the comprehensive in situ bleaching observations CRW has collected to date. Preliminary results from comparisons of bleaching patterns with CRW's satellite products will be discussed for coral reef regions around the globe.

DESIGNING AN ASIAN MARINE HERITAGE: FISHING FOR PEACE (Abstract ID: 30073)

Establishing a Network of Marine Protected Areas (MPA) in the West Philippine Sea (NeWPS) is a Philippine contribution to the goals of the Coral Triangle Initiative (CTI). Its "Strategic Action Plan," referred to as the Regional Plan of Action (RPOA), proposes to harmonize the multiple uses in this vast marine geographic area for the benefit of future generations. Multilateral efforts to institute a code of conduct, particularly by establishing MPAs, in disputed areas such as the South China Sea have been proposed. However, these have often been suspected as a prelude to other non-negotiable concerns, primarily as regards sovereignty. We explore the scientific tasks, opportunities, and global imperatives in pursuing the functionality of MPA networks for the region. These provide the impetus for scientific collaboration that can pave the way for consensus-building strategies. The basis and design of an MPA network as an Asian Marine Heritage shall emphasize: (i) marine biodiversity conservation, (ii) fisheries resilience through adaptive management, (iii) joint research and monitoring to meet the climate change challenge, and (iv) assured safety of navigation. Design considerations for cooperative arrangements are presented to explain how Science and Technology can Enhance Wise Stewardship and Resiliency of Development Systems. These processes can accelerate the resilience of social-ecological systems, and highlight shared and complementary responsibilities among network partners. Win-win solutions are proposed for these offshore reefs to sustain and move towards inclusive development by parking our differences for this threatened world heritage.

INDUCTION OF CORAL LARVAL SETTLEMENT BY CRUSTOSE CORALLINE ALGAE (Abstract ID: 27975)

Crustose coralline algae (CCA) are essential for the functioning of coral reefs ecosystems as they create reef structures through calcification, stabilize the reef framework by binding coral rubble, and induce coral recruitment. The presence of CCA is important for settlement of coral larvae, but whether the settlement-inducing compounds are produced by CCA or by their associated bacteria, is still not well understood. We conducted experiments to determine the mechanisms by which CCA induce the settlement of coral larvae, focusing on discerning the contribution of CCA itself and their associated bacteria. We used an orthogonal experimental design with four factors: 1) CCA species, 2) bacteria associated with CCA, 3) allelochemicals produced by CCA, and 4) dissolved organic carbon (DOC) produced by CCA. Equal number of larvae of the coral Acropora millepora was added to each treatment. The results showed that these larvae need environmental cues to settle. Nevertheless, larval settlement can be triggered only by certain CCA and the inductiveness varies among species. The CCA Titanoderma sp. exhibited a striking capacity to induce larval metamorphosis, up to 98%. The CCA allelochemicals were the primary inducers of coral settlement, while the DOC produced by the CCA and the bacteria associated with the CCA tissue played a secondary role in the inductive mechanism. However, the highest settlement rate was attained due to a synergistic effect between CCA and their associated bacteria. Thereby, my research identified key mechanisms driving coral larval settlement.

ORIGIN AND DEVELOPMENT OF THE DONGSHA ISLAND, SOUTH CHINA SEA IN THE HOLOCENE (Abstract ID: 28145 | Poster ID: 397)

The Dongsha Island is the only island of Dongsha Atoll in the north of South China Sea. The atoll stands about 300-400 meters above sea floor with a diameter of 25 km. The water depth in the lagoon is mostly 10-15 m, maximum 23 m. The island occurs on the inner (lagoonal side) reef flat between two wide channels on leeward (west) side of the atoll, and measures 2.7 km in length (East-West) and 0.88 km in width. The west tip of the island is 0.7 km away from the atoll margin. To explore the Holocene history of Dongsha Island, this study drilled 4 cores of 20-23.3 m in depth, 3 on the Island and 1 on the reef flat west to the island. Lithocolumns were established, and a total of 16 fossil corals were dated by AMS C-14 or U-Th methods and an E-W profile was reconstructed. The results suggest: (1) the Dongsha Island is a sand cay that formed by detrital deposition entirely with no Holocene coral reef or coral conglomerate underneath; (2) the sand-cay deposition might have started since 8150±130 cal yrBP and continued with sea-level rise; (3) the sand cay built up by aggradation with no sign of progradation; (4) the top of limestone basement under the island descends gradually from 13.6 bmsl at seaward margin to 19.8 m bmsl on the lagoonal side; i.e. the island formed where the water depth was relatively deeper. It is interpreted that the island formed mainly by: (1) deflection of waves from the east by the atoll; (2) tidal currents coming from north and south via the two channels; (3) northeast and southwest monsoons.

OSTREOBIUM DIVERSITY IN THE SCROLL CORAL, AGARICIA UNDATA, AT MESOPHOTIC CORAL ECOSYSTEMS FROM SAN ANDRES ISLAND, COLOMBIA. (Abstract ID: 29594 | Poster ID: 130)

Endolithic algae have important functions in reef ecosystems and will have a critical role in how coral tolerate climate change and ocean acidification. Endolithic algal filaments dissolve $CaCO_3$ crystals making reefs more susceptible to abrasion and dissolution and serve as food for bioeroders. These algae can also facilitate coral survival during bleaching events extending their survivorship without zooxanthellae. In the Caribbean, members of the family Agariciidae are commonly the dominant species in the deeper portions of coral reefs. Agaricia undata, inhabits deep reefs between 15 and about 90 m; this coral is associated with dinoflagellates of the genus Symbiodinium as well as endolithic algae (Ostreobium quekettii). A high abundance of Ostreobium sp. has been observed as depth increases. We took images of the Ostreobium and A. undata using light microscopy and SEM and we found a longitudinal growth and high density of the algae. Using the molecular marker rcbL, we examined the diversity of Ostreobium within A. undata from mesophotic coral ecosystems of San Andrés Island in Colombia to test if depth has an effect on Ostreobium composition. We identified five Ostreobium clades, but did not identify a depth-associated pattern. We have yet to determine if the different clades found in A. undata have an ecological significance. The genotypic diversity of Ostreobium, allows us to speculate that these algae could be physiologically diverse and have developed different adaptations that facilitate photosynthesis in low light environments

LOCAL VS GLOBAL STRESSORS: THE CASE OF CUBAN CORAL REEF (Abstract ID: 28087)

Coral reef studies from four regions of Cuba carried out between 2001 and 2014 were compiled to assess influence of local stressors versus global ones. Regions studied were Los Colorados archipelago (northwestern), Sabana – Camagüey archipelago (northeastern), Punta Francés (southwestern) and Jardines de la Reina (southeastern). Fishes (density and biomass) and stony corals (density, sizes, diseases and recruitment) were assessed in the four region using underwater visual censuses. The result were compared taking into account fishing pressure, law enforcement, pollution, sedimentation, sea temperature, frequency and strength of hurricanes, information gathered from several sources. Fish density and biomass, in general, were higher where fishing pressure was lower and where law enforcement was stronger. Large, endangered and top predator fishes were more abundant and larger in well-enforced protected areas than outside them. Jardines de la Reina Marine Reserve showed the best fish condition among the four region. Stony corals condition, in general, was better where pollution and sedimentation were lower, with diverse response to increase sea temperature and frequency and strength of hurricane. The fact that most affectations to stony coral were bleaching and ancient mortality is an indicator of a better condition of Cuban corals when compared to Caribbean and world ones. No consistent regional pattern was observed on stony coral among the four regions studied. These results support the hypothesis that Cuban coral reefs condition was more related to local stressors than to global ones.

MUESO SUBACUATICO DE ARTE (MUSA) AN EFFECTIVE PROJECT TO REDIRECT AND CONTROL VISITORS IN THE NATIONAL PARK OF CANCUN – ISLA MUJERES, MEXICO. (Abstract ID: 29444 | Poster ID: 604)

Protected areas management requieres the use of new ideas to provide effective conservation mechanisms. In Mexico, the use of Carrying capacities or Limits of aceptable change are, by law, mechanisms to incorporate in the management Programs in order to

control the number of visitors but these are diffcult to implement. In the National Park of Cancun Isla Mujeres, aproximately 700 thousand tourist visit this protected area of which 196 thousand (28%) scuba dive in the different coral reef formations. Between 2004 and 2005 coral reef coverage was severly reduced due to three hurricanes of which one was Category 5. Reef restoration Projects were implemented. However, it was decided that a Project redirecting tourist away from coral formations should be designed. The Project commenced with artifical hábitats. In 2008 the implementation of an uderwater Art Museum began to be designed. In 2009 first sculptures were installed and by 2015 more than 520 sculptures have been deployed. MUSA as it is now known has been very succesful. The redirection effect has been assessed and in only one coral reef formation close to 32 thousand tanks are now being used in one of the MUSA galleries. The Project has increased the income of small and large permissionaires and is raising contributions from visitors to increase and maintain the number of sculptures. Though controversial, this Project is now being seen as one great idea to be used in the management of areas with great numbers of visitors.

HOLOBIONT PHYSIOLOGICAL ADJUSTMENTS OF THE CORAL ORBICELLA FAVEOLATA ALONG A LARGE DEPTH GRADIENT (Abstract ID: 29642)

Light is the primary factor controlling coral photosynthesis rates and, consequently, CaCO3 production. The vertical species distribution of Scleractinian corals is directly related to the attenuation coefficient of light (Kd), which also modulates holobiont acclimation to the exponential loss of light intensity with depth. Little research has been conducted to understand the key physiological adjustments behind the plasticity inherent to species able to colonize large depth gradients, in addition to their documented morphological depth-related changes. The progressive increase in tissue pigmentation with depth allows maximizing solar energy collection, but has a structural limit related to tissue self-shading. This structural constraint could be central to determine Symbiodinium photosynthesis, and thus, holobiont capacity to maintain positive carbon balances under light limiting conditions. Here we present an analysis of the variation of holobiont photophysiology along a large depth-gradient (from 5 to 40 m, Akumal, Mexican Caribbean), for a very plastic coral species, Orbicella faveolata. We examined the variation in holobiont photosynthesis and pigmentation, and the effect of depth on the photosynthetic and light absorption efficiencies of the holobiont. We also determined the functional traits that allowed the holobiont to achieve positive carbon balances with depth, and, therefore, are central to maintain coral growth under light limitation.

PARTITIONING THE EFFECTS OF STRUCTURAL COMPLEXITY ON THE INTRA-HABITAT DISTRIBUTION OF CORAL REEF FISHES (Abstract ID: 28885)

Structural complexity is strongly linked to biodiversity and functioning throughout a number of systems. On coral reefs, the abundance and diversity of fish are often associated with habitat structure. This complexity is typically measured using a single, small-scale metric ('rugosity') that comprises of multiple components, each of which may affect fishes differently and limits our understanding of how fishes associate with reef structure. Recent developments in photogrammetry offer the potential to efficiently study reef complexity in greater detail, leading to measures of different aspects of complexity at multiple spatial scales. Here we assess the use of this technology and multiple components of complexity to explain the abundance of reef fish when compared against traditional metrics of structural complexity. Three damselfish fish species were chosen as model species, based on contrasting trophic habits and expected use of reef structure. 3D reef reconstructions were used to quantify the following complexity metrics: 1) exposure to predators and competitors (field of view), 2) density of predation refuges (crevices) and 3) food availability. Overall, these metrics explain the distribution of fish species between 4 and 400-fold better (40-97% of the variance) than the traditional measure of rugosity, and provide insights into which aspects of complexity are most important. Applying these technologies clearly improved on traditional approaches, while providing new insights into species associations with reef structure and the implications of flattening reefs.

KI'INA A'O LAWAI'A (Abstract ID: 30143)

This presentation will introduce concepts and traditions of lawai'a (Hawaiian Fishing Practices) which represents an applied pedagogy for marine resource management. The implementation of this cultural practice at the community level is vital to achieving long-term management success. Lawai'a provides a pathway for developing reciprocal relationships between resource users and the natural environment.

ECOLOGICAL DRIVERS OF LIONFISH AGGREGATIONS ON MESOPHOTIC REEFS IN BERMUDA (Abstract ID: 28391)

Invasive lionfish (*Pterois volitans* and *P. miles*) are now ubiquitous throughout the Caribbean and Western Atlantic, having established themselves in a variety of marine habitats. Recent surveys in Bermuda have revealed dense aggregations of lionfish on mesophotic reefs (60m depth), yet these densities are not pervasive across reefs at this depth. Using diver-led *in situ* surveys of mesophotic reef sites, this study examines how variations in prey fish communities may affect lionfish distribution. A significant correlation was found between prey fish biomass and lionfish density, where sites with a higher biomass of prey fish have higher densities of lionfish. Species-specific correlations of prey fish biomass with lionfish density revealed a significant positive correlation between lionfish density and juvenile *Paranthias furcifer* biomass, however correlations of lionfish density with other prey fish species were not significant. These data indicate that lionfish densities may be driven by distribution and availability of preferred prey types, as gut content analyses show that *P. furcifer* is a preferred prey source for lionfish in Bermuda. Targeted consumption of mesopredators, such as *P. furcifer*, may alter trophic structure affecting the biodiversity of reef communities, however, these data represent baseline assessments of mesophotic fish assemblages, and thus continued monitoring is needed to accurately assess the impacts of these invasive predators.

POPULATION STRUCTURE OF *MONTASTRAEA CAVERNOSA* ON SHALLOW VERSUS MESOPHOTIC REEFS IN BERMUDA (Abstract ID: 29466 | Poster ID: 332)

Mesophotic coral reef ecosystems remain largely unexplored with only limited information available on taxonomic composition, abundance and distribution. Yet, mesophotic reefs may serve as potential refugia for shallow-water species and thus understanding biodiversity, ecology and connectivity of deep reef communities is integral for resource management and conservation. The Caribbean coral, *Montastraea cavernosa*, is considered a depth generalist and is commonly found at mesophotic depths. We surveyed abundance and size-frequency of *M. cavernosa* populations at six shallow (10m) and six upper mesophotic (45m) sites in Bermuda and found population structure was depth dependent. The mean surface area of colonies at mesophotic sites was significantly smaller than at shallow sites, suggesting that growth rates and maximum colony surface area are limited on mesophotic reefs. Colony density was significantly higher at mesophotic sites, however, resulting in equal contributions to overall percent cover. Size-frequency distributions between shallow and mesophotic sites were also significantly different with populations at mesophotic reefs skewed towards smaller individuals. Overall, the results of this study provide valuable baseline data on population structure, which indicate that the mesophotic reefs of Bermuda support an established population of *M. cavernosa*.

SOCIAL AND ECOLOGICAL CONSIDERATIONS IN RESOURCE CONSERVATION: GEOSPATIAL PRIORITIZATION FOR SUBSISTENCE FISHERY MANAGEMENT IN SOUTHEAST BRAZIL (Abstract ID: 29546)

The subsistence extractive reserve (Reserva Extrativista - RESEX) of Arraial do Cabo is one of Brazil's first marine extractive reserves, and is setting a precedent for local resource management efforts in areas of complex stakeholder interests. In order to achieve objectives of the reserve and establish an effective management plan, there must be a better understanding of the spatial dynamics of the RESEX area and uses. Here, we aim to 1) identify areas of high user conflict, 2) identify areas of greater ecological value, and 3) make recommendations for spatial fishing regulations that would cause the least conflict among stakeholders and conserve marine resources. This integration of social and ecological information into a Geographical Information System (GIS) is directly applied to local conservation efforts, and intended to enhance the participatory management process as well as provide an adaptive tool for future monitoring efforts. Stakeholder objectives and concerns were gathered from participatory meetings, as was spatial information on the use of the study area. Ecological data of fish distributions and benthic community composition were drawn from surveys carried out over the past two decades. Mapping products contribute to community efforts a better understanding of the spatial reality of stakeholder use and resource distribution. By integrating local user knowledge and scientific data, we provide a visualized evaluation of priority management areas within the reserve, instrumental to a resource management plan that is participatory, adaptive, and effective.

THE ROLE OF SEDIMENT CHARACTERISTICS IN HERBIVORY DETERRENCE ON CORAL REEFS (Abstract ID: 28551)

Elevated inputs of terrestrial sediments are threatening coral reefs around the globe. These sediment loads contribute to coral reef degradation by reducing the survival of benthic organisms and by changing reef processes. Specifically, sediment loads in the epilithic algal matrix (EAM) deter grazing by herbivorous fishes and may compromise their critical roles on coral reefs. Currently however, the properties of sediments that drive herbivore deterrence are unknown. To understand how sediments inhibit herbivory, it is crucial to disentangle the effects of their various chemical, biological and physical properties. This is particularly important when assessing the specific impacts of terrestrial sediments on inner-shelf reefs. In this presentation I will describe the nature of benthic sediments on inner-shelf reefs of the Great Barrier Reef (GBR) and will discuss their influence on grazing by herbivorous fishes. I will present the results of aquarium based studies which revealed the specific roles of three key sediment attributes: sediment source, grain size and organic load, on grazing by abundant coral reef herbivores. Our findings illustrate the effects that different sediment characteristics may have on herbivory across the GBR. Differences in sediment grain sizes and organic content appear to be crucial drivers of rates of herbivory by grazing herbivores.

ECOLOGICAL RESTORATION OF DEEP CORAL GARDENS ON THE MEDITERRANEAN CONTINENTAL SHELF (Abstract ID: 27838)

Bottom trawling and trammel net fishing are currently causing the removal or damage of deep-water corals and gorgonians allover the world. Fragmentation and reduction of population density of these structural benthic species is one of the major threats for their viability, and may results in a drastic change in the ecological structural and functional role they play. In this presentation, we show a combination of (1) experimental work under controlled conditions and (2) field research used to perform and evaluate the effectiveness of the first ecological restoration targeted to recover deep gorgonian assemblages on the Mediterranean continental shelf. Laboratory experiments showed that a reduction in gorgonian population density significantly affects their capability to capture food and provide suitable conditions for the aggregation of zooplankton and fish larvae. These results demonstrate how fishing impacts not only affect the gorgonians directly removed or damaged, but also impacts the viability of the remaining populations and their ecological role. Based on experimental results, gorgonians entangled in nets were collected from fishermen, and transplanted at high density on artificial structures, which were deployed on the continental shelf in the north of Cap de Creus (Spain) at 85 m depth. Survival of transplanted gorgonians was monitored during one year by means of a remotely operated vehicle. Zooplankton and sediment samples were also collected to follow the recovering of the biodiversity and biomass of the associated fauna.

UNDERSTANDING DRIVERS OF HERBIVORE ABUNDANCE TO SUPPORT RESILIENCE-BASED MANAGEMENT IN HAWAII (Abstract ID: 29022 | Poster ID: 714)

For coral reef ecosystems, herbivorous fishes are believed to play a disproportionately large role in ecosystem processes of coral reefs. For example, by controlling algal overgrowth, herbivores contribute to reef resiliency to bleaching events. Herbivorous fish populations are distributed heterogeneously both between and within the Main Hawaiian Islands. While many herbivorous fish species are targeted by fishermen, human-related impacts must be considered alongside locally-varying habitat and oceanographic conditions. We use data on fishing pressure, human population density, oceanographic conditions and benthic habitat, as well as reef fish monitoring data from multiple sources to develop a series of hierarchical Bayesian models that explain spatial variation in herbivore biomass and diversity throughout the state of Hawaii. Results provide a basis for prioritizing areas for herbivore management within Hawaii - e.g. by identifying areas where there is considerable scope for herbivore recovery, and, conversely, where habitat and oceanographic conditions place a low limit on potential herbivore populations. Finally, using a range of estimates of potential trajectories in coral cover and habitat complexity, we estimate how herbivore carrying capacity for Hawaii reefs is likely to change over coming decades.

IMPACTS OF SEQUENTIAL SUPER TYPHOONS ON CORAL REEF COMMUNITIES AND THE CHARACTERIZATION OF THE RECOVERY POTENTIAL OF CORAL REEFS IN PALAU (Abstract ID: 28569)

Low latitude coral reefs rarely experience typhoons. However, climate change is altering typhoon trajectories. The low latitude reefs of Palau, Micronesia have been unimpacted by typhoon damage for 70 years or more. Yet, in 2012 and 2013, the island was impacted by two successive super-typhoons that catastrophically damaged the eastern outer reefs. Loss of coral cover was highest on the shallow eastern slopes approaching 60%. The density of juvenile corals decreased all around the archipelago, even on reefs where overall coral cover scarcely decreased. These findings suggest a potential stock-recruitment relationship with corals on the damaged eastern reefs. Fish communities were generally unaltered; except small parrotfish which doubled in density along the eastern reef slope and inner reefs following the second typhoon. The long-term recovery of the damaged eastern reefs is unknown. Further research will be conducted throughout 2016 to quantify the recovery potential of Palauan corals reefs, using a combination of historical monitoring data, current assessment of the reef including coral recruitment studies, and modeling techniques. The characterization of the recovery process of the damaged eastern reefs and the drivers that maximize reef recovery will then be adapted into management options.

CORAL GENETIC DIVERSITY AND DISEASE DYNAMICS (Abstract ID: 28528)

Disease outbreaks have decimated reef-building Acroporid corals in the Caribbean. Recent work has shown that certain Acroporid genotypes appear to be resistant to disease and may thus promote the recovery of these critical coral populations. However, resistant genotypes also appear to grow more slowly than susceptible genotypes. Here,

we use a series of spatially-implicit and spatial-explicit metacommunity models to understand the consequences of this tradeoff between growth and susceptibility on the genetic structure and persistence of coral populations experiencing disease outbreaks. We show that under low disease-induced mortality (i.e., virulence), genetic diversity amplifies the size of disease outbreaks when transmission is high but reduces it when transmission is low. Disease amplification occurs when high transmission and low virulence allow the fixation of susceptible but fast-growing genotypes because infected corals occupy patches for a long time and thus make it harder for resistant but slow-growing genotypes to colonize empty patches. Conversely, disease dilution occurs when low transmission and virulence lead to the fixation of resistant but slow-growing genotypes because there are fewer infected corals and thus more empty patches available for colonization. Overall, these results suggest that understanding these reciprocal feedbacks between coral genetic diversity and disease are critical for devising effective management strategies to ensure the persistence of these important ecosystems.

HOST FISH ECOLOGY INFLUENCES SYMBIONT POPULATION STRUCTURE AND SPECIFICITY IN A BIOLUMINESCENT SYMBIOSIS (Abstract ID: 28063)

The coral reef-dwelling cardinalfish, *Siphamia tubifer*, forms a specific pairwise symbiosis with the luminous bacterium, *Photobacterium mandapamensis*, harboring the bacteria in a light organ attached to the gut. At night, the fish forages near the reef while emitting bacterial light along its ventrum. The fish returns to a home site at dawn, where it seeks shelter among the spines of sea urchins and releases excess symbiont cells as waste. To examine the role of the ecology of the host in structuring populations of its symbiotic bacteria, we used double-digest restriction site associated sequencing (ddRAD-seq) to define patterns of genomic structure of both the host and symbiont. Analysis of >10,000 single nucleotide polymorphisms (SNPs) in the host fish across 300 individuals from 11 locations in Okinawa, Japan over 3 years yielded low Fst values and no evidence of genetic structure at spatial scales ranging from a few to one hundred kilometers. In contrast, analysis of >600 polymorphic loci in the bacterial genome yielded distinct genetic structure at spatial scales between 40 and 100 kilometers. The lack of population structure in the host fish implies that *S. tubifer* larvae disperse widely as plankton and do not recruit to natal reefs. In contrast, the presence of genetic structure in the symbiont suggests that host larvae acquire their symbiotic bacteria from a locally enriched pool near a settlement site. The site fidelity and homing behavior of the adult fish therefore may shape and maintain symbiont specificity over host generations.

OCEAN OASES: NEAR-ISLAND BIOLOGICAL HOTSPOTS IN BARREN OCEAN BASINS (Abstract ID: 29755)

Phytoplankton production drives marine ecosystem trophic-structure and global fisheries yields. Phytoplankton biomass is particularly influential near coral reef islands and atolls that span the oligotrophic tropical oceans. The paradoxical enhancement in phytoplankton near an island-reef ecosystem – Island Mass Effect (IME) – was first documented 60 years ago, yet much remains unknown about the prevalence and drivers of this ecologically important phenomenon. Here, we provide the first basin-scale investigation of the IME. We show that the IME is a near-ubiquitous feature among a majority (91%) of coral reef ecosystems surveyed, creating near-island "hotspots" of phytoplankton biomass throughout the upper water-column. Variations in IME strength are governed by key biogeophysical drivers, namely geomorphic type (islands versus atolls), bathymetric slope, reef area, and local human impacts (e.g. human-derived nutrient input). These ocean oases increase nearshore phytoplankton biomass by up to 86% over oceanic conditions, providing basal energetic resources to higher trophic levels that support subsistence-based human populations.

MOLECULAR AND PHYSIOLOGICAL ACCLIMATISATION REQUIRED FOR CORALS TO THRIVE WITHIN SOUTHERLY HIGH LATITUDE REEFS OF EASTERN AUSTRALIA (Abstract ID: 29779)

Southern high latitude reefs have been considered as potential coral refugia as oceans warm, but in the case of coastal urbanised systems requires that corals have a broad capacity to acclimatise to intense localised anthropogenic pressures. How this can be realised through "genetic reprogramming" (of the coral microbiome and/or coral host) versus physiological plasticity is unknown. We examined how corals have both genetically and physiologically acclimatised to thrive within the Sydney harbour area (~34oS); here, the geographically cosmopolitan Plesiastrea versipora and southerly-restricted Coscinerea mcneilli form relatively large veneering patch communities towards the extremes of their distribution in Australia. Populations were examined across three sites of differing water quality; discrete sampling revealed that Symbiodinium spp. (based on rDNA, microsatellite flanking, and plastid genes) were highly conserved indicating the presence of a single species whereas associated 16S rRNA-based bacterial diversity was highly variable across both host species and with season. Parallel ex situ experiments replicating seasonal conditions examined any differences in metabolic performance (photosynthesis, respiration and calcification) that accompanied the microbiome trends. We show for the first time the molecular and physiological properties required for corals to push their realised niche to southerly extremes.

FOLLOW THAT FISH: A SUPPLY CHAIN ANALYSIS OF HAWAII'S NEARSHORE FISHERY (Abstract ID: 30040)

Hawaii's coral reef fishery is eclipsed in the economy by the pelagic fishery that generates far more economic value and has been better studied. Data gaps, a lax reporting system in which fishers are required to report what they catch but dealers can voluntarily report what they purchase, backdoor fish sales, and a poor understanding of the total non-commercial catch complicate efforts to monitor this socially, culturally, and economically valuable fishery. In this study, we have traced the supply chain of Hawaii's nearshore fish species (coral reef and reef-associated species) and assessed the economic and social value provided by this fishery. We have utilized commercial catch records for 2009-2013, commercial sales records for the same time period, market price data, and estimations of non-commercial catch for the main Hawaiian Islands. We found that nearly half the fish caught by commercial fishers disappears before commercial sales reports are filed. Non-commercial catch significantly contributes to the supply of coral reef fish, and when the market value is applied, this catch is worth over $7million more than reported commercial sales, indicating that non-commercial fishing provides a significant food expenditure subsidy. The commercial and noncommercial supply provides over 4.3 million meals annually. Coral reef fish are an especially valuable resource to the state and one that until now has been poorly understood and laxly managed.

CORAL REEF RECOVERY AND REORGANISATION IN THE INDIAN OCEAN (Abstract ID: 28011)

Coral bleaching in 1998 was particularly severe in the Indian Ocean, where up to 90% coral cover was lost in some locations. I will talk about the unfolding dynamics from this disturbance event on Seychelles reefs, from both an ecological and geological perspective, and the changing structure of these reefs. Around half of the reefs in the inner Seychelles recovered towards pre-disturbance live coral states by 2014, while the other half underwent regime shifts to fleshy macroalgae. Functional diversity of associated reef fish communities shifted substantially following bleaching, returning towards pre-disturbance structure on recovering reefs, while becoming progressively altered on regime shifting reefs. These changes are also reflected in food chain lengths of reef meso-predators,

feeding on shorter, simplified chains on degraded reefs. Recovery was favoured when reefs were structurally complex and in deeper water, when density of juvenile corals and herbivorous fishes was relatively high and when nutrient loads were low. From a geological perspective, fewer reefs regained a positive carbonate budget following the bleaching event, with presence of macroalgae, massive corals, wave exposure and parrotfish biomass influencing carbonate budget outcomes. Worryingly, by 2014, few reefs had regained the attributes that promoted recovery from the 1998 event, rendering them vulnerable to future disturbance. Marine reserves had little bearing on reef trajectory, and the influence of this management system on the fish community appears to be changing.

BETTER LIVING THROUGH PHYSICS: MAPPING REEF RESILIENCE WITH SITE-SPECIFIC ECOLOGICAL FORECASTS FOR CORAL THERMAL STRESS (Abstract ID: 29628)

Ocean physics can be used to improve the understanding of environmental impacts on coral reefs, informing decisions to conserve reefs and to sustain coastal economies by preserving reef ecosystem services. Thermal stress is an ongoing physical threat to reefs, as witnessed by widespread bleaching-related mortality in 2014 and 2015. Reefs are also under pressure from other physical and biogeochemical stressors such as land-based pollution, ocean acidification, reduced circulation, and storm damage. Attempts to moderate the combined effects of these stressors presents a challenging management scenario. Spatially explicit science - accounting for key local features - can help to focus monitoring, management, and research for informed decision making. The authors use expert systems to alert managers to ecological impacts on reefs and fisheries. "Ecoforecasts" rely on a simple ocean physics model at <100 m resolution, integrating seafloor maps with coarser-resolution data for weather, oceanography, and turbidity. Climate, weather, and human activity drive many stressors; but at the scale of reefs, oceanography dominates variability in sea temperature, water mixing and circulation. Seafloor depth and slope prove key in predicting both sea temperature extremes and cross-reef water exchange, and remotely sensed turbidity can improve temperature and benthic light predictions. Results show how data integration, artificial intelligence, and a simple model can improve assessment and prediction of relative resilience between reef sites within a jurisdiction.

CHALLENGES AND OPPORTUNITIES OF CORAL REEF MANAGEMENT IN WEST AND CENTRAL AFRICA (Abstract ID: 28152 | Poster ID: 609)

The Abidjan Convention which is one of UNEP's regional seas flagship programme forming cooperative mechanism to promotes cooperation in the protection and development of the marine and coastal environment in the West, Central and Southern African Region. Pursuant its CoP decision CP 11/6 on Coral Reef Partnership: 1. To urge the Contracting Parties to consider the importance of preserving coral reefs and the services they render to ecosystems; 2. To request the Secretariat to develop collaboration with the Global Partnership on Coral Reefs of UNEP's Regional Seas Programme and other institutions, and to set up a working group charged with developing tools and methods that will allow for better management of coral reefs; 3. To exhort the Contracting Parties to respect and promote the objectives of sustainable management of the reefs, laid down in the Implementation Plan of the World Summit on Sustainable Development, in particular by establishing partnerships with the International Coral Reef Action Network (ICRAN) ; 4. To invite the Contracting Parties to contribute to the development of a global network of protected marine areas in order to better preserve the biodiversity of the coral reefs. Subsequently, two Coral Reef Projects (Sao Tome and Principe, and Cape Verde) have been identified with national Action Plans developed to support an effective management of respective Coral Reef projects.

RIDGE TO REEF INTEGRATED TERRESTRIAL-MARINE MONITORING TO ASSESS THE IMPACT OF WATERSHED RESTORATION ON CORAL REEF SEDIMENTATION IN ST. JOHN, US VIRGIN ISLANDS (Abstract ID: 29084)

Terrigenous sediment derived from unpaved roads is a significant stressor to coral reefs in the US Virgin Islands. The 10.7 km2 Coral Bay watershed was the focus of a NOAA-ARRA watershed restoration program completed in 2011, which included: sediment retention structures, road drainage improvements, and limited road paving. An ongoing terrestrial-marine monitoring program to assess the effectiveness of this restoration at multiple spatiotemporal scales measures: (a) terrestrial erosion and runoff-sediment yields; (b) marine terrigenous sedimentation at shoreline and coral reef sites; and (c) the sediment "residence time" using short-lived radioisotopes (SLR). Paving reduced road-segment-scale erosion rates to 4-29% of pre-paving rates, but watershed modeling showed that ~90% of the ~110 Mg yr-1 reductions were due to sediment retention ponds. The high variability of marine terrigenous sedimentation rates due to sediment resuspension limited the statistical significance of mean pre- vs. post-restoration terrigenous sedimentation rate comparisons. A more promising approach has been to select sampling periods with roughly equivalent rainfall patterns for pre- vs. post- restoration comparisons and to use SLR sediment ages and nephelometers to deduce the contributions of contemporary sediment input vs. resuspension to total sediment accumulation. The Coral Bay watershed restoration and monitoring program may serve as a case study on how to develop effective management and monitoring strategies that may be applied to other areas with similar ephemeral hydrologic behavior.

LARVAL DISPERSAL AND MOVEMENT PATTERNS OF CORAL REEF FISHES: IMPLICATIONS FOR MARINE RESERVE DESIGN (Abstract ID: 27963)

Connectivity is a key ecological factor to consider in marine reserve design to maximise benefits for fisheries management and biodiversity conservation. For reserves to protect biodiversity and enhance populations of fisheries species, they must sustain focal species within their boundaries and be spaced so they can function as mutually replenishing networks while providing recruitment subsidies to fished areas. Thus the configuration (size, spacing and location) of reserves within a network should be informed by larval dispersal and adult movement patterns. Our review of movement patterns (home ranges, ontogenetic shifts and spawning migrations) of 34 families (210 species) of coral reef fishes demonstrates that movement varies among and within species, and is influenced by many factors (e.g. habitat). Some species move <0.1–0.5 km (e.g. butterflyfishes), <0.5–3 km (e.g. most parrotfishes) or 3–10 km (e.g. large parrotfishes), while others move 10s-100s (e.g. some groupers) or 1000s of kilometres (e.g. some sharks). Larval dispersal distances tend to be <5–15 km and self-recruitment is common. Synthesising this information has allowed us to provide species, specific advice on marine reserve configuration where: reserves should be more than twice the size of home ranges of focal species; reserve spacing should be <15 km; and reserves should include critical habitats for the life history of focal species, and be spaced to accommodate movement patterns among these. This information is being used to improve marine reserve design in coral reef regions worldwide.

MODELLING THE CIRCULATION OF A SEMI-ENCLOSED ISOLATED CORAL REEF ATOLL (Abstract ID: 28633)

The hydrodynamics of coral reefs directly influence ecosystem diversity, productivity and community structure. Predicting the processes that drive reef circulation will facilitate understanding reef resilience when challenged by future climate change. Most studies on coral atolls have focused on shallow reef tops forced by surface waves, located primarily within microtidal regions. This study focuses on Scott Reef, an isolated reef atoll system that rises steeply from depths of 2500 m, ~300 km off northwestern Australia. The dynamics of North Scott, a shallow (~20m deep), semi-enclosed lagoon (exchange only through two narrow reef channels), with a spring tidal range of > 3 m, will be presented. A multidisciplinary research cruise took place during April 2015 to Scott Reef. To quantify the hydrodynamics of North Scott Lagoon, an array of moored instruments were deployed, including wave and tide gauges, and current meters/profilers. Field measurements indicate that the shallow reef crest acts to restrict exchange between the open ocean and the lagoon, resulting in a highly asymmetric tidal flows.

A numerical model (DFLOW-FM) was developed using flexible mesh gridding to account for the complex bathymetry of the reef and lagoon, and was able to replicate the hydrodynamics. Water quality variables will be incorporated into the model, to not only provide insight into the physical forcing associated with the circulation and flushing of the lagoon, but also give an indication of the system's responses to projected future environmental disturbances.

THE COMBINED EFFECTS OF CHANGES IN TEMPERATURE AND PCO2 ON PRODUCTION OF DIMETHYLSULPHONIOPROPIONATE IN MASSIVE PORITES CORAL SPECIES. (Abstract ID: 28783)

The biogenic sulphur compound dimethylsulphoniopropionate (DMSP) is a putative antioxidant produced by corals and their symbiotic zooxanthellae. DMSP has been shown to alleviate cellular stress such as that caused by increasing sea surface temperatures and decreasing oceanic pH (ocean acidification). In this study we acclimated small colonies of massive Porites corals to three different seawater pCO2 treatments (180ppm, 400ppm and 750ppm) and two temperature scenarios (25 and 28C) over periods of several months. We cultured 4 genotypes in each treatment including individuals of P. lutea and P. murrayensis. After acclimation we measured coral photosynthesis/respiration calcification and net seawater DMSP production in the light and dark. Our analyses to date indicate consistent patterns. The net production of DMSP is lower in corals cultured at 750 ppm seawater pCO2 compared to 400 ppm. Net seawater DMSP production is lower at 25°C than at 28°C in the light regardless of pCO2 treatment. P.lutea exhibited a net release of DMSP in both the light and dark at both temperatures. But we observed a net removal of seawater DMSP in the P. murrayensis genotype at 25°C, suggesting that bacterial catabolism in some coral colonies may act to reduce seawater DMSP.

CORAL GARDENS BELIZE: AN *ACROPORA* SPP. REFUGIA IDENTIFIED (Abstract ID: 28393)

The declining abundance of Caribbean Acropora cervicornis has been well documented, and few A. cervicornis-dominant reefs remain. Due to limited long-term monitoring of extant A. cervicornis it is difficult to assess whether existing populations are new, in recovery, or true refugia. Here we document the extent and persistence of one of the largest known extant Caribbean A. cervicornis populations. We used GIS data, survey data, and radiometric ages to show that A. cervicornis persisted and is thriving today at Coral Gardens, Belize despite a decline in abundance elsewhere. Over 7 ha of Acropora spp.-dominant reefs were mapped at Coral Gardens. Live coral was quantified from photographic data of over 130 $m^2$ quadrats each year from 2011-2014 at fixed locations. Mean live coral ranged from 33%-30% with 18% of individual quadrats having greater than 50% live coral in 2014. Live coral cover may be decreasing, but only comparatively slowly against a backdrop of rapid regional decline. To document a longer history of A. cervicornis at Coral Gardens, corals were collected at 5 cm stratigraphic intervals from a 2 m pit excavated beneath non-living reef framework. Dead corals were also carefully extracted from within living canopy using 1.5 m extendable tools. The age of 43 corals was determined using conventional radiocarbon methods and 8 (24 pending) using high-precision U-Th dating techniques. Data show corals persisting through the well documented 1980's-1990's regional die-off. We suggest that this location is a modern refugia for Acropora corals.

MARINE CONSERVATION THROUGH ART (Abstract ID: 28071)

The Marine Foundation, founded in 2009 by artist Celia Gregory,pioneered the Living Sculptures in the Sea Eco art program. As a dive master her creative eye provided a unique perspective into the underwater world. She travelled to reefs around the world and it was clear the environmental story was depressing. Eager to help find a solution, she worked with marine scientists,ideas of artificial reef and coral gardening and realised humans do not have to have a bad effect on the sea but can effect positive change. The living sculptures merges art and science, help damaged habitats regenerate as well as creating innovative works of art. Many thought her idea was mad but now the scientists she works with agree art is powerful and emotive. Our program is fun and could be seen as fluffy but there is a serious environmental agenda e.g.our sculptures are placed in agreed No Take Zones. Working closely with the community is a vital ingredient for success. We always partner with local NGO's and help them generate ecotourism attractions and alternative sources of income. We have inspiring imagery of how life has grown on the artworks. It is this ever changing, symbiotic relationship with nature that is so special. In the cyber world the inspiring visuals spread a positive Eco story, one that is a creative, action-based solution. Over the last 8 years, we have learnt from our success and failures, creating art in the sea presents its challenges! Some people say we should just leave the sea alone ' let it go back to nature' but is that realistic with billions on the planet? http://www.themarinefoundation.org

USING TIME LAPSE PHOTOMOSAICS TO MONITOR GROWTH AND EXPANSION OF ACROPORA CERVICORNIS THICKETS CREATED BY OUTPLANTING NURSERY GROWN CORALS (Abstract ID: 29006)

In the last decade, coral nursery operations in the Caribbean have expanded from just a few locations to over 50 programs around the Caribbean in over 20 different countries. These programs have proven to be effective at increasing the local populations of Acropora cervicornis where outplanting is conducted. Typical monitoring normally focus on individual colonies. Frequently, monitoring at the level of an individual colony becomes more complicated after 1-2 years as corals grow and intertwine, new colonies are created through fragmentation, tags can be hard to relocate as they are overgrown, etc. Longer term monitoring goals (3-5 years+) should look at a broader scale considering the whole community, the overall health of thickets, their size (expansion or reduction), asexual recruitment and changes in reef community. Photomosaics are a useful tool for this type of monitoring. The research presented here used photomosaics analyzed with Coral Point Count with Excel Extensions (CPCE) to monitor the growth and expansion of thickets that were outplanted at 2 grounding sites. Photomosaics were collected every 6-12 months. Changes in the benthic community were monitored by looking at percent cover using CPCE. Significant increases in coral cover by A. cervicornis and significant decreases in the presence of bare substrate were recorded. Several years after initial outplanting, the outplanted corals have developed into self-sustaining thickets that are expanding through assexual reproduction and have withstood impacts from multiple hurricanes and swells over 6m.

ABUNDANCE DRIVING PHYSICAL CONTACT INTERACTIONS WITH SCLERACTINIAN CORALS IN MARGINAL REEFS (Abstract ID: 27846 | Poster ID: 310)

Understanding the mechanisms structuring ecological interactions is a main challenge in Ecology, as it can help maintain communities in different environments. Despite the worldwide distribution of marginal reefs and its clear differences to more typical reefs, few studies focus on the biology and ecology of species in these systems. Here, we quantified physical contact interactions of benthic organisms with scleractinian corals in four marginal reef areas along the Brazilian coast. We characterized these interactions using tools derived from the complex network theory. We also investigated if the interactions occurred as expected by the organisms' abundance, or if biological characteristics, such as defense tentacles of hard corals, hampered contact with other organisms. We found that abundance is a key factor structuring benthic contact interactions, regardless species identity, species richness or physical characteristics of the reef. In each area, all coral species interacted more with the most abundant benthic group, the epilithic algal matrix; and in all networks, abundant organisms interacted more among them and few interactions occurred between low abundant groups. These results suggest that, in the studied range, competitive mechanisms may not play a very significant role in shaping interactions with corals. We hypothesize that this occurred due to the unusual reef environments for corals in Brazil. Hence, species tolerance to these conditions can be more relevant than biotic characteristics in affecting ecological interactions in non-optimal environments.

COMBINED RESPONSES OF THE CORAL MICROBIOME AND CORAL PHYSIOLOGY TO ELEVATED TEMPERATURE AND PCO2 (Abstract ID: 27996)

We experimentally investigated the links between changes in the coral microbiome and physiology in response to elevated temperature and pCO2 expected by the end of this century in two species of corals: Acropora millepora and Turbinaria reniformis. Corals were maintained under treatment (pCO2 of 750 µatm and 29.0˚C) or control (pCO2 of 364 µatm and 26.5˚C) conditions for 24 days and fed brine shrimp nauplii bi-weekly. Overall microbial communities differed between coral species, and between control and treatment fragments of A. millepora but not of T. reniformis. Under treatment conditions, A. millepora experienced a complete loss of Pseudovibrio, a 47% decline in Staphylococcus, and the appearance of Rhodococcus fascians along with a 55% decline in calcification and a 35% increase in protein content compared to controls. In comparison, control and treatment T. reniformis shared two OTU's in common (Sphingomonas and Rhodobacteraceae) and while treatment corals experienced declines in calcification and endosymbiotic algal density of 40 and 25%, respectively. Overall, protein content best described the microbial NMDS pattern of the corals with lipids being associated with the separation between treatment and controls. Thus, sensitivity of the coral microbiome to climate change is correlated with energy reserves. This is consistent with findings showing that energy reserves play a strong role in coral susceptibility and recovery to coral bleaching and suggests that energy reserves may be more crucial to coral holobiont resilience to climate change than previously appreciated.

PHYSICAL DRIVERS OF COMMUNITY STRUCTURE AND GROWTH AMONG MESOPHOTIC CORAL ECOSYSTEMS IN ST. THOMAS, US VIRGIN ISLANDS (Abstract ID: 28834)

Mesophotic coral ecosystems (MCEs) are deep (>30m), light-dependent communities that are abundant in the northern US Virgin Islands. Compared to their shallow water counterparts, MCEs remain understudied. South of St. Thomas, mesophotic coral cover on *Orbicella*-dominated reefs can reach 50%, but observations of the northern shelf at similar depths (30-45 m) suggest limited coral cover. The cause and extent of these differences is unknown. Using spatially explicit observations of coral health, species abundances, and coral population densities, we compared northern shelf bank MCEs to previously studied MCEs south of St. Thomas. Overall coral cover is lower on northern MCEs and reefs dominated by *Orbicella* species have not been found. Factors limiting coral growth on northern MCEs may include more frequent wave disturbance as well as nutrient loading, turbidity, and thermal stress associated with upwelling. To assess if disturbance and growth are driving community structure, we collected 30 colonies each of *Orbicella franksi* and *Porites astreoides* from 27 to 47 m depths on the north and south shelves of St. Thomas. Using CT to quantify calcification, we will identify environmental factors correlated with coral growth across sites. We predict slower growth rates of mesophotic corals north of St. Thomas, corresponding to lower light conditions and more frequent disturbance. These results will identify processes that influence the structure of MCEs and, thus, help to predict their global distribution and utility as refugia.

COMMUNITY PRODUCTION AND RESPIRATION IN AN EXTREME ENVIRONMENT: NEW INSIGHTS FROM TROPICAL TIDE-DOMINATED FRINGING REEFS (Abstract ID: 29424)

The cycling of carbon and nutrients within benthic reef communities is driven by a suite of environmental factors including water composition, hydrodynamic regime, temperature, and light. Although in the past most studies of reef biogeochemistry have focused on wave-dominated systems, tide-dominated reefs are frequently found throughout the Indo-Pacific and eastern Africa and yet the environmental forcing of these systems remains poorly understood. We conducted a study in the remote and pristine Kimberley region of Western Australia where large semidiurnal tides (12m range) drive rapid changes in light, temperature (up to 10 deg. C over 6 hours), and water chemistry. We measured community production and respiration in seagrass and algal-dominated communities present on an intertidal reef flat over a full spring-neap tidal cycle during both wet and dry seasons using a 1-D control volume approach. High rates of community respiration routinely drove reef flat oxygen levels to hypoxia at night. Gross community production was found to be free from photoinhibition in all communities, even during periods of exposure to high light. Results from this study highlight the phase difference between diurnal tide and light cycles as a key control on daily rates of community production and respiration. Overall, we find that reef communities in this shallow, tropical, and tide-dominated habitat are highly productive and display remarkable tolerance to life in a strongly variable environment.

INDIRECT EFFECT OF LONGTERM CLEANER WRASSE PRESENCE ON THE BENTHIC COMMUNITY (Abstract ID: 28552)

An ongoing manipulation of cleaner wrasse at Lizard Island, Great Barrier Reef, showed that the abundance and species richness of grazer fishes is reduced on patch reefs maintained free of cleaners for 8.5 y compared with controls (both treatments at 2 sites). Here, we tested whether this affected the benthos, by investigating potential flow-on affects to coral, algal turf, and sediment load dynamics after 12-14 y of manipulating reefs. The % cover of natural benthos (hard coral, dead coral, soft coral, algae, other) did not differ with cleaner presence; but algal subtypes (calcareous, fleshy, and low, medium, and high turf height) differed between sites. Algal height on settlement tiles (20 x 20 cm) over 2 y did not differ with cleaner presence, but varied among times sampled - possibly due to cyclonic events. When dried, algae plus detritus weight per tile decreased with increasing sediment but did not differ with cleaner presence; sediment weight did not differ with cleaner presence. Video showed the grazer/detritivore *Ctenochaetus striatus*as the most common large-bodied fish feeding off tiles, however many other fishes interacted with tiles including farming damselfishes. *C. striatus*abundance did not differ with cleaner presence but did between sites - possibly explaining observed differences in feeding and bite rates between sites. Tile composition and organic content, fish species composition and video analysis is currently underway. The study reveals the challenges of detecting potential indirect effects of fish and benthic interactions.

SEEDING OF EARLY-STAGE SEXUAL RECRUITS OF ACROPORA PALMATA FOR SPECIES AND HABITAT REHABILITATION (Abstract ID: 28790)

Populations of *Acropora palmata* , a keystone reef-building coral in the Caribbean, have decreased significantly since the 1970s. Although some populations still spawn, no significant recruitment of juveniles has been observed throughout the Caribbean, hence rehabilitation of denuded reefs to aid recovery is urgently needed. Here, we present the results of seeding one-polyp stage *A. palmata* sexual recruits on a degraded, former *A. palmata*reef. Two weeks after settlement, we introduced 500 SUs (=SExual COral REproduction Seeding Unit, SECORE SU) on 120 $m^2$ of degraded reef in Picudas, Puerto Morelos, Mexico. Larvae for this assay were obtained in August 2015 after collecting gametes from a spawning event in a nearby reef. The rehabilitation area was divided into 1 m width transects and SUs were wedged in natural crevices formed by the reef framework at a density of 4 SUs per $m^2$ without the use of concrete or fixative. To evaluate SU

performance as well as recruit survival and growth, 60 quadrants were chosen randomly and will be monitored for one year. Preliminary results show that two months after the seeding effort, 80% of the SUs remained in the area at a density of 3 SUs per $m^2$ with approximately 82% of the SUs having more than 10 recruits/SU. These results indicate the potential of rehabilitating *A. palmata* reefs using SUs with sexual recruits. Additionally, the reduction in pre- and post-settlement care significantly decreases costs and labor.

A TRANSCRIPTOMIC PIPELINE TO UNDERSTAND THE SYMBIODINIUM COMMUNITY CHANGE AND FITNESS IN POCILLOPORA DAMICORNIS DURING THERMAL STRESS (Abstract ID: 29679)

Since the proposition of the Adaptative Bleaching Hypothesis, stating that bleaching might allow corals to rapidly adapt to environmental change by modifying their *Symbiodinium* community, research on the diversity and physiological properties of coral symbionts has progressed significantly. However, the *Symbiodinium* assemblage of a given coral colony has still rarely been assessed over a stress event and, when studied, the molecular approaches to identify clades and subclades used the DNA of the holobiont as a template. While such approaches yield fine-scale assessments of the clades hosted by the corals, they do not allow for testing their fitness. To fill this gap, we developed a transcriptomic analysis pipeline using the data issued from a time series performed on the coral *Pocillopora damicornis*under simulated thermal stress. Our analysis was based on one chloroplastic (23S) and three nuclear (28S, ITS2, 18S) ribosomal markers of *Symbiodinium*and *P. damicornis*. Our approach follows three main steps: (1) creation of a database issued from all available *Symbiodinium* DNA sequences, (2) selection of unique kmers representative of each clade or subclade and (3) quantification of the markers' expression levels at each point of the stress test time series, by establishing clade and/or subclade/coral host expression ratios. Our results will be discussed in terms of marker robustness and the effects of thermal stress on *Symbiodinium* community change and fitness.

IMPROVING CAPACITY FOR CORAL REEF FISHERIES MANAGEMENT IN MICRONESIA THROUGH SOCIAL MARKETING CAMPAIGNS (Abstract ID: 30136)

Over the past four years, Rare has supported local organizations and individuals in undertaking social marketing campaigns for natural resource management through its Micronesia Program for Island Resiliency. Within the context of this program, local campaign managers were trained in behavior change and conservation strategies to enhance on-going efforts in improving coral reef fisheries and nearshore marine resource management. At seven sites across the region and with the assistance of numerous supporting partners, managers conducted basic research; developed conservation strategies; designed stakeholder and community engagement plans; and executed social marketing campaigns to improve awareness, compliance, and behaviors that support effective coral reef management. In many cases, managers equipped with new skills and tools were able to organize communities, assimilate information from a variety of sources, build and strengthen alliances of stakeholders and agencies, and improve compliance and management efforts. Examples will be presented of how campaigns increased interaction, communication, and collaboration among scientists, fishers, managers, traditional leaders, and politicians to undertake new initiatives that lead to improved management. Details will be provided on how these efforts supported community-based MPA improvements, rights-based fishery management development, new policy and regulations, increased compliance, and fish marketing enhancements that are intended to provide benefits to fishers and contribute to overall fisheries sustainability.

COASTAL HIGH-RESOLUTION OBSERVATIONS AND REMOTE SENSING OF ECOSYSTEMS (C-HORSE) (Abstract ID: 29966 | Poster ID: 539)

Coastal benthic marine ecosystems, such as coral reefs, seagrass beds, and kelp forests are highly productive as well as ecologically and commercially important resources. These systems are vulnerable to degraded water quality due to coastal development, terrestrial run-off, and harmful algal blooms. Measurements of these features are important for understanding linkages with land-based sources of pollution and impacts to coastal ecosystems. Challenges for accurate remote sensing of coastal benthic (shallow water) ecosystems and water quality are complicated by atmospheric scattering/absorption (~80+% of the signal), sun glint from the sea surface, and water column scattering (e.g., turbidity). Further, sensor challenges related to signal to noise (SNR) over optically dark targets as well as insufficient radiometric calibration thwart the value of coastal remotely-sensed data. Atmospheric correction of satellite and airborne remotely-sensed radiance data is crucial for deriving accurate water-leaving radiance in coastal waters. C-HORSE seeks to optimize coastal remote sensing measurements by using a novel airborne instrument suite that will bridge calibration, validation, and research capabilities of bio-optical measurements from the sea to the high altitude remote sensing platform. The primary goal of C-HORSE is to facilitate enhanced optical observations of coastal ecosystems using state of the art portable microradiometers with 19 targeted spectral channels and flight planning to optimize measurements further supporting current and future remote sensing missions.

LONG-TERM MONITORING OF AN ASSEMBLAGE OF THE HOST ACTINIAN, HETERACTIS MAGNIFICA, IN RAS MOHAMMAD NATIONAL PARK, SOUTH SINAI, EGYPT (Abstract ID: 28680)

The coral reefs around Sharm el-Sheikh, Egypt, are under heavy pressure from tourists and the dive sites are experiencing reduced growth and regeneration. An impressive assemblage of the host actinian, Heteractis magnifica, commonly known as "Anemone City", is located in the Ras Mohammad National Park at the tip of the Sinai Peninsula. The actinians are often located in clusters, which make Anemone City a special habitat for the inherent Red Sea Anemone fish, Amphiprion bicinctus. The actinian assemblage was monitored in 2002 and divided into 9 subpopulations on the reef. This study was a re-monitoring and assessment of the development from 2002 to 2015. The actinians were counted, mapped, classified as solitary or clustering and the area of oral disc was measured. The number of adult and subadult anemone fish was counted in each subpopulation of actinians. The study reveals that the assemblage has not changed much since 2002 in terms of total number of actinians, total actinian cover and number of clusters. However the actinians in the subpopulations in the periphery areas of the reef have in general increased their numbers, while they have decreased in the subpopulations at the central plateau. The amount of anemone fish has declined by 14 % for adults and 29 % for subadults. The decline in anemone fish abundance has resulted in an average of 1 anemone fish per actinian and only 0,42 adult anemone fish per actinian, which is highly unusual for an assemblage of host actinians. The findings are being discussed in relation to the diving practices in the Sharm el-Sheikh area.

THE ICRI GLOBAL CORAL ECOLOGICAL SERVICES AND FUNCTIONS VALUATION TOOL (Abstract ID: 28144 | Poster ID: 618)

The new International Coral Reef Initiative (ICRI) Coral Ecological Services and Functions tool was developed to account for the values inherent in different coral species of different size classes that grow in different habitats and sub-habitats. The tool can be used with any stony coral species worldwide and is easily adapted for any jurisdiction. The coral ecological value (CEV) of corals found in nature is defined as the product of individual values given to their morphology, rarity, endemism and size class with the CEV-metric acting as a unit-less metric. The valuation tool itself is very simple and does not require extensive knowledge beyond inputting a few variables: the species of coral for each colony impacted along with its dominant growth form and rarity in your area; the size of each colony impacted; and the type of sub-habitat (substrate) each colony occurs on. Each of these is selected from pre-provided lists. The tool itself is very transparent and provides guidance along each step as to what it is doing. The total coral ecological value (CEV) is then simply tabulated as the product of each of the individual metrics: The tool can be incorporated into any country's natural resource trustee activities for evaluating impacts from human activities, and for establishing both restoration and compensatory mitigation targets.

INTEGRATED CONSERVATION AND DEVELOPMENT: EVALUATING A COMMUNITY-BASED MARINE PROTECTED AREA PROJECT FOR EQUALITY OF SOCIOECONOMIC IMPACTS (Abstract ID: 29227)

Despite the prevalence of protected areas, evidence of their impacts on people is weak and remains hotly contested in conservation policy. A key question in this debate is whether socioeconomic impacts vary according to social subgroup. Given that social inequity can create conflict and impede poverty reduction, understanding how protected areas can differently affect people is critical to designing them to achieve social and biological goals. Here, we assessed whether the socioeconomic impacts of marine protected areas – designed to achieve the dual goals of conservation and poverty alleviation – differed according to age, gender or religion in associated villages in North Sulawesi, Indonesia. Using data from pre-, mid- and post-implementation of the MPAs for control and project villages, we found some empirical evidence that impacts on five key socioeconomic indicators differed according to social subgroup. We found significant inequality of impacts to environmental knowledge in relation to age and religion over the medium and long term. These findings help elucidate the pathways through which the impacts of the MPAs occurred, and may be used to improve targeting of management activities. Further, our evaluation identified some key limitations of current approaches to impact evaluation in relation to social equity, and thus provides guidance for future research in understanding how protected areas affect people.

DIVERGENCE THROUGH SPECIES INTERACTIONS: THE ROLE OF THE SPONGE CLATHRIA OXEOTA IN ECOLOGICAL SPECIATION OF THE OCTOCORAL BRIAREUM ASBESTINUM (Abstract ID: 29445)

Environmental variation and competition for resources can trigger phenotypic change in marine organisms. Thus life history traits such as growth rate, morphology, reproduction and ecological interactions may be modified increasing fitness. Morphological variation, if reinforced by divergent selection, may reduce gene flow and eventually lead to fixed differences in ecologically segregated populations. Ecological, morphological and genetic divergence between encrusting and erect morphotypes of the Caribbean octocoral Briareum asbestinum was studied in populations of Curaçao, Puerto Rico and Colombia. An interspecific association was found between the encrusting morphotype -also known as B. polyanthes- and the encrusting sponge Clathria oxeota identified through Cytochrome Oxidase I barcode. Furthermore, an overgrowing pattern affecting various species of octocorals was consistently reported when such association was present, suggesting a possible advantage for space competition. Genetic divergence was studied using the method 'fields for recombination', which is useful in delimiting species boundaries based on allelic exclusivity. Using the nuclear marker ITS2, an intermediate level of divergence, and a higher degree of allelic exclusivity was found in B. polyanthes than the erect morphotype B. asbestinum. By integrating eco-morphological and genetic information, we suggest that the interaction of B. polyanthes and C. oxeota, drives the ecological and morphological divergence and promotes genetic differences that potentially could be fixed between the two morphotypes of B. asbestinum.

USING *PTEROIS VOLITANS* INVASION TO DESCRIVE CONNECTIVITY IN MARINE PROTECTED AREAS IN THE GULF OF MEXICO AND CARIBBEAN. (Abstract ID: 28883)

The lion fish ( *Pterois volitans* ) has been responsible for one of the most successful and fast invasions of the Atlantic. Since its first apparition in the 90's in Florida, the scientists predicted that its dispersion would spread all over the east coast of the American continent. And in fact, this lionfish has invaded coastal seascapes from New York to Brazil. Due to its rapid dispersion, this lionfish could be an extraordinary tracker of connectivity in general and more specifically among marine protected areas in the Gulf of Mexico (GM) and the Grand Caribbean (GC). To further explore this relationship, a total of 475 samples were collected and identified by mtDNA as *Pterois volitans* . They were subsequently characterized with 12 microsatellite markers. Genetic analyses reflect a structured distribution suggesting restricted connectivity among marine protected areas with the GC appearing more isolated and differentiated. The Bayesian clustering analysis showed that individuals pertain to four genetic groups, suggesting that currents and topography patterns play an important role in the distribution of the allelic frequency of this specie. These results also indicate that the GC and GM groups might issued from two different roads of invasion. This results are important for management populations of coral reef fish, because even though this species is invasive with a successful breeding and high rate of survival in extreme conditions, it shows some limited trend of connectivity in GC and GM.

GLOBAL MICROBIALIZATION OF CORAL REEFS (Abstract ID: 28248)

Microbialization refers to the observed shift in the trophic structure of ecosystems from macrobes to microbes. The increased but less efficient microbial activity drives down dissolved organic carbon (DOC) concentrations depleting availability of these resources to higher trophic levels. The posited mechanism for the observed microbialization is a positive feedback loop, where DOC released by ungrazed fleshy algae fosters copiotrophic, potentially pathogenic bacteria, ultimately leading to coral disease and increased algal competitive dominance (DDAM: DOC, Disease, Algae, Microbes). Here we provide geochemical and microbiological evidence that microbialization is tightly coupled to phase shifts in benthic reef communities on a global scale. Using an unprecedented dataset of >400 samples on 60 coral reef sites in the Atlantic, Pacific, and the Indian Ocean we show that increased algal cover correlates with lower concentrations of DOC and higher microbial abundances. Metagenomes constructed from a subset of reefs demonstrated a shift in microbial community metabolism away from efficient glycolysis towards faster, but less efficient alternative catabolic pathways. Sacrificing energetic efficiency to outgrow and deprive competitors of food is a common ecological strategy referred to as the yield to power switch. This global dataset provides evidence that fleshy algae foster, genomically adapted microbial communities that threaten reefs directly through higher disease prevalence and by depleting oxygen and organic nutrients at the expense of higher trophic levels.

STABLE MUCUS-ASSOCIATED MICROBIAL COMMUNITIES IN BLEACHED AND NON-BLEACHED PORITES FROM THE ARABIAN SEAS (Abstract ID: 27888)

Coral reefs are subjected to a serious threat due to a phenomenon called coral bleaching, which is described by the physical whitening of the coral colony due to loss of its endophotosymbiotic algae. While the importance of bacteria to coral holobiont functioning is well established, there are comparatively few studies that studied bacterial communities associated with coral mucus. A substantial number of the coral microbial community resides within the mucus layer, however the effect of bleaching on the mucus-associated microbial community is poorly understood. In this study, mucus from bleached and healthy Porites colonies were collected from multiple reefs in the Red Sea and the Arabian Gulf in order to investigate microbial changes associated with health condition and site. Using 16S rRNA gene amplicon sequencing, we found that microbial richness and composition was similar in bleached and healthy colonies, but differed by site. Our data show that bacterial taxa composition of coral mucus seems to be stable and almost unaffected by bleaching emphasizing the ephemeral nature of coral mucus. The notion that distinct bacterial taxa structure the microbiomes of Porites in the Red Sea and the Arabian Gulf indicate that prevailing environmental conditions might be a strong driver of coral mucus microbiome structure. At the same time, specific bacterial groups, e.g. nitrogen-fixing bacteria seem to be site-specifically affected. Further research is needed to unequivocally resolve the distinct contribution of this group of bacterial to coral bleaching.

WHO MAKES THE SETTLEMENT CUE FOR LARVAE OF THE CORALIVOROUS NUDIBRANCH *PHESTILLA SIBOGAE*? (Abstract ID: 28981)

When larvae of the nudibranch *Phestilla sibogae* are exposed to seawater (SW) in which pieces of the nudibranch's prey coral, *Porites compressa*, have been soaked, they settle and metamorphose. The inducer is a small (<500 DA) polar molecule. Knowing that any hermatypic coral is a community of coral, symbiotic dinoflagellates, bacteria, and probably fungi, we here ask, which partner makes the settlement inducer? This study attempts to eliminate all but one of the possible sources. To eliminate the dinoflagellate as a source, live coral pieces were maintained in full darkness for 5 dy, with daily transfers to fresh SW. The last batch of SW was filtered and subjected to a larval assay. Despite a shutdown in photosynthesis, the inducer was still present. Maintaining coral in the dark in the presence of the photosynthesis inhibitor DCMU also failed to reduce induction,

further reducing the likelihood that dinoflagellates make the inducer. To examine a role for bacteria in production of the inducer, corals were steeped in SW containing one of seven different antibiotics, representing five different modes of action, and the resulting SW tested for induction. All preparations remained strongly inductive. Although SW containing fungicides to which corals had been exposed killed the larvae, fungi isolated and cultured from the coral produced no soluble settlement inducer. Thus, results to date support the hypothesis that it is the coral itself whose metabolite is the inducer of recruitment of its nudibranch predator.

REFLECTIONS ON MODERN AND HISTORIC APPROACHES TO MAPPING CORAL REEF ENVIRONMENTS AT ALDABRA ATOLL (Abstract ID: 29025)

In February 2009, a team from Cambridge Coastal Research Unit embarked on an expedition to map the lagoon of Aldabra Atoll, western Indian Ocean. Here, we reflect on the modern and historical mapping techniques applied across the lagoon and atoll rim. Ground referencing was conducted from a boat to support the production of a lagoon map from three high resolution satellite remote sensing images. Topographic surveys were undertaken with a level and staff to accurately determine the height of a tide gauge deployed in a lagoon channel in relation to a control point some 1.5 km away. Our experiences highlight the changing nature of field survey techniques, in particular the amount of effort required to record observations for the purpose of mapping. The broader value of maps as important sources of time-specific information on the configuration of landforms such as coral reef platforms and islands is considered using a range of case studies from the Atlantic, Indian and Pacific Oceans. These explore the ways in which David Stoddart's maps have been used to assess shoreline movements at Diego Garcia, to validate models of island response to environmental change on the Great Barrier Reef and to assess changes to mangrove environments on the Belize cays. These examples illustrate the importance of the many reef platform and cay maps that are part of the legacy of David Stoddart's reef geographical expeditions.

PHYSIOLOGICAL RESPONSES AND DIFFERENTIAL MORTALITY OF THE SEA ANEMONE EXAIPTASIA PALLIDA TO LONG TERM OCEAN ACIDIFICATION AND A SIMULATED TEMPERATURE ANOMOLY (Abstract ID: 29659 | Poster ID: 416)

Recent experimental and natural studies note positive outcomes of high CO2 exposure for symbiotic sea anemones. Yet, as with scleractinian corals, the majority of data comes from short-term, single parameter studies. We quantified physiological responses of Floridian E. pallida, separately hosting three Symbiodinium strains, to long term, diel cycling, high CO2 (1010-733 ppm, 111 days), combined with a simultaneous thermal increase to 32 C (5 days). Photosynthesis to respiration (P:R) ratios increased under high CO2 in animals hosting two different strains of Symbiodinium type A4, but declined under combined heat and high CO2. P:R in animals with Symbiodinium minutum (B1) showed minimal change to CO2 and an earlier decline with combined heating. Levels of photodamage, bleaching and mortality under the combined heating/CO2 treatment were significantly higher in anemones hosting B1 than A4. Similar to previous results with a clonal host line, asexual reproduction under high CO2 increased markedly in animals hosting B1, but only within the first month of exposure, while those hosting the A4 symbionts displayed minimal change in reproduction due to CO2 exposure. Among juvenile anemones, those hosting B1 displayed the greatest mortality with heating, while less, yet differential, mortality was noted between anemones hosting the A4 symbionts. While clonal animals reveal some effects of high CO2, our data provide evidence that the positive effects of increased CO2 on symbiotic sea anemones might not persist in an environment characterized by stochastic high-temperature anomalies.

PUBLIC INVOLVEMENT IN CORAL REEF MANAGEMENT, THE RESULT OF THREE CITIZEN PARTICIPATORY APPROACHES CONDUCTED IN SULAWESI, INDONESIA (Abstract ID: 27964)

Environmental problems are highly dynamic and complex, i.e. 'wicked'. They, therefore, require a creative and transparent decision-making process that accommodates a diversity of needs, forms of knowledge and human values. A growing body of research has shown the need for public involvement in any environmental management effort, including the management of coral reefs. This paper reports the results of three different public deliberation exercises centering on coral reef management in Sulawesi, Indonesia. Three deliberative group discussion methods, namely Planning Cells, Focus Group Discussions and Musyawarah, were employed in three different locations on Sulawesi. The outcomes of these exercises revealed that the majority of the threats in these areas are anthropogenic. Destructive and illegal fishing activities are still occurring as the result of limited monitoring and low level of law enforcement. To improve coral reef ecosystem and its management, the participants proposed to improve community awareness and participation, to increase the effectiveness of monitoring and law enforcement, and to implement an accepted fisheries management regulation.

PLASTICITY OF SEA ANEMONES ALONG VOLCANIC PH GRADIENTS (Abstract ID: 29497)

Natural CO2 vents are recognized as in situ study sites to understand effects of ocean acidification on marine organisms and there is evidence that non-calcifying Cnidarians proliferate in these environments. The symbiotic anemone *Anemonia viridis* and the non-symbiotic anemone *Actinia equina*are prevalent at all pH sites around the CO2 vent found at Levante Bay (Vulcano, NE Sicily, Italy). The aim of our study was to determine if these species are highly plastic or if they are acclimated to each pH site, as well as to determine if an intertidal species (*A. equina*) response differs from a subtidal species (*A. viridis*). To answer this, short term translocation experiments were performed, examining physiological response when organisms from one pH environment were exposed to other pH environments. Anemones were translocated from low (7.4), mid (7.6), high (8.1), and reference (8.1 – outside of volcanic area) to each pH environment and exposed for 30 minutes to evaluate respiration rate for *A. viridis* and *A. equina*, and photosynthetic rate, symbiont density, protein and chlorophyll for *A. viridis*. We observed significant decreases in photosynthesis only when*A. viridis* from mid sites were translocated to high sites. We also observed that respiration rates of *A. equina* were highest at reference sites and did not change when exposed to other pH environments. Low variability in translocation response indicates plasticity in both of these organisms along pH gradients.

WHY DO CORAL REEFS THRIVE IN ICEHOUSE WORLD CLIMATES? CLUES FROM LARGER BENTHIC FORAMINIFERS (Abstract ID: 28698 | Poster ID: 292)

In the past 25 years, foraminifers that host algal endosymbionts (aka large benthic forams or LBF) have become widely used as bioindicators for carbonate-depositional environments, both fossil and modern. This is particularly true for *Amphistegina*, which is nearly circumtropical in modern oceans and has a long fossil record. They exhibit bleaching, induced by photo-oxidative stress similar to bleaching in zooxanthellate (Z-) corals, though responding more directly to photic stress. Yet though Z-corals have declined dramatically on the offshore reefs of Florida, LBF have continued to thrive in the clearest offshore habitats. The highest coral cover is now on patch reefs, where LBF populations tend to be low or highly variable. The Cenozoic fossil record provides clues to this divergence. During the Eocene, when global temperatures and atmospheric $CO_2$ were higher than pre-Industrial modern levels, LBF were important producers of carbonate buildups; Z-corals typically occupied mesophotic conditions, either deeper or at reduced water transparency. A long-recognized paradox of Z-corals is that, despite requiring warm-water to thrive and build substantial reefs, coral reefs became prominent with the onset of Icehouse World climates. By their production of calcite rather than aragonite, and by hosting a diversity of symbiont taxa, the LBF provide additional models of how organisms with potential to hypercalcify respond to environmental conditions and especially to changes in the suites of conditions, useful to the study of reefs in the past, present and future.

RESHUFFLING OF GLOBAL MARINE BIODIVERSITY UNDER CLIMATE CHANGE (Abstract ID: 27993)

Anticipating the effect of climate change on biodiversity, in particular on changes in community composition, is crucial for adaptive ecosystem management but remains a critical knowledge gap. We use climate velocity trajectories, together with information on thermal tolerances and habitat preferences, to project changes in global patterns of marine species richness and community composition under IPCC Representative Concentration Pathways (RCPs) 4.5 and 8.5. Our simple, intuitive approach emphasizes climate connectivity, and enables us to model over 12 times as many species as previous studies. We find that range expansions prevail over contractions for both RCPs through the year 2100, producing a net local increase in richness globally, and changes in composition driven by the redistribution rather than loss of diversity. These invasions homogenize present-day communities across multiple regions. High extirpation rates are expected regionally, particularly in the tropics (for example, Indo-Pacific) and under RCP8.5, leading to strong decreases in richness and likely creation of novel communities where invasions are common. The overlap of these patterns with contemporary human impacts highlights where current action can help promote resilience to climate change. These results strongly suggest that conservation plans based on current global marine diversity patterns will likely fail in the long run.

REPRODUCTIVE PERIODICITY OF BROODING CORAL SPECIES IN SOUTHWESTERN PHILIPPINES (Abstract ID: 29186)

Understanding the reproductive biology of corals is critical to the management and conservation of coral reefs. Sexual reproduction is important to the recovery and persistence of corals. Data on the sexual reproduction of corals in Southwestern Philippines are lacking. Here, we report the first documentation of the lunar and diel timing of planulation of three brooding coral species: Pocillopora damicornis, Seriatopora caliendrum and Porites cylindrica in Bongao, Tawi-Tawi. We monitored the planulation of these corals from August 2014 to September 2015. All three species released larvae all year round. Planulae of P. damicornis and S. caliendrum were released around the last quarter moon and new moon. Planulae of P. cylindrica were released throughout the lunar phase but more planulae were released around the last quarter moon and new moon. All three species released planulae all day. The peak release of larvae for P. damicornis, S. caliendrum and P. cylindrica on a diel cycle occurred at 2000 to 0800 h, 0300 to 0700 h, and 2000 to 0200 h respectively. Our findings on timing of planulation will facilitate expanded research on these species.

HYPERSTABILITY MASKS DECLINES IN BUMPHEAD PARROTFISH (BOLBOMETOPON MURICATUM) POPULATIONS (Abstract ID: 28455)

Bolbometopon muricatum, the largest species of parrotfish, is a functionally important species that is characterised by the formation of aggregations for foraging, reproductive and sleeping behaviours. The locations of aggregations are often known to local fishers and therefore vulnerable to overfishing, and are likely to exhibit hyperstability, the maintenance of high catch per unit effort (CPUE) while population abundance declines. In this study we provide a clear demonstration of hyperstable dynamics in a commercial B. muricatum fishery in Isabel Province, Solomon Islands. Initially we used participatory mapping to demarcate the Kia fishing grounds into nine zones that had experienced different levels of historical fishing pressure. We then conducted comprehensive underwater visual census (UVC) and CPUE surveys across these zones over a 21 month period in 2012-2013. The individual sites for replicate UVC surveys were selected using a generalized random tessellation stratified variable probability design, while CPUE surveys involved trained provincial fisheries officers and local spearfishermen. A comparison of fishery independent abundance data and fisheries dependent CPUE data indicate extreme hyperstability, with CPUE maintained as B. muricatum abundance declines towards zero. Our finding of hyperstability may explain the sudden collapses of many B. muricatum spear fisheries across the pacific, and highlight the limitations of data-poor fisheries assessment methods for evaluating the status of commercially valuable coral reef fishes that form predicable aggregations.

SPATIAL DISTRIBUTION OF DAMAGE AFFECTS CORAL TISSUE REGENERATION, SKELETAL GROWTH, AND MORPHOLOGY (Abstract ID: 28732)

Many coral predators remove coral tissue, leaving small areas of exposed coral skeleton. While the effects of scar shape and size on tissue regeneration are known, the effect of spatial distribution of scars on healing, growth and morphology is still unknown. Polyps share nutrients with their neighbors, and thus, scar distribution likely affects recovery from damage, as well as contributes to variation in morphology due to differing calcification rates during recovery. To determine the effects of damage patterns on coral response, we conducted several studies in Moorea, French Polynesia: 1) field surveys documenting the spatial distribution of scars on corals, 2) field experiments testing the effect of the distance between scars on coral tissue healing, skeletal growth, and morphology, and 3) field surveys relating predator (corallivorous snail) presence to coral morphology and linear extension. These studies show scars were located close to one another and coral tissue regeneration was highest in scars >25 mm from each other, although skeletal growth is lowest. Additionally, scars near one another reduced linear extension a year later, while corals with scars far apart showed no difference in growth from control corals. Finally, corallivorous snails were associated with lower rates of skeletal growth and bumpier areas of the colony. These results suggest clustered coral damage has a greater effect on coral growth and recovery from damage than damage spread throughout the colony and could contribute to topographically diverse reefs.

POPULATION STRUCTURE OF THE CORAL, AGARICIA LAMARCKI FROM SW PUERTO RICO AND U.S. VIRGIN ISLANDS (Abstract ID: 27774 | Poster ID: 336)

Drastic declines in coral abundance and health have been documented worldwide within the past few decades, threats to these ecosystems range from both local and global inputs. Shallow coral reefs are highly affected, conversely, deeper reefs below ~30 meters, otherwise known as mesophotic coral ecosystems (MCEs) remain relatively healthy. The Deep Reef Refugia Hypothesis (DRRH) has been proposed to test if MCEs might be acting as larval resources for the highly impacted shallow reefs, although a bulk of contemporary studies suggests a lack of gene flow between shallow and deep reefs across many coral taxa. However, within southwestern Puerto Rico plating corals, Agaricia spp., displays both a wide depth distribution, aids significantly in reef growth and habitat formation and encompasses several species and related taxa, yet no specific population information is available in this genus. This study aims to estimate structure and/or connectivity of a particularly conspicuous member of the genus, A. lamarcki from horizontally and vertically segregated populations across southwestern Puerto Rico (PR) and the U.S. Virgin Islands (USVI). By using single nucleotide polymorphisms (SNPs) generated by double digestion restriction site associated DNA sequencing (ddRAD), we will be testing the DRRH, as well as infer levels of gene flow from both local and distant populations across the PR and USVI platform. Information from this investigation will be used to aid managers in establishing effective Marine Protected Areas and highlighting reefs with high genetic diversity.

DO SMALL SCALES MAKE A BIG DIFFERENCE? UNRAVELING THE INFLUENCE OF RECENT THERMAL HISTORY ON CORAL BLEACHING SUSCEPTIBILITY AT DAILY AND WEEKLY TIME-SCALES (Abstract ID: 29582)

Recent thermal history plays a critical role in coral susceptibility to bleaching. Degree Heating Weeks and large-scale remote sensing products can accurately predict bleaching episodes across oceanic-scales. However, there is often a mismatch between these metrics and small-scale geographic and temporal variability during local bleaching events. In an effort to reconcile regional predictions with local patterns of variability, we performed a high-resolution examination of the influence of recent thermal history on coral bleaching susceptibility of *Porites lobata* and *Goniastrea retiformis* on Ofu Island, American Samoa. Clonal replicate nubbins from multiple colonies of each species were transplanted from a source site with moderate temperature variability to 3 sites representing low, moderate, and high temperature variability. After acclimation to contrasting conditions, individuals from each site were assayed for thermal tolerance five times (after six months and six months plus 2, 7, 14 and 18 days). Multivariate analyses will be used to explore the influence of fine-scale thermal history on the bleaching susceptibility of these species. We aim to reveal temporal differences in coral thermal tolerance by exploiting the natural variability of Ofu Island's nearshore environments.

SLIM, A HIGH-RESOLUTION MULTI-PURPOSE DISPERSAL MODELING TOOL FOR THE GREAT BARRIER REEF (Abstract ID: 28320)

High-resolution ocean circulation models are required to simulate the complex and multi-scale currents that drive physical connectivity between marine ecosystems. However, standard coastal ocean models rarely achieve a spatial resolution of less than 1km over the >100km spatial scale of dispersion processes. Here we use the high-resolution unstructured-mesh coastal ocean model SLIM that locally achieves a spatial resolution of ~100m over the scale of the entire Great Barrier Reef (GBR). Using such a high-resolution model allows us to simulate the classical cascade from large-scale to small-scales, but also a feedback from the small-scale to the large-scale. By coupling SLIM with a biophysical model of larval dispersal we can track the position of virtual larvae or propagules released into the simulated domain. Connectivity matrices are then generated from the positions of the particles at the start and at the end of the simulations. Useful information can be extracted from these large matrices by using graph theory tools such as community detection, page rank, influence rank and HITS algorithms. These methods are illustrated for different applications including connectivity between submerged and near-sea-surface coral reefs, dispersion of seagrass propagules and crown-of-thorns starfish outbreaks. Our study suggests that combining a high-resolution ocean model with novel graph theory algorithms is a powerful tool for studying physical connectivity between marine ecosystems and informing management decisions.

DECOUPLING OF PHOTOSYNTHESIS AND EXTRACELLULAR SUPEROXIDE PRODUCTION BY CORALS AND THEIR SYMBIONTS (Abstract ID: 29633 | Poster ID: 86)

The reactive oxygen species (ROS) superoxide has been implicated in both beneficial and detrimental effects in cnidarian corals, ranging from pathogenic disease resistance to coral bleaching. At present, heat-induced impairment of photosynthetic electron transport in *Symbiodinium* is considered the primary process responsible for ROS production in symbiotic corals. Nevertheless, there exists a paucity of studies directly measuring ROS, including superoxide, in corals and their symbionts. Here, we quantified in situ extracellular superoxide levels at the surfaces of *Porites astreoides* in aquaria and both pigmented and bleached *P. compressa*colonies over a diel cycle within reefs during a natural bleaching event in Hawaii. Our results demonstrate high in situ concentrations of superoxide at the surface of pigmented and bleached corals that were not correlated with*Symbiodinium* abundance or significantly different over a diel cycle. Given the inability for superoxide to cross biological membranes, this superoxide is attributed to the activity of external bacterial symbionts or coral animal itself. Further, diel extracellular superoxide production by *Porites*-derived symbionts, including *Symbiodinium* and *Endozoicomonas*, were found to be light-independent, indicating that this production was decoupled from photosynthetic activity. These findings highlight the need to obtain discrete measurements of ROS in the coral holobiont to define the sources, regulation, and consequences of these species to coral health.

UNDERWATER HYPERSPECTRAL IMAGING OF A COLD-WATER CORAL REEF (Abstract ID: 28373)

Cold-water coral reefs have a wide range of ecological functions. Large-scale mapping of the reefs is resource demanding. The standard method of visual seabed mapping today involves video transects and still imagery, which is a proven, yet time consuming and subjective method. A more robust and objective method is needed to improve the efficiency in benthic habitat mapping for better management. Underwater Hyperspectral Imager (UHI) utilizes high spectral resolution of the visible light reflected from objects on the seafloor to automatically identify Objects of Interest (OOI). A custom-made software including a spectral library containing optical fingerprints of a range of OOI's are used together with classification algorithms, for automated sea floor identification. The aim of this work was to demonstrate UHI-mapping of a coral reef and to optimize the classification algorithms for the reef-building coral *Lophelia pertusa*. Coral reefs in Norwegian waters was mapped with UHI mounted on a remotely operated vehicle. The two color morphs of live *L. pertusa* (white and orange), dead corals and associated fauna were identified. Maps of the distribution of the organisms are visualized in GIS format. Further, the reflectance spectrum of *L. pertusa* was measured in laboratory. Information on the variability of the spectral signatures are used to enhance the identification process. We propose that the UHI technology represents an efficient and high-quality tool for future environmental mapping and monitoring.

CAN CORAL REEFS AND LARGE-SCALE DREDGING PROJECTS COEXIST? (Abstract ID: 28986)

Port expansion projects throughout the tropics have created a conflict between ports, environmentalists, regulators, and the public. Various reports from some projects show extreme impacts while others show little or none. Which is correct? Are there BMPs that can be employed to minimize impacts? When impacts do occur, are they expected and reasonable? And finally, can they be restored or mitigated? Using case studies, we highlight factors that work! The lessons learned from earlier projects show that the best course of action is the careful preparation and vetting of a pre-project environmental assessment that allows for a description and quantification of all anticipated impacts. This assessment should detail avoidance and minimization options as well as protective measures to assure for environmental permit compliance. During construction, quantitative monitoring of key biotic and abiotic parameters need to be performed so that corrective adaptive management measures can be employed mid-stream. It is imperative that monitoring programs carefully employ far-field controls for comparison. In addition, a spatially and temporally appropriate monitoring protocol should be employed to detect impacts in real-time. Finally, to make the public whole for any impacts, there is a need for restoration of injured resources and mitigation to offset those that are lost/displaced during construction. Through all project phases, open transparent communication between stakeholders is necessary to resolve conflicts between the various groups, many with disparate goals and interests.

MODELLING AND MAPPING FISHING PRESSURE AND FISH STANDING STOCKS ACROSS MICRONESIA, AND ASSESSING THE POTENTIAL IMPACTS OF CLIMATE CHANGE (Abstract ID: 28495)

Reef fisheries are vital to Micronesian economies, but are threatened by over-exploitation and other stressors. As part of The Nature Conservancy's Mapping Ocean Wealth project, we assembled a database of 1127 fish surveys across five jurisdictions of Micronesia to model and map fishing pressure and current standing stocks. Using mean parrotfish size as an indicator of fishing pressure and controlling for biophysical gradients, we demonstrate that fishing is best predicted by distance to the nearest port and human population pressure within 200 km. This metric of fishing pressure and biophysical variables were then used to model standing stock. Standing stock increased with increasing oceanic productivity, upstream larval supply, depth, and coral cover, and decreased with increasing sea surface temperature and fishing pressure. The models were then used to predict fishing pressure and current standing stock across all reefs in the study area, providing the first continuous maps of these variables for Micronesia. Furthermore, we mapped potential gains in standing stock that might be obtained in no-take reserves by simulating zero fishing pressure. The ratio of current to potential standing stock also generated spatially explicit estimates of fisheries status and potential time to recovery. Finally, the models also provide insights into the impacts of rising sea surface temperatures that are expected to alter fish distributions and reduce body size. These maps and models are important regional resources to inform policy and aid protected area design and fisheries management.

WHALE SHARK KINSHIP AND GENETICS: INVESTIGATING TWO POPULATIONS WITH DIFFERENT ECOLOGIES (Abstract ID: 29548)

Juvenile whale sharks are known to aggregate near coral reefs, usually due to high food availability, at several locations globally. A recent global study of whale shark population genetics has allowed for better understanding of genetic connections between aggregations in both the Indo-Pacific and Atlantic. This overview included an aggregation found within the Red Sea near Al Lith, Saudi Arabia; however, the Mafia Island, Tanzania, aggregation was not part of the study. The ecological behavior of these aggregations differs with the Saudi Arabian individuals showing strong seasonality, while acoustic telemetry data revealed cryptic residency at Mafia Island. Genetic analysis using microsatellite markers was performed on both populations, using a combination of primers sourced from previous studies and other newly developed primers to compare individuals within each population between seasons. The Red Sea population was compared between 5 seasons spanning 6 years from 2010-2015. The Tanzanian population was compared for 2 field seasons from 2012-2014. Genetic diversity was analyzed using allelic richness for 5 seasons in the Red Sea with no significant change seen. Contrasting to other whale shark aggregations allelic richness in the Red Sea shows no sign of reduction. Finally, kinship was analyzed for both aggregations, with two potential sibling pairs at the Tanzanian aggregation, but no possible sibling pairs within the Red Sea. This result suggests that the dissimilarity between the aggregations might not lead to differences in population relatedness.

POLEWARD-SHIFT OF CORALS: TRANSPLANT EXPERIMENT OF JUVENILES FROM SUBTROPICAL TO TEMPERATE REEFS IN JAPAN (Abstract ID: 29426)

Recently, ocean warming causes poleward-shift or expansion of some corals from tropical/subtropical to temperate regions. In this case, coral larvae should be able to reach new locations and successfully settle, however no information is available on how tropical coral juveniles survive after settlement in temperate regions. Juveniles of many corals are known to acquire symbiotic algae, *Symbiodinium* from the environment. Establishment of symbiosis is important for the survival and growth of the early stage corals. However, in a poleward expansion situation, it is likely that the environmental symbiont community at the settlement location will differ from this in the original reef. Here, we examine the potential of subtropical coral juveniles to settle and initiate growth in a temperate reef in Japan. We used in situ transplant of acroporid corals to measure size and survival, and also genotyped *Symbiodinium* of the juveniles. The species studied are either known to be already expanding their distribution to the north or not. Interestingly, no major differences in survival and growth could be observed between expanding and non-expanding species 3 months after settlement. Symbionts of adult corals were all identical, whereas various types were found in juveniles from both locations and differed more between locations rather than between species. This confirms that coral juveniles acquire multiple symbiont types depending on the local environments where they settle and change over time instead of species-specific symbiont acquisition.

DETERMINING THE HYDRODYNAMIC CONDITIONS REQUIRED TO DEPOSIT CYCLONE LINKED BOULDER DEPOSITS IN THE SOUTHERN GREAT BARRIER REEF (Abstract ID: 29366 | Poster ID: 389)

Cyclones are potentially catastrophic events for coral reefs that can result in widespread loss of coral cover and biodiversity. Large reef-derived boulders have been used to reconstruct the effects of extreme events on coral reefs and are crucial to our understanding of cyclone events on coral reef structural diversity, geomorphic change, and coral cover. Previous studies linking large coral boulders to cyclones often do not evaluate the specific hydrodynamic processes required to produce such deposits. This is an important knowledge gap since establishing a greater understanding of the hydrodynamic conditions required to deposit coral boulders will allow for more accurate predictions of coral reef change during high energy storm or cyclone events. In this study, we revisit boulders that have been linked to cyclone events on Heron and One Tree Reefs. The hydrodynamic conditions required to break, transport, and deposit the boulders on the reef flats were calculated by using a number of scenarios and transport models from previous studies of cyclone deposited boulders on coral reefs and rock platforms. We find that contrary to previous assumptions the boulders on Heron and One Tree Reefs could have been deposited during storm events on the east coast of Australia and do not necessarily require cyclonic conditions for transport and deposition. We also find the initial conditions of the boulder (e.g. attached or freely submerged) greatly influences this interpretation with attached boulders requiring waves generated by cyclones to be transported onto reef flats.

PLANNING FOR THE FUTURE: INCORPORATING GLOBAL AND LOCAL SCALE DATA TO HELP MANAGERS PRIORITIZE CONSERVATION EFFORTS (Abstract ID: 28623)

Most managers seek to reduce reef vulnerability to climate change, but in the face of both global and local stressors, how should managers prioritize conservation efforts? We present one of the first examples of using a vulnerability assessment to prioritize efforts to reduce climate vulnerability. For twelve MPAs in Indonesia, we combined 1) state-of-art downscaled (4-km) climate model projections of bleaching conditions, 2) maps of anthropogenic stress, and 3) ecological monitoring data. These data cover both vulnerability components: exposure and resilience. In collaboration with local managers, we created a matrix of action options to aid in prioritizing conservation efforts. Sites that are high priorities have both low projected thermal stress and high resilience potential. At the other end of the scale are 'sacrificial' low priority sites that are already in poor condition and are projected to have high future stress. Between these extremes, our options matrix highlights and identifies specific sites where local conservation efforts are likely to have the biggest impact achieving specific MPA objectives. This is among the first vulnerability assessments to combine downscaled climate model projections with ecological monitoring data, an approach which can be replicated in other areas where managers face the familiar challenge of using limited conservation resources in the face of rapid global change and uncertainty. It is essential that local communities have the tools to easily and accurately assess tradeoffs in conservation efforts.

THE ROLE OF MARINE PROTECTED AREAS IN THE REPLENISHMENT OF LOCAL FISHERIES (Abstract ID: 28137)

The precarious state of many coastal marine ecosystems has prompted the use of marine protected areas (MPAs) as a tool for management and conservation. However, the effectiveness of MPA networks is contingent upon our understanding of the processes that affect population dynamics. Since coral reefs are a naturally patchy and fragmented environment, the degree of connectivity between discrete populations is critical to the persistence of populations and by extension, the subsistence of local fisheries. We com-

pare observed patterns of larval dispersal over successive years for two exploited species of coral reef fish in the Keppel Islands, Great Barrier Reef. We combine parentage analysis with emergent analytical tools in graph theory to determine the consistency of larval export from a small network of no-take MPAs to nearby fished areas. Further, we test the old adage that bigger, older and fatter fish make the greatest contribution to the replenishment of fished populations, and provide empirical evidence for the relationship between fish size and local reproductive success. Our findings give important insight into the mechanisms shaping connectivity patterns in coral reef fish and the role of no-take MPAs in the replenishment of local fisheries.

LARGE-SCALE MASS CORAL LARVAL RESEEDING ENHANCES CORAL RECRUITMENT FOR REEF RESTORATION (Abstract ID: 28587)

Scleractinian reef corals are foundation species on coral reefs but are increasingly threatened by chronic anthropogenic stressors interacting with natural perturbations, resulting in the degradation of coral and reef communities in many reef regions globally. Coral populations are naturally resilient through sexual reproduction and recruitment of juveniles and can recover from many natural disturbances given sufficient time and absence of large or chronic disturbances. However, where larval supply is limited, natural recruitment rates may be too slow or variable to restore coral populations within appropriate timescales, therefore active restoration processes need to be considered. Synchronous coral spawning events provide access to millions of larvae that can be used for mass larval rearing and settlement on degraded but recoverable reef areas. Most previous larval 'reseeding' studies have been done using small enclosures, whereas large-scale active interventions are needed to be ecologically meaningful. This study uses larger-scale mesh enclosures to contain millions of coral larvae after spawning during their embryo and larval development and subsequent settlement period on degraded reef areas in the northwestern Philippines. Use of large-scale mesh enclosures to rear millions of coral larvae combined with in situ settlement can significantly enhance initial settlement rates and stimulate coral recruitment on degraded but recoverable reef areas, thereby initiating reef restoration.

CORAL REPRODUCTION AND RECRUITMENT ON A HIGH-LATITUDE REEF IN SOUTH AFRICA: RESILIENCE IN THE YOUNG? (Abstract ID: 29610 | Poster ID: 373)

The sexual reproduction and recruitment of corals, key processes in the maintenance and resilience of coral communities, are understudied on the marginal high-latitude reefs in South Africa. Furthermore, the impact of increasing water temperature and acidity on the early life stages of corals warrants investigation to establish how these corals may respond to predicted climate change. In this study, gravid colonies of two representative coral species, *Hydnophora exesa* and *Acropora austera* ,were collected from Two-mile Reef at Sodwana Bay (-27° S, 32° E) and spawned in the laboratory. Gametes were used to assess how increased water temperature and acidity (as predicted by the IPCC) would affect the fertilization, embryonic development, and recruit growth rates of these two species. Increased water temperature and acidity negatively influenced the early life stages of these corals, with changes in temperature having a greater effect than pH. However, fertilization and recruit growth still occurred under predicted climate change conditions. This study is the first to investigate the influence of increasing sea temperature and ocean acidification on the early life stages of corals on the high-latitude reefs of South Africa. Determining whether recruitment rates experienced during increased water temperature and acidity are sufficient to maintain reef resilience remains to be quantified.

FISH ASSEMBLAGES ASSOCIATED WITH RED GROUPER PITS AT PULLEY RIDGE, THE DEEPEST PHOTOSYNTHETIC CORAL REEF IN THE CONTINENTAL U.S. (Abstract ID: 29421 | Poster ID: 188)

Pulley Ridge is a series of drowned barrier islands on the southwest Florida Shelf and is known to be the deepest photosynthetic coral reef in the continental U.S. The fishes at Pulley Ridge are unique in that they comprise a mixture of shallow water and deep species. With the majority of the ridge being low rugosity habitat comprised of algae and plate corals, fish densities are low compared to other mesophotic reefs. The exceptions to this are the pits which red grouper excavate throughout the area. These pits form high rugosity rock habitat which act as small biodiversity hotspots. ROV dives were conducted annually at Pulley Ridge from 2012 to 2015 to characterize grouper pits, examine their importance to the ecosystem, and determine the impact of lionfish invasion on their species composition. Approximately 66% of red grouper and 71% of lionfish observed were associated with a pit. Juveniles and small fish species were also associated with the excavations, particularly those that contained red grouper and/or lionfish compared to pits with neither species present. Lionfish and red grouper abundances both increased between 2012 and 2014 and then decreased in 2015 while abundance of juveniles and small fish displayed the exact opposite trend. PRIMER analyses also indicate that fish species assemblages were distinct among pits depending on red grouper and/or lionfish presence. Future analyses will compare fish assemblages from the current data with those conducted in 2008 & 2009, before the lionfish invasion, to examine the impact this species has on the ecosystem.

MOLECULAR MODIFICATIONS IN CORAL REEF TAXA AND THE METABOLOMIC RULES OF COMMUNITY ASSEMBLY (Abstract ID: 28788)

Lipid-based molecules are fundamental building blocks of life on Earth. In addition to providing structure, lipids are involved in processes ranging from intracellular signaling to inter-organismal defense. Many physiological processes are activated by the enzymatic addition or removal of small molecules (e.g., acetyl groups) from lipids. This constant fluctuation in atomic composition of parent molecules gives rise to exceptional molecular diversity and reflects physiological changes within an organism, both of which we captured using a novel metabolomics approach. Metabolomes, comprised primarily of lipids, were extracted from 235 samples of benthic reef taxa. Samples were analyzed using liquid chromatography with tandem mass spectrometry followed by molecular networking to connect related molecules and identify modifications. Our data demonstrate that reef corals, sponges, tunicates, and algae exhibit distinct molecular modification capacities within and among taxonomic groups. In particular, taxa exhibit unique patterns of lipid methylation, acetylation, and phosphorylation. To better understand the ecological consequences of distinct modification capacities, we are determining how modification patterns are altered by benthic competition and whether these changes reflect competitive outcomes. The extent to which organisms differ in their capacity to modify molecules reflects the suite of functions they possess, thus our approach provides a robust way to examine whole-organism physiology within ecological frameworks such as the competition for benthic space.

A RAPID, SIMPLE TEST FOR THE CORAL PATHOGEN VIBRIO CORALLIILYTICUS USING A SENSITIVE LATERAL FLOW "DIPSTICK" IMMUNOASSAY. (Abstract ID: 28781)

Vibrio coralliilyticus is a bacterial pathogen of both corals and shellfish larvae that is currently difficult to detect and manage. Commercial shellfish hatcheries are frequently experiencing dramatic losses due to vibriosis and we have developed a novel lateral flow immunoassay (LFA) that can detect V. coralliilyticus contamination in these rearing facilities. However, as the organism is also known to cause severe disease in corals and we are now exploring the possibility of utilizing this test as a coral disease diagnostic tool. The test is a rapid LFA that can measure extremely low levels of a protein toxic for corals and shellfish (the VcpA zinc-metalloprotease) secreted by V. coralliilyticus. We report here that the LFA test can measure VcpA levels as low as 5 ng/ml, which is 20-fold lower than the level of VcpA that causes noticeable mortality of shellfish larvae in the laboratory. LFAs are simple and easy to perform (home pregnancy test kits are common examples) and do not require any external instrumentation other than an eyedropper to apply several drops of sample to the sample port. Readout is visual and can be qualitative (plus/minus) or quantitative, as the signal strength is proportional to the amount of antigen present in the sample. We anticipate that this test will provide a useful tool for coral disease diagnostics as it provides real-time, on-site, early detection of bacterial presence.

MICROBIAL PROCESSES IN THE SEDIMENT AT A SHALLOW-WATER HYDROTHERMAL VENT IN A TROPICAL CORAL REEF (Abstract ID: 28329)

Shallow-water hydrothermal vents occurring in tropical coral reefs are often used as analogs for future climate change scenarios. Hydrothermal venting can cause extreme physicochemical conditions, e.g. decreased pH and increased temperature, which may be detrimental to reef organisms. Given the importance of microbial processes in nutrient cycling on the reef, little is known about how these processes may differ in sediments subject to hydrothermal venting. Here we studied a hydrothermal vent system in Papua New Guinea, combining biogeochemical observations with metagenomic and metatranscriptomic sequencing of the microbial community in the sediment. Our results suggested changes in major element cycles (carbon, nitrogen, sulfur) related to hydrothermal venting. We detected a shift in the active photosynthetic community with a decrease in cyanobacterial and an increase in diatom gene transcripts. Net photosynthesis seemed to be negatively affected at the vent, presumably due to a trade-off between increased $CO_2$ availability and increased trace element stress. Furthermore, gene expression patterns suggested increased nitrification, whereas nitrogen fixation and denitrification to ammonia might be reduced. The composition of the sulfate reducing community was altered at the vent, and sulfate reduction rates and gene expression were severely diminished. We propose that hydrothermal activity in a tropical coral reef may drastically alter nutrient cycling in the sediment, potentially resulting in the degradation and simplification of such a diverse and complex system.

FOLDSCOPE: AN ORIGAMI-BASED SOLUTION TO SCALABLE FIELD MICROSCOPY (Abstract ID: 28315)

Recent efforts in citizen science have shown that crowd-sourced wildlife observations can substantially contribute to our understanding of local and regional biodiversity. However, direct observations by citizen-scientists are usually limited to relatively large, macroscopic organisms, often neglecting the much larger range of species richness found at microscopic scales. This is because 1. microscopy is often viewed as an activity limited to scientists, and 2. microscopes are often expensive, fragile, and difficult to carry into the field. As a solution to these issues, we have developed the Foldscope: a rugged, ultra-low cost (<$1 in materials), origami-based microscope that is assembled by folding a pre-cut sheet of paper and can provide >400x magnification. Foldscopes can be operated independently of electricity, or they can be coupled to smartphone cameras to capture images and videos of live organisms while in the field. To date, we have manufactured and distributed 50,000 Foldscope units to participants in 135 countries (see their findings at https://microcosmos.foldscope.com), and Foldscopes have thus far been used to view organisms in a diverse range of settings including the Amazon rainforest, a tiger reserve (Kaziranga National Park) and major river (Brahmaputra River) in India, the Ngorongoro Conservation Area in Tanzania, and marine environments along the Pacific coast. Our aim is to provide a scalable tool such that any curious person in the world can explore his or her local microcosmos and broadcast his or her findings to a global community. http://www.foldscope.com

ARE NOT SMALL PATCH REEFS WORTH MUCH MORE THAN A SINGLE LARGE CONTINUOUS REEF IN TERMS OF REEF FISH HABITAT? (Abstract ID: 27812 | Poster ID: 83)

Patchy habitats may enhance species coexistence through interspecific tradeoffs between dispersal and competitive ability. Hattori & Shibuno (2010) examined the species-area relationship of damselfishes over 84 patch reefs in a back reef of Ishigaki Island, Japan: a large reef harbored less species than small reefs of an equivalent area. Hattori & Shibuno (2013) found that interspecific competition was intense on large reefs. Hattori & Shibuno (2015) reported that the total volume of 3D reefs can be used to predict species richness. The present study assessed how to estimate 3D reef structure counting the host anemone *Entacmaea quadricolor*. Hattori & Kobayashi (2007) found the number of *Amphiprion frenatus*, which can be an indicator species of healthy back reefs, was highly correlated with the number of the hosts which in turn was highly correlated with the total area of reefs. A stereoscope was used to detect 3D reefs using high resolution aerial photographs. The total area of detected 3D reefs was not correlated with the number of the hosts, but the total area of reefs observed in photographs as dark colors was highly correlated with the number of hosts. Field observations revealed that dark colors indicated reefs (>0.5 m in height; 0.25 m in diameter), and the upper sections of large 3D reefs showed no dark colors (no corals). Thus, assuming that the number of hosts is the estimator of fish species richness, it is concluded that small patch reefs are worth much more than a single large continuous reef in terms of reef fish habitat, if the total area is equivalent.

CURBING SEDIMENATION OF CORAL REEFS THROUGH COMPREHENSIVE STAKEHOLDER ENGAGEMENT; A CASE STUDY FROM FAGA'ALU, AMERICAN SAMOA (Abstract ID: 29212)

Although comprehensive stakeholder-engagement is recognized as essential for a holistic and effective approach to conservation, efforts often fall short in one sector or another. This presentation will share lessons learned from Faga'alu, American Samoa, a small Pacific island tropical watershed, where a collaborative ethos continues to push initiatives to curb sedimentation of coral reefs. Faga'alu's coral reefs demonstrate relatively high coral cover and serve as a critical habitat for a variety of marine species, including threatened species and organisms with cultural significance as a supplemental food source for subsistence fishing. In 2011, the community of Faga'alu developed a Village-based Conservation Plan, identifying sedimentation as a priority threat to their immediate environment. In response, a sediment budget study commenced, identifying the local quarry as the primary contributor. Five years later, Faga'alu has developed extensive private-public partnerships by leveraging federal assistance through its designation as a United States Coral Reef Task Force Watershed Partnership Initiative site and pursuing incentive-based approaches with the local quarry to reduce the introduction of sediments into the natural environment.

PARTITIONING OF RESPIRATION IN AN ANIMAL-ALGAL SYMBIOSIS: IMPLICATIONS FOR DIFFERENT AEROBIC CAPACITY BETWEEN SYMBIODINIUM SPP. (Abstract ID: 28470)

Cnidarian-dinoflagellate symbioses underpin coral reef productivity. However, certain aspects of this symbiosis, such as the partitioning of respiration between animal host and algal symbiont, remain enigmatic. We quantified mitochondrial enzyme activity as a proxy for aerobic respiratory capacity in the symbiotic sea anemone Exaiptasia pallida. Host, symbiont, and combined host + symbiont (holobiont) mitochondrial citrate synthase (CS) activity were strong predictors of holobiont respiration. There was a positive association between symbiont density and host CS activity, and a negative correlation between host- and symbiont CS activities. We also found differences in symbiont CS activity between anemones hosting different Symbiodinium species (ITS2-type A4 Symbiodinium or Symbiodinium minutum [ITS2-type B1]). Notably, partitioning of total CS activity between host and symbiont, in both natural and re-infected E. pallida, differed from the respective host/symbiont biomass ratios. Moreover, the relationship between the partitioning of total CS activity and the host/symbiont biomass ratio was influenced by the specific identity of the symbiont. These data suggest that the long-held assumption of equivalency between symbiont/host biomass and -respiration ratios may lead to an overestimation of symbiont respiration, and erroneous conclusions regarding carbon budgets in these symbioses. Interspecific variability in symbiont aerobic capacity provides further evidence for physiological differences that should be considered when studying diverse cnidarian-Symbiodinium associations.

DEVELOPING AN ASSESSMENT FRAMEWORK TO EVALUATE CORAL REEF CONDITION IN OFFSHORE MARINE PROTECTED AREAS (Abstract ID: 29848)

Cold-water coral reefs exist at all latitudes. Bottom fisheries, oil and gas exploration, mining, ocean acidification, and other human activities threaten them. The United Kingdom has discovered significant areas of these reefs and has in recent years actively designating Marine Protected Areas (MPAs). Sites are in deep water many miles offshore and are difficult to monitor so the availability of direct, observational evidence is currently relatively low. In the short-term, we require indirect assessment methods to undertake condition assessments so that regulatory authorities can be informed about the need for appropriate management measures. JNCC recently developed methods for assessing the likely impact of human activities on sensitive benthic habitats and species like Lophelia pertusa for

regional scale assessments. We have started to look at how these vulnerability assessments can be adapted to work at MPA scales, but also combined with indicators of health to provide an assessment of likely condition of these reefs. The evolving assessment framework incorporates a decision support tool that identifies options for the assessment of a particular reef depending on the type and amount of in-situ data available. A key aim of the tool is to record in a formal audit trail how a decision about reef condition was reached. These site scale assessments often need to consider cumulative pressures acting over the same spatial areas. Given this complexity, we need to be transparent in how we arrive at an assessment and in our level of confidence in the outcomes.

LONG-TERM TRENDS IN BENTHIC COVER OF A HIGH LATITUDE REEF SYSTEM OFFSHORE SOUTHEAST FLORIDA, USA (Abstract ID: 29425 | Poster ID: 314)

The northern extent of the Florida Reef Tract (FRT) is a high latitude (>25° N) marginal system offshore southeast Florida (SEFL), USA. SEFL reefs are exposed to variable seawater temperatures and are adjacent to a highly developed mainland adding additional anthropogenic water quality and physical stress to the environment. This system is also unique in that it exists as continuous linear reefs rather than the often observed isolated, non-continuous patch reefs seen in other high latitude systems. In 2003 the Southeast Florida Coral Reef Evaluation and Monitoring Project (SECREMP) was established as a northern extension of the existing Florida Keys program (CREMP). SECREMP provides long-term benthic cover data via annual image analysis of fixed sites along the upper FRT. This analysis focuses on the trends in benthic cover over the lifetime of the project (2003-2014) and the latitudinal gradient. Stony coral cover has remained relatively unchanged over the gradient through time, which is atypical compared to other systems throughout the Florida Keys, Caribbean and worldwide. Additionally, the reef community persists with a lack of extreme change in other major benthic taxa, such as sponges, octocorals and macroalgae. The lack of declining stony coral cover is a unique trend and suggests that this high latitude system, although possessing continuously low cover, is not experiencing the extreme decline of cover seen elsewhere.

HIGH DENSITIES AND SELECTIVE FEEDING OF COTS THREATENS POST-BLEACHING RECOVERY OF CORAL REEFS IN NORTH-WESTERN AUSTRALIA (Abstract ID: 28903)

Successive, extensive bleaching events have reduced coral cover and altered species assemblages significantly in the Montebello and Barrow Islands in north-western Australia. In particular branching *Acropora* populations were dramatically reduced while massive coral forms such as portid and faviid corals were less impacted and now dominate coral assemblages. Subsequent to this perturbation, there have been changes in the abundance and/or distribution of the coral eating crown of thorns starfish (COTS), *Acanthaster planci* which have further impacted coral communities. We surveyed the Montebello and Barrow Island groups for COTS and documented coral cover throughout the region. The overall density of COTS was 8.9 $ha^{-1}$, but was as high as 186 $ha^{-1}$ in hotspots. The highest densities of COTS corresponded to the relatively small refuge areas where coral survival from the bleaching event had been greatest. We also studied the feeding preferences of COTS under post bleaching conditions to determine their likely impact on coral communities. We found that even when *Acropora* and *Pocillopora* were extremely rare, COTS demonstrated a preference these genera although they also consumed non-preferred taxa such as portid, faviid and merulinid corals in greater abundance. The consumption of non-preferred genera and families of corals was influenced by their local (between site) abundance. Where COTS populations exceed outbreak threshold densities they are likely to retard recovery of coral communities in this region.

POTENTIAL DIAGNOSTIC MARKERS FOR SEVERAL FISH HYBRIDIZATION CASES (Abstract ID: 28640 | Poster ID: 36)

The development of molecular genetic techniques that generate taxon-specific markers to characterize individuals as pure species or hybrids and to document patterns of gene exchange and introgression is very important for hybridization studies. To investigate potential diagnostic markers, a suite of different primers for several nuclear genes were tested for several fish hybridization cases. The sequencing results from potential diagnostic markers were cross-referenced with the results from microsatellite data, RADseq data, and morphological data. The diagnostic consistencies were tested on purebred reference samples from large sampling spatial ranges. Combined with mtDNA data, the presence/absence of introgression and parental contributions for each hybridization case were considered as well. These potential diagnostic markers could serve as a quick test to discriminate species that may otherwise be ambiguous, could confirm putative hybrid cases between these species, and could even suggest the directions of introgression in closely related species. Once diagnostic markers have been confirmed, they provide a cheaper, faster, and less laborious approach (and require few fewer samples) than alternate methods such as microsatellites or next generation sequencing. A more detailed understanding of introgression and a more efficient confirmation of hybrids will facilitate a more general understanding of the role of hybridization in global biodiversity patterns.

COMMUNITY STRUCTURE OF CORAL-ASSOCIATED FAUNA ON REEFS IN THE CHAGOS ARCHIPELAGO, CENTRAL INDIAN OCEAN (Abstract ID: 29539)

The majority of reef biodiversity is comprised of the cryptofauna, defined as small, often cryptic, mainly invertebrates, which inhabit the reef structure. Despite this the cryptofauna are understudied relative to fish and coral faunal components. Here we present an assessment of reef cryptofauna biodiversity (with a focus on the decapods, Crustacea) on dead branching corals, the most productive reef microhabitat, and we identify some key processes underpinning their community structure in the Chagos Archipelago. The Archipelago represents one of the most resilient reefs globally, partly because of its remote location away from the majority of human pressures. To assess decapod biodiversity we combined molecular and morphological identification techniques, allowing for a rare empirical evaluation of species delimitation methods, providing guidance for future studies. Whilst assessing decapod diversity an unanticipated high prevalence of obligate coral-dwellers were discovered on the dead coral microhabitats. Obligate coral-dwellers are almost universally found on live coral, inferring they have a strong reliance on live coral for food, habitat and/or recruitment. We examine potential biological reasons for this spill-over to dead coral microhabitats and whether these microhabitats may have a poorly known functional role in the life cycles of these species. These results add further complexity to our limited knowledge of the relationships between corals and the high diversity of motile invertebrates that inhabit live and dead colonies. These relationships are, however, fundamental to understanding the consequences of coral loss on species persistence and biodiversity.

CONNECTING A RESEARCH INSTITUTION TO THE PUBLIC, BUILDING ON A 5 YEAR TIMELINE WHILE THINKING 7 GENERATIONS OUT (Abstract ID: 29180 | Poster ID: 716)

The Hawaii Institute of Marine Biology sits on an island, Moku o Lo'e, in a bay off of Oahu, Hawaii. Moku o Lo'e pre-contact history includes a cautionary legend about responsibility and sharing. In modern times it became part of multimillionaires' dreams of paradise, followed by desires to make a difference and donation of the island to the University (which has far less resources). In building our Community Education Program over the last six years, we have followed a few basic guidelines - be true to the island's history and look to the future for our community and research institution. We do not see these as separate. For our relatively new education programs at a research institute, we have considered how to make a positive impression on faculty and the community, as well as becoming fiscally stable on both 5 and 10 year horizons and from an indigenous perspective, thinking seven generations out. We describe our current offerings, as well as our next 5 year plan as it relates to the future.

EFFECTS OF AQUACULTURE ON MUCUS PROPERTIES IN THE CORAL FUNGIA (Abstract ID: 29438)

South East Asian sea cage farms are often located within 1km from a reef. The cage farms release nutrients and on top of that, large quantities of antibiotics are used. The aim of this study was to investigate how these multi-stressor point sources impact coral mucus composition, the associated bacterial diversity, antibiotic resistance, and the anti-

biotic function of the mucus itself. We investigated the coral Fungia fungites mucus and associated bacteria in Nha Trang Bay, Vietnam. Coral mucus where sampled from eight sites along a gradient from sea cage farms. Total carbon, nitrogen, and phosphorous was measured. Coral mucus bacteria where isolated and genetically identified by sequencing the 16s rRNA gene. Furthermore, antibiotic resistance was assayed by the disc diffusion susceptibility test. We also tested the antibiotic activity in the coral mucus by growth inhibition tests. We found clear gradient effects with changed bacteria community composition, coral mucus NPC concentration and composition, antibiotic resistance, and antibiotic properties. Counterintuitive we found decreased concentrations of nutrients in mucus close to cage farms where the water is nutrient rich. The mucus also loses its antibiotic function when exposed to cage farming effluents. This will weaken the defence against bacteria and other pathogens. A combination of changed mucus nutrient composition and concentration together with lost antibiotic activity can be the explanation for changes in mucus bacterial composition and increased prevalence of coral diseases.

UNRAVELLING FACTORS SHAPING INDIVIDUAL PERFORMANCE OF CORAL OFFSPRING: THE NEED OF A SELECTIVE APPROACH IN SEXUAL REPRODUCTION (Abstract ID: 28825)

During spawning events, millions of coral eggs and larvae are released into the water column to ensure reef persistence. However not all eggs and larvae created are equal and this variability among individuals may alter their efficiency to cope with a changing world. In this context, it is of paramount importance to select offspring with the best performance to environmental changes. Thus, we studied a) how parental effects (spawning behavior and thermal tolerance of adults) alter the larvae released and b) which larval traits may allow selecting the « winner » larvae. To do that, larvae of the corals Pocillopora damicornis were collected from « winner » and « loser » adults (to thermal stress) during different spawning days and months. Results showed that the parental thermal resistance of P. damicornis colonies has strong effects on the larva condition: bigger size, faster swimming speed, and better attraction to crustose coralline algae for larvae released from "winner" corals. Moreover larvae differ physiologically among the days they are released: late-release larvae being less competent than early-release larvae (slower swimming speed and lower thermal resistance). Finally green-fluorescent larvae displayed better recruitment and survival rate than red-fluorescent larvae. To conclude, our work underlined an important variability of the physiological and behavioral performances of coral larvae to face a warming world. This emphasized the need to develop a selective approach in sexual reproduction to enhance restoration efficiency in the future.

USING ECOSYSTEM PROPERTIES TO DETECT TRANSITIONAL STATES IN CORAL REEF FISH ASSEMBLAGES (Abstract ID: 28901)

Ecosystem-based fisheries management requires the means to detect ecosystem change. Indicators based on single species, food webs, or subsets of the full community (e.g. biomass in a particular trophic group) have utility, but may not be sensitive to cumulative effects, or to variation in system level processes. System level indicators, such as those that relate to the distribution of energy across trophic levels, provide a means to identify whether a system is moving into or out of a state of disturbance or recovery. These cumulative biomass indicators have recently been shown to be robust and reliable for discerning ecosystem perturbation in > 100 different marine ecosystems. Therefore, integrative trophic level information appears to be a suitable entire-system indicator of global application. There is, however, uncertainty over how and to what extent these indicators are affected when there are large inputs of allochthonous nutrients, as is common in systems such as estuaries and coral reefs, thus limiting the utility of this approach to those systems. Here, we test the effect of allochthonous material on the accumulation of biomass across trophic levels in coral reef fish assemblages. We find strong differences in the basal biomass and trophic level inflection point (the point where maximum biomass is observed) in relation to background oceanic productivity, temperature and fishing pressure. By accounting for these natural environmental drivers, we can improve upon the utility of this system level metric as an indicator of human-induced perturbation for coral reefs.

CHARACTERISING CORAL RESTORATION EFFECTIVENESS: A REVIEW OF CURRENT LIMITATIONS AND CHALLENGES AT A SOCIO-ECOLOGICAL SCALE (Abstract ID: 28268)

Coral reef restoration initiatives are burgeoning as the need for novel management strategies escalates to address dramatic declines in coral cover globally; however, coral restoration programs typically lack rigour and critical evaluation of their effectiveness. A review of 74 peer-reviewed papers using coral transplantation for reef restoration reveals that growth and survival of coral fragments were the most widely used indicators of restoration success, with 89% of studies using these two indicators either solely (51%) or in combination with a limited number of other ecological factors (38%). In 53% of studies, reef condition was monitored for one year or less, while only 4% of reefs were monitored for more than the recommended five years post-transplantation. These results highlight that coral reef restoration science has been focused primarily on evaluating the feasibility of techniques for coral restoration and the initial establishment phase post-transplantation, rather than longer-term community level outcomes. Here, we outline eleven socio-ecological indicators to comprehensively evaluate the effectiveness of coral reef restoration across the four pillars of sustainability. In summary, evaluation of the effectiveness of coral restoration programs should integrate ecological characteristics with socio-cultural, economic, and governance considerations to assess the efficacy of coral restoration as a tool to promote reef resilience and ensure the sustainable delivery of reef ecosystem services.

HOLOTRANSCRIPTOME ANALYSIS REVEALS SYMBIODINIUM CLADE IDENTITY INFLUENCES CORAL HOST GENE EXPRESSION (Abstract ID: 30010)

Specific clades and subclades of the dinoflagellate symbiont Symbiodinium have been shown to affect the physiological response of their coral host to environmental conditions. However, little is known about the genetic underpinnings of these interactions. Here we use whole transcriptome sequencing and a system genetics approach to analyze gene expression in the coral Montipora capitata and its Symbiodinium symbionts from Hawai'i Island. In particular, we examined the effects of multiple factors on gene expression in the holobiont and its individual constituents, including collection site, presence of the coral disease Growth Anomaly (GA), and symbiont clade composition. We found that a large majority of colonies harbors only one clade of Symbiodinium, consistent across multiple marker genes. This pattern is unaltered by the presence of GA. Overall gene expression profiles and the number of differentially expressed genes revealed low to moderate differentiation between coral colonies affected and unaffected by GA and from different collection sites, respectively. Unexpectedly, we detected transcriptional changes with respect to Symbiodinium clade identity not only in gene expression of Symbiodinium, but also of the coral host. This suggests the symbiont influences its host at the transcriptional level. Network analyses revealed several modules of coexpressed genes in the holobiont and its consituents that are associated with clade identity, providing further opportunity to study the genetic architecture of this symbiosis.

IMPACTS OF HABITAT DEGRADATION ON THE TROPHODYNAMICS OF CORAL REEF MESOPREDATORS (Abstract ID: 29003)

Mesopredators play a key ecological role on coral reefs, transferring energy from lower trophic levels to apex predators. Many mesopredator species also have great economic value in subsistence, commercial, and recreational fisheries. Despite their ecological and economic importance, there is a lack of understanding about how this functional group is affected by habitat degradation in coral reef ecosystems. As coral reef habitats are modified by disturbance, the prey fish community available to piscivores becomes altered. We show that mesopredators may be able to switch their diets to adapt to changing prey availability, feeding at a lower trophic level as food chains become shortened. Given this trophic adaptability and the longevity of many predatory fish, altered reef conditions may only affect their population sizes in the long term, yet impacts may

become evident sooner as a modification of the life histories of these species. We ask whether there are sub-lethal costs of habitat decline and changing prey availability, that may not be evident in the short term. Using stable isotopes, morphometrics, lipid analyses, histology and caging experiments, we investigate whether piscivorous coral reef mesopredators experience a loss of condition due to diminished energy reserves, resulting in reduced fecundity, growth and survivorship. Sub-lethal effects such as these can have a significant effect on mesopredator populations in the long term, with implications for reef fisheries, management and conservation.

EXPANSION OF THE CORAL REEF EARLY WARNING SYSTEM (CREWS) NETWORK THROUGHOUT THE CARIBBEAN (Abstract ID: 29525)

The NOAA Coral Reef Early Warning System (CREWS) Network is a growing number of oceanographic and meteorological monitoring stations situated at coral reef areas of critical concern. The near real-time data from these stations are archived at NOAA and form the basis of daily ecological forecasts for coral bleaching, hydrodynamic events, and other marine environmental events of interest to environmental managers, researchers, and the public. The Network began over 15 years ago with NOAA funding as a station in the Bahamas, and grew to include stations in Puerto Rico, St. Croix, Saipan, and with other sources of funding, Jamaica and Little Cayman. However, storms and other realities resulted in the destruction or removal of all of those stations, excluding Little Cayman, which continues operating today as a new buoy design. A new collaboration between NOAA and the Caribbean Community Climate Change Center has resulted in the expansion of the network to include two stations each in Belize, Tobago, and the Dominican Republic, plus one in Barbados. Each of these sites has required collaborations among each country's environmental managers and agencies before agreement as to where to place the stations and as to who would be conducting maintenance. The second phase will include four to six new stations among these likely candidates: Antigua & Barbuda, Aruba, Bonaire, Cuba, Dominica, Grenada, Grenadines, Montserrat, San Andres, St. Kitts & Nevis, and St. Lucia & St. Vincent. http://www.coral.noaa.gov

INCORPORATING THE MANAGEMENT OF CRITICAL ECOLOGICAL PROCESSES FROM SEAGRASS ECOSYSTEMS INTO THE SPATIAL MANAGEMENT IN A HIGHLY IMPACTED COASTAL SYSTEM (Abstract ID: 28515 | Poster ID: 630)

Ecosystems worldwide experience numerous stressors. However, the loss of key processes such as herbivory and predation can be particularly detrimental to overall functioning of an ecosystem. We examined the removal of algae by herbivory within seagrass beds, a key process in structuring these communities. The study aimed to determine the relative influence of herbivore abundance, the spatial arrangement of habitats, physico-chemical water quality variables and marine reserves on herbivory rates in seagrass beds. Herbivory rates were higher in seagrass beds that were suitable for the commercially fished rabbit fish Siganus fuscescens, with the abundance of this species being highly correlated with high levels of herbivory. A species-distribution model to determine areas of high importance for this species, and thus herbivory, suggested that temperature, salinity and seagrass bed size were all positively correlated with the abundance of this species. Our results highlight the importance of understanding herbivory in the management of highly impacted ecosystems, emphasizing how fragmented seagrass beds and poor water quality can diminish the significance of herbivory that occurs within seagrass ecosystems. Fragmentation and poor water quality not only drive decreases in key processes in seagrass, with similar issues facing inshore coral reefs. An ecosystem wide approach is needed to reduce the impact of increased sedimentation on both seagrasses and coral reefs in highly impacted coastal systems.

ARE NET CALCIFICATION AND ISLAND VERTICAL ACCRETION RATES OF THE NORTHWESTERN HAWAIIAN ISLANDS KEEPING PACE WITH RISING SEA LEVEL? (Abstract ID: 29850)

The rising atmospheric and hence surface ocean pCO2 is forecasted to alter rates of calcification and dissolution of coral reef ecosystems globally. Much of what is known about marine CO2-carbonic acid system chemistry is based on either analysis of open ocean waters or intensive characterizations of specific reefs on a small spatial scale. However, analysis of coastal ocean reef systems is lacking. In particular, whether the accretion rate of low lying coral atolls and islets can outpace the projected sea level rise is unknown. Four years of carbon system data were analyzed to characterize the net calcification of the reef ecosystem of the Northwestern Hawaiian Islands in the Papahānaumokuākea Marine National Monument (PMNM). Discrete bottle samples (n=1073) were collected via CTD hydrocasts (n=275) to measure alkalinity and pH from nearshore transects along the 1,500-mile archipelago. A consistent and significant mean alkalinity deficit between 3.4 and 32.8 µmol/kg (compared to open ocean waters) was detected up to 7.0-23.4 km from emergent land with a significant latitudinal trend. At French Frigate Shoals, the spatial characteristics of the alkalinity deficit, bathymetry, surface currents (HYCOM), and island density proxies were used to calculate net CaCO3 production and island platform vertical accretion rates. These results provide vital insight into whether these islands will outpace sea level rise and plate subsidence and will determine the viability of this critical nesting and rearing habitat for endangered/threatened monk seal, sea turtle, and seabird species.

KULIA MARINE SCIENCE SCHOLARS CLUB - BUILDING CAPACITY WITHIN OUR LOCAL HIGH SCHOOLS FOR CORAL REEF SCIENCE (Abstract ID: 28976 | Poster ID: 715)

The KULIA Marine Science Scholars program is a unique High School after-school club program that builds capacity at the HS level by engaging and training local students in coral reef science through the school year, then encouraging them to pursue additional training during the summer via our various partners and colleague's summer intensive programs. Funded by a Native Hawaiian Education grant and funds from the Smithsonian Institution, the program links under-served students from local schools to current research efforts at the Hawaii Institute of Marine Biology/University of Hawaii-Manoa. The program will ultimately have our High School level students assisting in long term data collection for a Smithsonian coral reef monitoring site (MarineGEO), as well as having them collaborate with H.S. students from other sites nationally and internationally on projects. It is part of a culturally appropriate, linked system we are building to provide our local students with pathways into science and reef management careers by using the cutting edge tools our researchers are using, including 3-d video imaging, e-DNA, ARMS and biofilms assessments. By creating a program that extends and supports our colleagues' training efforts, we all become more attractive for private and government funding streams.

CORAL BLEACHING IN RAPA NUI: ENSO-RELATED? (Abstract ID: 29956 | Poster ID: 319)

Coral reef ecosystems of isolated islands and high latitudes offer unique opportunities to study effects of seawater temperature anomalies. Rapa Nui (Easter Island) is the southeastern most island and coral reef habitat in the Pacific Ocean, where seawater temperatures normally range between 20 and 25 °C. In this study, we quantify coral bleaching in Rapa Nui coincident with the 2015 El Niño Southern Oscillation (ENSO), when seawater temperatures were 1.0 °C higher than maximum monthly means for the region. We quantify coral cover and bleaching for four sites and two depths (10 and 15 m): Anakena (north), Manavai (west), Motu Nui (southeast), and Vaihu (southeast). The mean percent cover of coral was 77.1% (68.3 – 89.7%) and did not differ significantly by depth or site. *Porites lobata* was dominant at Anakena (77%) and Manavai (83.4%), while *Pocillopora* spp. was dominant at Motu Nui (69.8%) and Vaihu (66%). The mean percent cover by bleached coral was 84.9% (73.1 - 94.6%) and differed significantly among sites but not between depths. Most corals were pale and partially bleached rather than totally bleached. Corals in Rapa Nui bleach near 26.5°C during La Niña and El Niño events. Despite Rapa Nui's sub-tropical location, high wave energy, and extreme isolation and, coral abundance is relatively high. Future research in this region should examine recovery from bleaching and changes in benthic composition.

EXPLORING CORAL-ASSOCIATED BACTERIA OVER AN EXTREME DEPTH GRADIENT: ASSESSING THE PRESENCE OF UBIQUITOUS SYMBIONTS (Abstract ID: 29157)

Bacteria have an important functional contribution to the health, nutrition, and nutrient cycling of coral reefs, yet almost nothing is known about the bacterial and microbial communities of corals in the mesophotic zone. Coral-associated bacteria are responsive to coral host habitat and the high observed variability of coral-bacterial interactions has lead to the hypothesis that there are only a few ubiquitous bacterial symbionts. We assessed bacterial communities from shallow down to lower mesophotic depths (0-80 m), using this steep environmental gradient to test the ubiquity of specific bacteria interactions in corals. Utilizing 16S rRNA amplicon sequencing on the Illumina MiSeq platform, we conducted an exhaustive characterization of the coral bacterial community in three dominant depth-generalist coral species (*Pachyseris speciosa*, *Acropora aculeus* and *Mycedium elephantotus*) from nine reef locations on the Great Barrier Reef and the Coral Sea (n = 312). We identified a range of ubiquitous bacteria along the depth gradient and spatial scales, suggesting the existence of permanent and stable coral-bacteria symbioses across reef environments. Nonetheless, mesophotic corals showed persistent bacterial communities different in richness compared to shallow corals, supporting the argument of habitat partitioning and ecological diversification over depth. The identification of ubiquitous bacteria highlights important candidates for in-depth functional studies regarding their role in the health and survival of scleractinian corals under a wide range of environmental conditions.

CHARACTERISTICS AND DRIVERS OF CORAL-REEF FISHERY LANDINGS IN POHNPEI, FEDERATED STATES OF MICRONESIA (Abstract ID: 28386 | Poster ID: 556)

Island societies are reliant upon sustainable coral-reef fisheries for food and ecosystem services. Pohnpei is typical of many small island nations in that evidence points towards unsustainable harvesting regimes over the last decades. Yet, species-level monitoring of fisheries landings remains rare despite their fundamental need for improving management. Extensive sampling of landings coupled with socioeconomic surveys of commercial fishing activities provided new insights into Pohnpei's reef fisheries. Pohnpei's commercial landings were dominated by only a few species, the use of nighttime spearfishing, and by a small community of fishers. These characteristics suggest a strong, targeted economic reliance currently exists for a few species by a subset of fishers. Further, strong dependence was found between fishing success, and catch composition, upon favorable fishing conditions associated to conditions of low wind/swell and moon illumination. Catch trends also mirrored ecological trends from long-term monitoring efforts, as reef conditions were previously predicted by fish assemblage structure, which was most favorable on the windward side of the island with least fishing access. Several fisheries policies have been developed in Pohnpei in recent years yet, enforcement and compliance remains challenging. Available datasets suggest limited impacts of management to date. Our findings provide an improved foundation for tailored outreach and enforcement actions that would maximize returns given challenging resources limitations.

CORAL REEF FISH POPULATION DYNAMICS: A STUDY CASE OF CONNECTIVITY PATTERNS IN PROTECTED AND UNPROTECTED MARINE AREAS. (Abstract ID: 29500)

Connectivity among marine populations is a key element to metapopulation dynamics and species persistence in fragmented habitats. We explored the influence of connectivity on population and metapopulation growth rates for a fish species, Abudefduf saxatilis, in some protected and unprotected reefs in an upwelling area at the South Caribbean. We assessed the demographic effects of connectivity patterns, empirically parameterized, using stage-based matrix models coupled with connectivity matrices. Quantitative metrics and local population explorations were used to quantify the connectivity value of individual reefs in the metapopulation. We found that population dynamics were highly variable with the upwelling cycle phases. The highest population and metapopulation growth rates occurred when calm and weak upwelling events took place. Local populations at marine protected areas, with highly complex habitat and coral cover, emerged as source populations and were identified as the most valuable reefs within the metapopulation in terms of connectivity. Elasticity analyses suggest that adult survivorship has the greatest influence on population growth at low levels of connectivity, although this influence decreases as levels of connectivity increase. The relative importance of vital rates on the resulting population growth rate also depends on the levels of population connectivity. Our results confirm the importance of spatial and temporal connectivity patterns among networks of protected and unprotected marine areas for the maintenance of coral reef fishes on time.

THE UNLIKELY PERSISTENCE OF RESTORED STAGHORN CORAL (ACROPORA CERVICORNIS) POPULATIONS IN A WARMING WORLD: LESSONS LEARNED FROM A MODELLING APPROACH (Abstract ID: 28802)

Low-tech coral propagation has become critical for the recovery of depleted populations. But little is still known about restored population demographic dynamics in response to recurrent acute disturbances such as massive bleaching and disease outbreaks. Stochastic modeling was used to address on a 2-year old restored population of Staghorn coral (Acropora cervicornis) in Puerto Rico the impact of the 2005 massive coral bleaching and simultaneous white band disease and shutdown reaction outbreak. An initial cohort of 105 colonies of three size stages (<25 cm, 25-100 cm, >100 cm) was out-planted and monitored between 2003 and 2005. Three independent matrices were analyzed based on disease prevalence: 1) low disease (<7%); 2) high disease (36%); 3) massive bleaching + high disease (78%). In the absence of continuous input of new fragments to the restored population, even under low disease prevalence, the population will go into extinction within less than a decade. But adding 1,000 + Nt+1 small colonies each year will improve abundance from 1,000 in t=0 to 35,980 in 25 y, even under recurrent bleaching and disease events. When adding the same amount of medium colonies, abundance increased to 51,382 in 25 y. Elasticity analysis showed that in the absence of major disturbance survival of small colonies is critical. But under disturbance, survival of medium colonies becomes the critical stage. This suggest the importance of maintaining a continuous supply of medium corals to restored populations in order to maintain a dynamic stability under current ocean warming trends.

INCIDENCE OF SCUBA DIVING AND CARRYING CAPACITY OF DIVE SITES AT JARDINES DE LA REINA NATIONAL PARK, CUBA (Abstract ID: 27808 | Poster ID: 567)

Contemplative diving is one of the main tourist attractions in the Jardines de la Reina National Park (PNJR), located off the southern coast of the provinces of Sancti Spiritus, Ciego de Avila and Camagüey. A study was conducted to determine the effect of this activity on the coral reefs of the area, particularly on stony corals. 28 sites were surveyed during a ten-day period and areas with high, medium, low diving intensity and with no diving were compared taking into account the percentage of stony coral cover. 220 line transects were used and 51 divers were observed. In sites with high diving intensity, 36 species of stony corals were identified. The most representative species were S. siderea, A. agaricites, P. astreoides, M. alcicornis and O. faveolata. Of the 51 divers observed, 48 violated diving regulations by making contact with the corals. Suspensions of sediments and to a lesser extent, mechanical damage (breaking of organisms) were also among the negative effects of the activity. Gorganians, followed by stony corals, were the most contacted organisms. The amount of touches per diver was 5,8/minute. Effective carrying capacity in Jardines de la Reina ranged from 15 to 35 divers/site/day. The surveyed sites showed no signs of deterioration in spite of the impact of recreational diving recorded on the said sites. However, monitoring of affected organisms to follow up post-damage evolution and the compliance with the number of divers/site/day suggested in this study is recommended.

THE INFLUENCE OF THERMAL HISTORY ON CORAL BLEACHING RESPONSE DURING HIGH TEMPERATURE STRESS (Abstract ID: 28253)

Thermal history has been identified as a key factor for coral reef resilience. The National Oceanic and Atmospheric Administration's (NOAA) Coral Reef Watch (CRW) has developed a suite of Thermal History products for reef locations based on the 28-year (1985-2012) Pathfinder satellite sea surface temperature (SST) dataset. The spatial resolution is 1/24° (~4 km), enabling reef-scale examination of spatial patterns. Products are described within six themes: 1. Trends (SST rates of change); 2. Climatology (long-term average conditions); 3. SST Variability (warm season & annual); 4. Annual History (maximum SST, anomaly, and accumulated thermal stress, by year); 5. Stress Frequency (number of events for different stress levels); and 6. Onset Timing (expected onset & variability). Images and data layers for this product suite are publicly accessible on the CRW website. These provide managers and reef stakeholders a detailed understanding of spatiotemporal changes in historic exposure to thermal stress and temperature variability. Of more than 60,000 reef pixels globally, 97% have shown positive SST trends with 60% warming significantly. Bleaching-level stress occurrence increased three-fold globally, but varied regionally. Example links between thermal history and observed bleaching will be described to offer insight into how these products can be applied to identify resilient reefs. Such research efforts have myriad applications in marine spatial planning as the current global coral bleaching event creates opportunities to contrast thermal history with bleaching severity.

THE ROLE OF SOMATIC MUTATIONS IN THE ADAPTIVE EVOLUTION OF A SCLERACTINIAN CORAL IN RESPONSE TO ACIDIFICATION STRESS (Abstract ID: 28771)

The capacity of coral reefs to adapt to environmental changes has been a hot topic over the last decades. The speed at which corals adapt might be too slow to keep up with these changes. However, this only considers selection on the genetic variation that is passed from one generation to the next. Here, we investigate the potential role of somatic mutations in the evolution and adaptation of a scleractinian coral under future ocean acidification conditions. A single clone of *Stylophora pistillata* has been maintained in the aquarium system of the Centre Scientifique de Monaco since 1989. Samples were taken from multiple colonies as well as from replicate nubbins subjected to different pCO2 treatments (pH 7.2 and 8.1) for four years. All samples were genotyped using RAD sequencing. Two different restriction enzymes were used so that independent data sets could be obtained for each sample. This approach allows us to identify PCR duplicates and produces long sequencing reads, thus increasing the number and fidelity of identified polymorphisms. With these data we aim to (1) discover SNP markers for the identification of somatic mutations, (2) estimate the frequency at which they accumulate over time, (3) determine how they contribute to genetic variation within and between colonies, and (4) to determine if somatic mutations play a role in the evolutionary adaptation of corals. Results of this study will provide us a better understanding of the adaptive significance of somatic mutations in corals when coping with rapid environmental changes such as ocean acidification.

DRIVERS OF LIONFISH DISTRIBUTION ACROSS BROAD SPATIAL SCALES IN CARIBBEAN CORAL REEFS (Abstract ID: 28889)

Lionfish is recognized as the most damaging invasive species in Caribbean reefs causing ecological and socio-economic impacts. Yet, drivers of its abundance and spatial distribution are under debate, hampering progress towards diminishing its threat to the region's reefs. Here, we explore the broad-scale patterns of lionfish abundance to understand the importance of habitat structural complexity, coastal development, overfishing, marine based pollution, sedimentation and protection status on the fish distribution. Lionfish abundance was estimated using photographic records collected along 2,300-m2 belt transects in eight countries across Caribbean. These results will support matrix models to explore the contribution of extrinsic factors to the overall growth of local. In summary, lionfish distribution was spatially heterogeneous and highly clustered, implying controlling mechanisms acting on their spatial distribution. Results suggest that degradation due to anthropogenic stressors could be facilitating the establishment of this invasive opportunistic species, while marine protection status down regulates the fish abundance. The potential role that environmental scenarios have on interconnected populations is here discussed in terms of management prioritization for resource exploitation. Our results confirm the region-wide and spatially variable distribution of lionfish, highlight the potential role of anthropogenic drivers and MPA on the distribution patterns of this species and provide evidence that local control efforts may be effective for managing lionfish populations.

DRIVERS OF REEF SHARK MOVEMENT: WHAT'S MOST IMPORTANT? (Abstract ID: 28284)

Predator presence has been reported to influence the movement and behaviour patterns of prey species in various ecosystems. The movement of predators is thus key to the behaviour patterns of prey populations and defining their corresponding movements. However, the drivers of movement patterns in predators are much more difficult to define, especially in aquatic environments. Here we explore the movement patterns of reef sharks as a case study in drivers of marine predator movement. Long-term acoustic telemetry data collected from reef sharks (grey reef, blacktip reef, silvertip, tiger and bull sharks) within the Great Barrier Reef over a five year period were examined to determine potential drivers of movement. Telemetry data revealed complex movement patterns of reef sharks that vary by size, sex, species and habitat type. Some of the common drivers for coastal species, such as environmental conditions, appear to be irrelevant to most reef shark movements. This indicates biological drivers are more important in the movement patterns of these individuals. This talk will consider the importance of various drivers of reef shark movements and the implications of these drivers for defining ecosystem dynamics and within the context of conservation management.

LINKING COMPLIANCE AND ECOLOGICAL OUTCOMES IN A MARINE PROTECTED AREAS NETWORK: A CASE STUDY IN THE BIRD'S HEAD SEASCAPE (Abstract ID: 27852)

The general scientific consensus is that establishment of a network of Marine Protected Areas (MPAs) could mitigate coral reef decline and maintain biodiversity and sustain fisheries. The importance of compliance with MPA regulations has been highlighted, but studies on the relationship between ecological performance and enforcement effort in MPA networks remain limited. In the Bird's Head Seascape of the Coral Triangle, which supports highest coral reef and reef fish biodiversity in the world, local community, governments and partners developed a network of Marine Protected Areas (MPAs). In efforts to promote compliance with MPA regulations, enforcement efforts have evolved from 2007 to the present, becoming more structured and better designed. In parallel, large scale ecological monitoring was developed and implemented periodically, focusing on changes in hard coral mortality, cover, and morphology, and fish abundance and size of different trophic groups. Initial results indicate that ecological performance varies among MPAs with stable, increasing and decreasing trends all present. Further analyses investigating the relationship between the enforcement efforts and ecological changes provide insights into promoting compliance in this MPAs Network.

COLD STRESS RESPONSES OF TEMPERATE ZONE CORALS (Abstract ID: 28433)

The distribution of corals in Japan covers a wide range of latitudes, encompassing tropical to temperate zones. However, coral communities in temperate zones contain only a small subset of species. Among the parameters that determine the distribution of corals, temperature plays an important role. Rising temperature has resulted in a poleward shift/expansion of corals' distribution in Japan (Yamano et al., 2011). We tested the resilience to cold stress of three coral species belonging to the genus *Acropora* in incubation experiments. *Acropora pruinosa*, which is the northernmost of the three species, bleached at 13°C, but recovered once the temperature was increased. The two other species, *A. hyacinthus* and *A. solitaryensis*, which have a more southerly range, died rapidly after bleaching at 13°C. The physiological effects of cold bleaching on the corals included decreased rates of photosynthesis, respiration, and calcification, similar to the physiological effects observed with bleaching due to high temperature stress. Contrasting with hot bleaching, no increases in antioxidant enzyme activities were observed, suggesting that reactive oxygen species play a less important role in bleaching under cold stress. These results confirmed the importance of resilience to cold stress in determining the distribution and northern limits of coral species, as cold events causing coral bleaching and high mortality occur regularly in high latitude zones.

FOCUSING ON THE FOUNDATION: EARLY STAGES OF DATA GENERATION AND MANAGEMENT (Abstract ID: 28341)

Data managers are responsible for data management plans, ensuring projects adhere to established policy, and maintaining data portals for data distribution and archiving. However, there is a front end of data management that is just as important and often overlooked, the early stages of data generation. This includes planning, field data collection, data entry, and data assurance processes. We focus on this early stage of the data management lifecycle and highlight the importance of being involved on the frontlines of data management. Today's coral reef ecosystem monitoring programs leverage resources among partners to efficiently implement field surveys. In large jurisdictions these programs may consist of many field personnel from numerous agencies, organizations and institutions. It is increasingly important to understand the impacts to data organization and quality associated with a large team, and it's critically important from a logistical standpoint to ensure the monitoring is implemented according to protocol and delivered according to the data management plan. This person will work with partner managers and scientists in the field and follow the data lifecycle through quality assurance checks, concluding with data delivery to the data steward or other data managers. Lessons learned from simple and complex monitoring programs are addressed along with suggested guidelines for best practices to streamline the data management process.

REDUCING ECOSYSTEM EFFECTS OF COMMERCIAL FISH TRAP FISHING (Abstract ID: 29797)

Fisheries can have unintended effects, particularly in highly integrated coral reef ecosystems. Bottom tending gears can affect benthic habitat characteristics, and the removal of non-target species can disturb ecosystem processes. To examine effects, this multiyear, multifaceted research used observer trips, port samples, and trip tickets to document the species composition and quantities of bycatch by gear from St. Thomas commercial fisheries (U.S. Virgin Islands). High catches of ecologically important species, particularly herbivorous fishes known to assist corals in their competition for space, encouraged further study of ways to reduce bycatch in fish traps. Cooperative research, combining scientists and commercial fishermen, examined vent size, placement, and number per trap. Well-designed escape vents proved an effective means to increase size selection for key target species (e.g., *Epinephelus guttatus* – increased mean catch length by 5 cm TL) and to reduce bycatch and bycatch mortality of herbivorous species (from 20-90%). Expanded use of escape vents throughout the commercial trap fisheries of the USVI is underway with the potential to benefit corals and the integrity of the coral reef ecosystems.

THERMAL STRESS, BLEACHING AND CARBON FATE: A METABOLOMICS APPROACH (Abstract ID: 28031)

Major gaps remain in our understanding of how symbiont metabolic function (mobile product translocation) responds to thermal stress and bleaching, yet this exchange is critical for symbiotic cnidarians. Our study applied stable isotope tracers ($^{13}$C bicarbonate) coupled to gas chromatography-mass spectrometry, to trace the fate of photosynthetically fixed carbon (individual compounds), during thermal stress and bleaching. To this end, we applied a model symbiosis (*Aiptasia-Symbiodinium* ITS 2 type B1) and a common Pacific coral (*Acropora aspera* dominant *Symbiodinium*ITS 2 type C3). Our data uncovered clear metabolic and cellular responses to thermal stress and bleaching in both symbioses, in terms of both the quantity and composition of the labelled free metabolite pool. Primarily, changes associated with alterations to lipid metabolism and non-enzymic antioxidant mechanisms. Most interestingly however, even with advanced thermal stress and bleaching, we observed significant fixation of carbon, biosynthesis of labelled organic products and translocation to the host (primarily as glucose). These data suggest that even during severe episodes of thermal stress and bleaching, remaining *in hospite* symbionts may be metabolically functional, in terms of their continued provision towards host metabolism. These data therefore have implications for our understanding of the cellular and metabolic changes that occur during symbiosis dysfunction during thermal stress and bleaching.

ADAPTATION OF TROLL FISHING EQUIPMENT AND METHODOLOGIES FOR USE IN TOWED UNDERWATER SENSOR PLATFORMS (Abstract ID: 29950)

Towed underwater platform systems such as Teardrop (ICRS 2012) are being used with high-resolution video cameras to map out underwater terrain and monitor coral reefs. The use of cameras in the mapping method requires that these towed underwater platforms be stable as they are being towed and require the ability to control tow depth and offset in order to access areas that need to be surveyed. In this paper we explore the adaptation of commercial troll fishing equipment and methods to create a system that provides a stable underwater platform whose tow path depth and offset can be controlled. The system is composed of a typical troll fishing setup such as a rod, a reel, tow line, appropriate trolling devices and a specially designed "Towpedo" which acts as the towed platform designed to carry the sensor package. The trolling devices utilized in the system are (1) divers designed to control and maintain tow depth and (2) planer boards designed to control the tow path offset from the towing vessel. The Towpedo is designed for stability and houses sensors internally such as a video camera for image mosaicking and mapping. The system as a whole provides advantages over existing towed underwater platform systems in terms of stability, resistance to wave action, tow path depth and offset control, portability, scalability to tow an array of towed platforms from a single towing vessel, allows for operations in shallow waters where tow vessels cannot directly traverse and the towing in deeper waters where existing systems are limited.

PROBLEMS IN CAPTURE FISHERIES IN RAGAY GULF, PHILIPPINES: COST OF INACTION (Abstract ID: 28992 | Poster ID: 575)

The status of fish stocks in Ragay Gulf, Philippines was assessed using catch and effort monitoring, experimental fishing and gear-fisher inventory. Results show catch rates of 8 of 13 gears decreased 48 to 98% between 1995 and 2006. Catch composition shifted from more-valued species to lesser-valued. Six of 8 top species are exploited way below their size at first sexual maturity. The condition of demersal fish stocks decreased 45% during the same period. The problems in capture fisheries in the gulf include high fishing pressure, intense competition for fishing grounds between municipal and commercial fishers, deteriorating habitat quality and lack of political will to enforce the law. Projections of catch biomass can increase 3x with a corresponding 4x increase in monetary value if fish were allowed to grow to maturity before they are captured. Schemes to achieve profitable fishing schedules in the area and important strategies such as market denial schemes and self-policing members of fishing cooperatives are explored to improve fishing practices in the area are discussed.

WATER QUALITY AND HEALTH OF CORAL REEFS (Abstract ID: 28013 | Poster ID: 424)

Coral reefs are the "rainforest of the sea" and are economically and ecologically valuable resources (Swart, 2013). Corals have experienced significant decline worldwide likely due to anthropogenic pollution, invasive species, climate change, and abnormal weather phenomenas (Hendee et al., 2001; Santavy, 2011). This study aims to fill in this gap in the literature and estimates the impacts of degraded water quality parameters and warmer climate on coral reef abundance in the Florida Keys National Marine Sanctuary (the Keys). ArcGIS geospatial analysis tools combined witg statistical regressions; were employed to identify the effects of elevated inorganic nutrients, turbidity levels, and temperature on coral abundance. Regression results indicate that enhanced levels of nitrite and nitrate combined significantly reduce total coral coverage in the Keys. Initially, elevated level of silicate enhances the abundance of corals, however excessive levels result in significant decline in coral coverage. Our results also show that the increased turbidity are associated with low coral coverage. Stony corals exhibit more sensitivity to nutrient pollution, however both corals remain sensitive to warmer climate and increased turbidity. These effects are likely more severe in unprotected areas. Regarding policy making related to the Keys Marine Sanctuary, this research suggests that management efforts geared towards efficient water pollution control can significantly enhance coral reef abundance in the Keys.

COUPLED BIOGEOCHEMICAL AND HYDRODYNAMIC MEASUREMENTS OVER A PALAUAN SEAGRASS BED: CAN SEAGRASSES MITIGATE LOCAL ACIDIFICATION STRESS? (Abstract ID: 29001 | Poster ID: 102)

Interest in seagrass beds as a tool to locally mitigate ocean acidification is growing rapidly. Much of the interest in seagrasses is motivated by their root structure, which is able to sequester carbon over interannual and longer timescales. Far less is known about their biogeochemistry over shorter diel timescales, yet we know that diel cycle variation in CO2 chemistry on coral reefs can be substantial. Understanding short-term seagrass biogeochemistry is critical to evaluating if, and how, seagrasses may eventually be utilized to mitigate OA on coral reefs. We present the results of a high-resolution, 24-hour control volume experiment conducted along a 50m x 100m seagrass bed in the Republic of Palau. Our dataset includes diel cycles of hydrodynamic (current profiles and turbulence), biogeochemical (pH, pCO2, TA, DIC, and O2), and environmental (temperature and salinity) parameters. We use these coupled hydrodynamic-biogeochemical measurements to estimate ecosystem metabolism and to better quantify the capacity of seagrass to alleviate local acidification stress through the photosynthetic uptake of CO2. Combining our field observations with box model predictions allows us to gain insight into the mechanisms that control seagrass metabolism and their potential to buffer CO2 for downstream corals.

GLENN ALMANY'S CAREER IN REEF FISH ECOLOGY, CONSERVATION, AND FISHERIES: FISH COMMUNITIES, CONNECTIVITY, AND COMMUNITY-BASED MANAGEMENT (Abstract ID: 28199)

Despite his career being cut tragically short, Glenn Almany was a world leader in the ecology, conservation, and management of coral-reef fishes. Completing his BS at San Francisco State in 1996, he entered Mark Hixon's lab at Oregon State with an NSF predoctoral fellowship. He completed his PhD in 2002, publishing 6 papers in top journals. Glenn's novel field experiments showed that prior residents have strong effects on subsequent colonization of patch reefs. With lab mate Michael Webster, he also explored the intense early post-settlement mortality suffered by reef fishes. Glenn received a Fulbright Postdoctoral Fellowship in 2003 to study at James Cook Univ, where he began work with Geoff Jones and colleagues on larval connectivity. He was instrumental in developing and applying new methods to track larval dispersal in pelagic spawning fishes, publishing a seminal paper in Science in 2007. A second postdoctoral fellowship with the ARC Centre of Excellence for Coral Reef Studies enabled Glenn to apply these methods to determine the fate of larvae from grouper spawning aggregations in PNG, where he worked closely with remote local communities. He received a prestigious ARC Future Fellowship in 2010, and in the space of only 4 years published 20 papers, focusing predominantly on marine reserve design, connectivity and conservation of tropical fisheries resources. This period of his career was some of his most ambitious in scale, leading to substantial engagement in developing regional management programs in support of local fisheries within PNG and the Solomons.

METABOLIC AND GROWTH RESPONSES TO ELEVATED PCO2 AND TEMPERATURE FOR TWO SPECIES OF TROPICAL NON-CALCIFYING MACROALGAE (Abstract ID: 28829)

The effects of increasing sea surface temperature and ocean acidification are predicted to influence macroalgal metabolic and growth responses differentially depending on their inorganic carbon source. Algal metabolic rates may increase under elevated temperatures, however, beyond their thermal tolerance, can have negative effects on their physiology. Elevated CO2 is expected to benefit macroalgae, specifically carbon-limited algae. The combined effects are less known and may positively or negatively affect macroalgae, thereby affecting relative algal abundances and potentially shift community composition. The interactive effects of temperature and OA were tested on *Dictyota bartayresiana* (HCO3- -user) and *Amansia rhodantha* (CO2 -user) in Moorea, French Polynesia. Both species were subjected to 400 or 1000 µatm pCO2 conditions at 25, 27, or 30°C in a short-term mesocosm experiment, measuring photosynthesis, respiration, and growth rates of each species. Growth rates of *A. rhodantha* were relatively higher in comparison to *D. bartayresiana* between temperature treatments. Additionally, photosynthesis and respiration rates differed among species within temperature treatments but not pCO2 treatments, specifically *A. rhodantha* having overall higher metabolic rates at 27°C while *D. bartayresiana* had negligible differences across treatments. These results illustrate the importance of examining how multiple stressors may result in varying responses in macroalgae and how they might differ based on their source of inorganic carbon.

EPIGENETIC MODIFICATION OF AN ANEMONE GENOME THROUGH CYTOSINE METHYLATION REVEALS PLASTICITY IN RESPONSE TO TEMPERATURE STRESS AND SYMBIONT TYPE. (Abstract ID: 28333)

Assessing physiological plasticity of marine invertebrates within the context of global climate change is a growing area of research within the coral reef community. Epigenetic DNA modification through cytosine methylation provides an important mechanism for modifying gene expression patterns in response to environmental cues. Here we utilize a NGS technique to describe changes in methylation patterns within the anemone Exaiptasia pallida under ambient (26oC) and elevated (32oC) temperature conditions and between anemones hosting either B1 or D1 Symbiodinium. Overall, methylation conservation between treatment groups was high, with more than 70% of queried CpG sites showing no significant change in methylation status. The CpG sites that did evidence an average net change in response to both temperature and symbiont type were more prevalent in promoter regions as compared to gene bodies. In response to elevated temperature, 29% of the net change in methylation was attributed to genes associated with Metabolism. For differences between hosts with B1 vs. D1 symbionts, 25% and 22% of net change in methylation was attributed to genes associated with cellular processes and disease (cell recognition), respectively. This work represents a first look at changes in methylation pattern within an anemone in response to both symbiont type and temperature stress. Our results are further discussed within the context of CpG frequency of the underlying genome and the capacity for variability in gene methylation patterns as a potentially important component of physiological plasticity.

ORIGINS OF HAWAIIAN REEF FAUNA (Abstract ID: 29695)

All living inhabitants of the Hawaiian archipelago necessarily originate elsewhere, due to the volcanic history of the island arc. Two prominent hypotheses regarding the origins of Hawaiian marine species maintain that colonists arrive either from the south (via the Line Islands and Johnston Atoll) or from the west (via Japan). Previous research has shown that Hawaiian endemic limpets (genus Cellana) arrived from Japan 3 - 7 million years ago (Ma; Bird et al. 2011 Mol. Ecol. 20:2128 – 2141). Orange-band surgeonfish colonized from the Central Pacific about 0.5 Ma (Gaither et al. 2015 Mol. Ecol. 24:1543-1557), and butterflyfishes may have colonized from both the West Pacific and South Pacific (Craig et al. 2010; J. Biogeogr. 37:2125 – 2136). Hodge et al. (2014 J. Biogeogr. 41: 2115-2127) resolved two waves of marine colonization into Hawaii at 0 - 3 Ma and 8 – 12 Ma. Finally, Andrews et al. (2014; PLoS One 9: e91665) report evidence for a colonization pathway from the south (Johnston Atoll) to the middle of the archipelago in the protected Papahanaumokuakea Marine National Monument (PMNM). Here, we synthesize available data, and introduce a new data set based on three endemic Hawaiian blennies (Blenniidae) compared to widespread sister species, in order to further elucidate the ages and origins of Hawaiian reef fauna. One emerging conclusion is that a dispersal corridor between Johnston Atoll and the PMNM may constitute an important

entry point for colonization into Hawaii, which provides insight into factors that promote and maintain endemic reef biodiversity.

UNDERSTANDING THE MAINTENANCE OF SPECIES BOUNDARIES BY EXAMINING HYBRIDISIATION IN CORAL REEF FISHES (Abstract ID: 28592 | Poster ID: 35)

Coral reef fishes comprise the world's most diverse vertebrate communities. Determining how so many coexisting species maintain reproductive isolation is fundamental to understanding the evolution and maintenance of biodiversity on coral reefs. Suture zones, where multiple species-pairs hybridise at biogeographic borders, provide the natural laboratories for studying the maintenance of species boundaries. Comparisons between coexisting species that hybridise and those that do not, provide unique insights into the barriers to reproductive isolation. In this study, we examine the pre-zygotic processes that lead to the breakdown in assortative mating of coral reef fishes. We first use a literature review and field studies to identify locations where hybridisation is common in coral reef fishes. These hybrid hotspots were concentrated at biogeographic borders and represent suture zones: southern Japan; Hawaii-Marshall Islands; Cocos-Christmas-Indonesia; and Socotra-Somalia. At these suture zones we conducted detailed field surveys of abundance, distribution, habitat use, and combined with behavioural observations and dietary analysis. We found that a lack of conspecific partners (low abundance), niche overlap, cohabitation, acceptance and formation of heterospecific social groups, and deliberate mating between species are important promoters of hybridisation. We conclude that mate choice is likely to be the most critical pre-zygotic process and determining how reef fishes choose mates is central to understanding the maintenance of reproductive isolation.

SEEING THE REEF FOR THE CORALS: A QUANTITATIVE CASE FOR REMOTE SENSING (Abstract ID: 28749)

Coral reefs provide very valuable ecosystem goods and services, but they are severely threatened. An estimated 33-50% of reefs worldwide have already been severely degraded, and the rest are threatened with destruction by mid-century. Despite the severity of the problem, state of the art coral reef assessment remains firmly diver-centric. For a concept study exercise, I downloaded all publicly available data for three well-surveyed coral reef regions: the Great Barrier Reef, Hawaii, and Florida/Puerto Rico/U.S. Virgin Islands. Data were compiled to geolocated values of coral cover, then binned to 1×1 km grid cells to approximate the reef ecosystem scale. Observations were very sparse, both within reefs and across regions. The binned data do not exhibit any trends with large-scale physical parameters (PAR, thermal history, wave history) except for possibly a negative relationship with aragonite saturation state. Coral cover does appear to increase with coral species richness, but also appears to increase with increasing human threats, except overfishing. Overall, the observed patterns contradict the prevailing understanding of how reefs relate to their environment. In truth, because they are so sparse, the available benthic cover data are not actually representative of the ecosystem scale. Thus, the comparison with reef-scale biogeophysical forcing parameters is not sound. Remote sensing is the only feasible means to gather uniform, high-density, ecosystem-scale data across vast coral reef regions.

REDUCED DISTURBANCE RISKS TO IMPORTANT SOURCE REEFS IMPART SYSTEMIC RESILIENCE TO THE GREAT BARRIER REEF (Abstract ID: 28585)

Coral populations on Australia's Great Barrier Reef (GBR) suffer the combined impacts of stressors such as cyclones, bleaching, and crown-of-thorns starfish (COTS) outbreaks. However, not all of the GBR reefs will have an equal risk of being affected by these disturbances. Marine reserve networks can help the coral recovery by protecting the adult stocks of source populations important for the recolonization of the disturbed reefs. We explored this natural recovery process by identifying the GBR reefs that simultaneously exhibit high potential for replenishment and low risk of disturbances. By combining connectivity and environmental models, we found that a surprising number of the GBR reefs with high replenishment potential also benefited from a reduced risk of disturbances. While the GBR has lost much of its coral cover in recent decades, the presence of reefs with such desirable characteristics will impart a degree of natural systemic resilience to the GBR. Without this inherent resilience, the state of the GBR reefs may have become far worse. With limited options for direct interventions that help coral recovery, management plans should support this intrinsic recovery potential and work in synergy with connectivity processes to sustain the natural resilience of the GBR. We discuss how uncertainty in the recovery processes can be mitigated by prioritising protection of reefs in response to specific disturbances such as cyclone impacts and COTS outbreaks, as well as those reefs that aid the sustainability of the key tourism assets on the GBR.

RESPONSE OF MELANIN-CONTAINING CELLS IN GUAM PORITID CORALS TO SEDIMENTATION STRESS (Abstract ID: 28066)

A dose response experiment was conducted to evaluate tissue and cellular responses of three species of Porites corals to sedimentation stress. Fragments of P. cylindrica, P. rus, and P. lutea were collected from parent colonies in Apra Harbor, Guam; acclimated to the laboratory; and subjected to varying doses (100 to 400 mg cm-2 day-1) of fine (<1.4 mm) and/or coarse sediments (1 to 20 mm) daily for 4 weeks. Subsets of specimens were sacrificed for histology immediately following collection, acclimation, and 2 and 4 weeks of exposure, respectively. In all three species, abundance of melanin-containing cells (MCC) concurrently decreased in the gastrodermis and increased in the epidermis during acclimation, suggesting cell migration. Following 2 weeks of fine sediment exposure ≥100 mg cm-2 day-1, MCC were absent in both tissues of P. lutea and P. rus. MCC in remaining treatments of P. lutea and P. rus and all treatments of P. cylindrica declined at a slower rate, with absence after 4 weeks of exposure. Accumulations of eosinophilic granules were first observed in P. rus following 2 weeks, and in P. cylindrica and P. lutea following 4 weeks of sediment exposure at ≥100 mg cm-2 day-1. These accumulations were sometimes clumped together and similar in shape and size to MCC. Therefore, accumulations of eosinophilic granules may represent granular amoebocytes capable of forming new MCCs. This study suggests threshold levels for sediment exposure and duration for three species of poritid corals and offers insight regarding MCC as a diagnostic tool to evaluate coral stress.

THE GEOGRAPHY OF SPECIATION IN CORAL REEF FISHES: THE RELATIVE IMPORTANCE OF BIOGEOGRAPHICAL BARRIERS IN SEPARATING SISTER-SPECIES (Abstract ID: 28186)

Patterns of biodiversity result from evolutionary processes of speciation, range-size transformation and extinction. The influence of geography on these processes has intrigued biologists for centuries. Here we aimed to understand how geography has influenced biodiversity by examining the relative importance of biogeographical barriers in the divergence of extant coral reef fish species. We focused on sister-species identified from a recent phylogeny of four families (Chaetodontidae, Epinephelidae, Labridae and Pomacanthidae). Biogeographical analyses of IUCN range maps revealed species-level vicariance across six major biogeographical barriers: the Amazon and Orinoco rivers, Isthmus of Panama, Hawaiian Archipelago, Indo-Pacific, and a previously understudied barrier termed the Mid-Indian Ocean Barrier. Remarkably, of all six barriers, the Mid-Indian Ocean Barrier showed the strongest vicariant signal. The strength and ongoing influence of the Mid-Indian Ocean Barrier appears to be driven by river outputs and turbidity currents. Interestingly, the majority of sister-species were non-allopatric; their overlap was concentrated in the Central Indo-Pacific, concordant with the hotspot of reef fish diversity. Vicariance and overlap in the Central Indo-Pacific highlight its importance as an area of evolutionary dynamism, where the separation of Indian and Pacific Ocean species, and their subsequent range expansion, has led to increased species overlap and higher regional biodiversity.

NEW EVIDENCE OF CORAL RECOVERY IN EASTERN PANTHALASSA AFTER THE END-TRIASSIC MASS EXTINCTION (Abstract ID: 29717 | Poster ID: 230)

During the Triassic period corals and reefs reached maximum diversity with the development of extensive carbonate platforms. The end-Triassic breakup of Pangea resulted in rift volcanism leading to prodigious releases of volcanic gases. Ocean acidification and other global perturbations caused reefs to collapse along with the extinction of most corals and marine biotas. After the end-Triassic mass extinction it took almost 25 million years for corals and reefs to recover to their former diversity and biotic structure. Early Jurassic corals are thus rare. Corals of the Hettangian to Sinemurian contain

Triassic holdover species and by the Pliensbachian include many new species. The Toarcian adaptive radiation was a time of major turnover, with evolution of complex coralla and the loss of most Triassic taxa. Corals from the earliest stages of the Jurassic are extremely rare in North America. Here we illustrate previously undescribed corals from Alaska representing the earliest Jurassic appearances in North America. The Hettangian to Sinemurian corals occur as new species of simple, solitary forms belonging exclusively to the family Stylophyllidae. These corals provide new data on Triassic holdover taxa surviving the extinction in island-arc refugia or an earlier Hispanic corridor migration from the Tethys to the Panthalassa Ocean. These Early Jurassic corals allow an opportunity to assess paleoecology, paleobiogeography and biotic recovery during the critical interval following the mass extinction and may offer insight for the recovery phase of the modern reef crisis.

NEW FRONTIERS: CONSERVATION DRONES IN THE MARINE ENVIRONMENT (Abstract ID: 28999)

Unmanned aerial vehicles (UAVs or drones) represent a new frontier in environmental research and management. Their use has the potential to revolutionise the field if they prove capable of improving data quality or the ease with which data are collected beyond traditional methods. We apply conservation drones to a variety of marine environments, particularly for monitoring purposes, in tropical to polar systems. Our results indicate that the use of this technology can increase monitoring precision, provide access to hard-to-reach sites and be more cost effective than traditional techniques. While careful consideration will be required to ensure coherence of UAV-derived data with historic data-sets, this technology has the potential to improve the speed and quality of evidence based decision making.

RISK AND RESLIENCE: COP21, CORAL REEFS AND THE NEXT FEW DECADES (Abstract ID: 29345)

Ocean warming and acidification represent the greatest long-term threats to coral reef ecosystems through their influence on the risk and resilience of ecosystem components and processes. Scientific consensus like that of the IPCC (2014) have concluded that coral-dominated ecosystems will be rare or non-existent by mid-century if tropical ocean conditions are not stabilized over the next few decades. Fortunately, the international community has listened to the scientific consensus on this and other threats from climate change, resulting in a commitment by over 190 signatories to the UNFCCC (COP21, December 2015) to hold "global average temperature to well below 2°C above preindustrial levels and (pursue) efforts to limit the temperature increase to 1.5°C" (UNFCC COP21). If fully implemented, Earth is likely to have significant coral reef ecosystems by century's end. While a landmark achievement, very significant questions and challenges remain. Firstly, a better understanding of the changing risk environment as global conditions shift toward stability is required if we are to plan effective adaptation responses. Secondly, the details of how non-climate change factors modify the resilience of ecosystem components and processes requires greater scrutiny and detail. In both these cases, manipulative experiments as well as the widely used modelling approaches need to be expanded. Lastly, it is essential that the coral reef scientific community continue to demonstrate and communicate the relative straightforward yet informative example of coral reefs in a changing climate.

A MUSHROOM CORAL TRIANGLE BASED ON SPECIES PRESENCE / ABSENCE DATA (Abstract ID: 28690)

Many Indo-West Pacific (IWP) reef coral species show wide-spread ranges with a maximum overlap in the Indo-Australian Archipelago (IAA). This centre of marine biodiversity is popularly known as the Coral Triangle (CT), which is also a focus area for coral reef conservation. The position of its boundary is still under investigation and has changed during the last decade, depending on progressing insight. Research on mushroom corals (Scleractinia: Fungiidae), using presence / absence data obtained from field surveys since 1983, suggests that some areas outside the CT may be richer in species than previously assumed. Within the CT, also variation in species numbers can be observed, which can be attributed to different levels of habitat heterogeneity. Most mushroom coral species show widespread IWP ranges, a few occur in restricted areas, and others show ranges that resemble a supposed centre of mushroom coral diversity. Species of the latter category predominantly occur on deeper reef slopes, which migrated up and downward with fluctuating sea level stands. From an evolutionary point of view, these are not the youngest species, implying that this diversity centre represents a centre of survival rather than a centre of speciation.

MACROALGAL-HERBIVORE FEEDBACKS AND THE DYNAMICS OF CORAL REEFS (Abstract ID: 29037)

Coral reefs are in global decline with many being overgrown by large fleshy macroalgae. Once established, such regime-shifts are difficult to reverse. Theoretical models have suggested that the stability of these states arises from interactions among elements that form positive feedbacks; reinforcing and maintaining the state. Despite their potential importance there is a current lack of empirical evidence for feedbacks, and hence our understanding of how feedbacks build or erode the resilience of reef systems is limited. Using a combination of natural and experimental macroalgal beds I examined how the structure and composition of macroalgal beds influence patterns of habitat use and foraging of herbivorous coral reef fishes, and the replenishment of herbivorous fish populations. Patterns of habitat use and foraging by herbivorous fishes were influenced by the composition and density of macroalgal stands, with most fishes avoiding areas of dense canopy-forming macroalgae. Comparisons with macroalgal mimics indicate that fishes were responding to the physical structure of the macroalgae. Interestingly, the avoidance these areas extended beyond the boundaries of the macroalgal stands themselves and into adjacent areas that were relatively free of macroalgae. Such edge effects are likely result in a feedback that promotes macroalgal expansion on coral reefs. In contrast to patterns of foraging, there was considerable variation in the settlement preferences of herbivorous fishes, with some species settling almost exclusively to areas of dense canopy-forming macroalgae.

SELF-RECRUITMENT IN THE RAPIDLY SPREADING INVASIVE LIONFISH *PTEROIS VOLITANS*: IMPLICATIONS FOR POPULATION CONTROL (Abstract ID: 28364)

Since its introduction in the Atlantic, the Pacific Red Lionfish has spread rapidly, colonizing most reefs in the Caribbean in a matter of 5 years. Eradication is impossible; therefore population control has become the focus of management efforts. Population models have been used to estimate the amount of removal required to effectively control lionfish populations and prevent recolonization, however, these models assume completely closed populations in which local adults produce all the recruits to the local population. Understanding the degree of local recruitment is therefore critical to better estimate removal effort for lionfish control. Using genetic parentage analysis we estimate the self-recruitment rate and track local dispersal of lionfish within a reef system in Belize. Self-recruitment estimates ranged from 0.5% to 2.7%; individuals that dispersed within the local reef system moved on average 4 $\pm$ 3 km from their putative parents, recruiting into nursery habitats. We modified an existing lionfish population model to investigate the effect of low self-recruitment rates on population growth and recolonization under various adult removal scenarios (single or monthly removals). The model predicts rapid recovery of lionfish populations after adult removals except when self-recruitment is extremely high. Model results indicate that effective control of lionfish populations will require frequent removals (monthly) at relatively high rates of removal (20 – 45% of the population) if the worst effects of this invasive predator are to be staved off.

SPATIAL HETEROGENEITY IN RATES OF REASSEMBLY OF CORAL COMMUNITIES FOLLOWING LANDSCAPE-SCALE DISTURBANCES (Abstract ID: 27930)

A variety of perturbations including cyclones, bleaching, and coral predator outbreaks can result in sudden landscape-scale loss of coral and dramatically affect community structure and function. The most commonly used metric to gauge subsequent recovery is the degree to which the reef regains coral cover. However, this metric does not reveal whether the reef community reassembles to its previous composition, or the mechanisms that influence the rate of reassembly. We explored these issues for six sites on the fore reef around Moorea, French Polynesia. Between 2008 and 2010, the reefs were impacted by an outbreak of Crown-of-Thorns Seastars and a cyclone, which together resulted in almost complete loss of coral. Five years later, the rate of re-establishment of

coral cover differed greatly around the island, and contrary to expectation, coral cover is returning most rapidly at sites where the least amount of live coral remained after the disturbances. Although the sites differ in the pace of recovery, all show evidence of reassembly to their pre-disturbance structure in terms of relative abundance of coral genera and of the main functional groups of benthic space holders. The primary driver of spatial variation in rates of recovery was coral recruitment, while subsequent growth and survivorship were of lesser importance in shaping the spatial pattern. Our findings suggest that not all sites are likely to fully recover given the observed heterogeneity in rates of reassembly and the re-occurrence probability of major disturbance events to the fore reef of Moorea.

CONSIDERING MULTIPLE FACTORS IN ASSESSING THE EFFECTIVENESS OF A LARGE-SCALE MARINE PROTECTED AREA FOR CONSERVING TARGETED FISH COMMUNITIES (Abstract ID: 29216)

The Ningaloo Marine Park is situated on the mid-west coast of Australia and incorporates approximately 300km of tropical/sub-tropical fringing reef system. Originally gazetted in 1987, the park is a popular recreational location that has received steadily increasing visitation over the past two decades. Recreational fishing is one of the most common user activities, with spatial zoning and bag limits being the primary management strategies for the conservation of fish communities. However, despite the relatively large spatial coverage of no-take areas (NTA's; ~34% of the total area) and the length of time in which they have been in place (9-29 years), meta-analysis of surveys conducted over the past 29 years indicates that there has been no change in the effect size of NTA's on highly targeted fish communities through time. While the vast majority of surveys indicate higher target species abundance within NTA's, data collected at high use areas provides evidence for steady declines in the abundance of the primarily targeted fish group (Lethrinidae) both inside and outside of these protected areas. Here we investigate the potential causes of these patterns including the influence of fishing intensity, non-compliance, benthic habitat, reef zone, zoning design and recruitment supply. We scrutinise evidence to support each of these factors and conclude that it is a combination of many of the aforementioned aspects influencing the abundance of target fish groups. Our results highlight the complex nature of drivers of marine populations and the need to consider multiple factors when assessing the efficacy of conservation and marine protected area management strategies.

EMERGENT CLIMATE CHANGE REFUGIA FROM IMPERFECT CONNECTED REFUGES (Abstract ID: 28747)

As coral reef habitats fragment due to climate change and coastal development, resilient populations and their connectivity become critical for metapopulation persistence. Consequently, there has been an increased scientific focus on coral reef refuges – both natural environments removed from stress, and protected or curated environments such as marine protected areas (MPAs). Although there has been considerable research into the effects of MPAs on local persistence, our understanding of how metapopulation persistence – the ability of an interconnected network of populations to avoid extinction – emerges from the interactions of perturbed, natural refuge and protected environments is still poor. We developed a novel patch occupancy model to evaluate the effects of differential habitat resilience on metapopulation persistence. Habitats were assigned vulnerabilities from a range of beta distributions, which more closely reflects reality. A key finding suggests that refuges need not be invulnerable to perturbation to support metapopulation resilience, so long as habitats remain sufficiently connected. Resilience and connectivity can interact to produce effective refugia from perturbed environments. We thus propose that metapopulation refugia is rarely composed of a few isolated resistant populations, but is instead an emergent property of connected populations with diverse characteristics.

RE-OPENING HIGH ENERGY WINDOW: CORAL REEF RESPONSE TO SEA-LEVEL RISE AND TROPICAL CYCLONE AT END OF 21ST CENTURY (Abstract ID: 28945 | Poster ID: 402)

Past coral reefs were affected by high wave energy until the late Holocene, where reef growth reached present sea-levels. The present-day coastal areas are generally protected from storm waves because the reef crests serves as a natural breakwater. However, the effect of natural breakwater will decrease if coral cover and its species diversity declines and vertical reef growths stop, because of global and local stresses. Moreover, sea-level rise and intensified tropical cyclones will cause a decrease in the ability of reef to reduce wave energy. In this study, we analyze the effect of natural breakwater on Melekeok reef in Palau at the present and at the end of the 21st century with projected sea-level rise and tropical cyclones. On the present-day reef, wave simulation using the CADMAS-SURF reveals that the reef crest reduces wave height by 96.3 % (incident significant wave height (SWH) is 7 m and significant wave period (SWP) is 12 s). Moreover, this study indicates that the reef crest dissipated 71.1–78.4 % of the incident SWH (8–10 m) under a global sea-level rise and an effect of intensified tropical cyclones at the end of 21st century. Furthermore, the SWH at the coastline is estimated to be 1.2 m (incident SWH is 7 m and SWP is 12 s): the height is 1.5 times higher than that of present day. The above findings imply that the effects of sea-level rise and tropical cyclones will probably cause re-opening of high energy window on the reef. Consequently, it will lead to greater economic and social loss associated with coastal erosion and flooding.

USING SOCMON TO ADDRESS SOCIO-ECOLOGICAL MANAGEMENT IN THE GULF OF MANNAR (GOM) AND PALKBAY: MARINE ECOSYSTEMS SHARED BY INDIA AND SRILANKA (Abstract ID: 27986)

Coastal communities often rely on goods and services provided by coral reefs and related resources for their livelihood and nutritional needs. At the same time these resources get degraded by over-extraction and harmful extraction techniques. An Ecosystem Approach to resource management can promote sustainable use of marine goods and services for sustaining livelihoods. In this paper we talk about two Marine areas the Gulf of Mannar and Palkbay - where the sea provides for 1,16,747 fisherman families, living in 304 fishing villages along the gulf of Mannar coast in Srilanka and Tamilnadu, India. The paper draws on socioeconomic assessments and monitoring carried out at selected sites in Tamilnadu and Srilanka in 2015. Which in turn provided a holistic understanding of the linkages between the ecological health of the fisheries and associated ecosystems and the people who depend on them. Data has been collected using selected tools from the SocMon SA guidelines. The tools used include a combination of participatory appraisal methods, interviews and surveys of 450 households and 850 individuals to understand the perception of people as well as their ecological and traditional knowledge. It also compares the attitudes of artisanal and trawler fishers towards conservation and management. The paper addresses transboundary usage issues, social resilience and concludes, that to improve compliance both countries, follow the same management plan, species protection and consider co-management or support artisanal fishers to set up LMMA's within their customary fishing areas.

REVERSING IMPACTS OF DYNAMITE FISHING WITH SOFT CORAL ARTIFICIAL REEFS (Abstract ID: 30147 | Poster ID: 299)

The reef slopes surrounding Pom Pom Island, Malaysia are covered in loose rubble due to extensive dynamite fishing. Stabilizing reef slopes creates available substrate for stony coral colonization, an important step in restoring reef structure and rebuilding a healthy community. Current research covers usage of stony coral artificial reefs for rubble stabilization, but there has been little work on using soft corals for the same purpose as Octocorals are not documented reef builders. We constructed artificial reefs at three sites on Pom Pom in July 2015 using nets with 15x15 cm cells. Each site has two controls and two replicates of each treatment: netting planted with soft coral attached to rubble and netting planted with only rubble. Each quadrat planted with soft coral has approximately 150 experimental soft coral colonies, for a total of 900 replicates. Along the top and bottom of each net and the control quadrats, painted and numbered rubble pieces, called "drop rubble fragments," were placed at 10-cm intervals. Before placement, all drop rubble fragments were weighed, measured, and evaluated for degree of branching. Drop rubble fragment movement was analyzed using ANOVA. In addition

to measuring vertical movement of these fragments over time, we measured soft coral survival and growth using ImageJ. We hypothesized that artificial reefs planted with soft coral attached to rubble would show less rubble movement than artificial reefs planted with only rubble. Furthermore, we predicted that soft coral growth would be inversely correlated with rubble movement over time.

SYNERGISTIC EFFECTS OF RE-ZONING AND FISHERIES RESTRUCTURE ON CORAL TROUT ABUNDANCE AND CATCH DYNAMICS (Abstract ID: 28509)

Marine no-take reserves, where fishing and other extractive activities are prohibited, are well-known for their conservation benefits, yet their impacts on fisheries remain contentious. Typically, reserves are established alongside other management interventions (including direct changes in the management of local fisheries), making the causal attribution of post-intervention changes to fisheries and fished populations problematic. Typically, such changes are assumed to be due mainly to the implementation of reserves. Here, we explicitly partition the response of catch and population biomass changes of coral trout between reserves and coincident management interventions associated with the 2004 re-zoning of Australia's Great Barrier Reef Marine Park (GBRMP). First, we show that a metapopulation model successfully predicts the response of catch, catch rate, and population biomass to the rezoning and fisheries restructure. Then, we use a sensitivity analysis to show that the reduction in fishing effort that coincided with the rezoning substantially enhanced the conservation benefits of the reserve network, and successfully socialised the fishery cost of the rezoning. Specifically, we show that the approach adopted in the GBRMP produced greater biomass, catch, and catch rate than would have occurred if the rezoning had occurred alone. Our findings indicate that it was the use of effort controls alongside the rezoning that prevented individual fishers from experiencing decreases in catch rate, which are typically associated with reserve establishment.

EXPLORING TRADE-OFFS, LIKELIHOOD OF IMPLEMENTATION AND EQUITABILITY IN TRANSBOUNDARY MARINE RESERVE NETWORKS IN THE PHILIPPINES (Abstract ID: 28293)

Scholars and development groups have created guidelines for optimal designs of marine reserve networks that could achieve multiple objectives. However, as in the case of individual marine reserves, effectively implementing and enforcing these network designs depend on social, economic and political factors. There is increasing recognition that the spatial fit of governance, ecosystems, and ecological processes is also a key factor to consider when designing and implementing reserve networks. Configurations of marine reserves within a network will vary depending on the spatial extent of governance units. Hence, institutional arrangements that can accommodate transboundary arrangements for reserves will be required for reserve networks that span multiple governance units. These arrangements will also require mechanisms that can reallocate costs and benefits of implementing marine reserve network designs equitably across governance units. In the Philippines, alliances of local governments are advocated to scale up to form marine reserve networks. These alliances usually have 2-3 local government members, some including all coastal local governments within provinces. We explore how varying governance arrangements affect network design configurations for different objectives, and discuss the trade-offs between achievement of objectives and likelihood of their functionality for each scale. Some mechanisms are proposed that could ensure that the costs and benefits of networks are equitably distributed across governance units.

MACROSCOPIC AND MOLECULAR ASPECTS OF REGENERATION IN THE CARIBBEAN STAR CORAL, MONTASTRAEA CAVERNOSA (Abstract ID: 28787 | Poster ID: 34)

Absolute coral cover in the Caribbean has decreased more than 70% since the 1970s. Given this extreme decline it is critical to determine the factors that most strongly affect coral regeneration in this region as well as the molecules that are active during the regenerative process. Transects in marine regions of interest in the coastal waters of Grenada and Carriacou were photographed weekly during fall 2014. Images were captured every 0.5 m along 0.5 m x 30 m long belt transects near targeted coral heads both inside and outside marine protected areas. Twelve mm diameter x 2 mm deep circular lesions were made on 124 healthy M. cavernosa colonies at 10-12 m depths. Water samples were collected weekly for organic nutrient component analysis. Analysis of benthic diversity as a proxy for ecosystem heath, organic nutrient levels, and the presence of a marine protected area were examined for their potential impact on M. cavernosa tissue regeneration rates. Using these predictors, separate mathematical models for gross tissue regeneration were developed for Grenada and Carriacou. During fall 2015, identical circular lesions were made on 30 healthy M. cavernosa colonies at 10-12 m depths at sites in Carriacou selected from the previous year. Lesions were re-sampled bi-weekly during the regeneration process to collect tissues for proteomic analysis. Differential expression of proteins associated with regeneration was assessed in regenerating and non-regenerating tissues using mass spectrometry.

A NEW CLASSIFICATION SYSTEM FOR MARINE PROTECTED AREAS (Abstract ID: 30150)

Marine protected areas (MPAs) are now a global conservation and management tool. MPAs are used to enhance the resilience of linked social-ecological systems with the aim of conserving biodiversity and providing ecosystem services for sustainable use. However, MPAs implemented worldwide include a large variety of zoning and management schemes from single to multiple-zoning and from no-take to multiple-use areas. The current IUCN categorization of MPAs is based on management objectives which many times have a significant mismatch to regulations creating a strong uncertainty when evaluating global MPAs effectiveness. Here we present a novel global classification system for MPAs based on regulations of uses aimed at replacing IUCN categories. We built scores for uses weighted by their impact on biodiversity. Each zone within a MPA was scored and a MPA index integrates the zone scores taking into account their size. Our approach thus classifies MPAs as well as each MPA zone individually. We show that this system unambiguously discriminates the impact of uses whereas IUCN categories do not. Clearly distinguishing between different levels of uses is central to inform MPAs establishment and conservation targets. We anticipate this novel classification system to be rapidly and widely applied by managers, spatial planners, policy-makers and scientists, when designing new MPAs, assessing existing ones and comparing outcomes at a global scale.

FISHING PRESSURE, DESTABILIZATION OF CORAL-REEF FOOD WEBS, AND ECOSYSTEM-BASED MANAGEMENT (Abstract ID: 28035)

Managing fisheries for ecosystem resilience is essential, but practical guidance is limited by food-web complexity. Key processes and mechanisms behind ecosystem overfishing in coral-reef systems were revealed by combining novel food web models with extensive field datasets. The food webs were constructed by grouping species functionally, and not taxonomically, based upon the way they capture, process, and transfer energy. We find that fishing pressure enhanced the strength of direct interactions within food webs, including density dependence, competition, and predation, and stripped away the benefits of indirect, asynchronous interactions that harmonized the structure and function of food webs. Fished systems became more synchronized and productive when approaching maximum sustainable yield (MSY), but larger fluctuations diminished catch stability, and subsidized competitively-superior algal pools that threaten coral-reef habitats. Three fisheries management scenarios were contrasted with respect to economic objectives and ecosystem states. The results agreed with conservative multispecies biomass-based targets from the Caribbean and Indian Oceans, but offered dynamic guidance that was specific to individual guilds. We find that many well-established fisheries policies have foundational flaws when applied to coral reefs, and offer practical guidance to help ecosystem-based management evolve.

SPATIAL DISTRIBUTION AND SURVIVAL OF *AMPHIPRION BICINCTUS*AND THE CONSEQUENCES OF THE DECLINE OF THEIR HOST ANEMONES IN THE GULF OF AQABA, ISRAEL (Abstract ID: 28175)

Anemonefishes' obligatory mutualism with sea anemones dictates their occurrence on coral reefs. We examined whether the spatial location, number and size of the host sea anemones *Heteractis crispa* and *Entacmaea quadricolor* affected the settlement, habitat usage, and survival of the two-band anemonefish, *Amphiprion bicinctus*. In a 300 X 30 m study site off the coast of Israel in the Gulf of Aqaba, we followed the fish and anemone populations for 13 consecutive censuses from October 1996 to August 1997. Settling anemonefish tended to cluster together but displayed significantly dispersed distributions in relation to adult fish and breeding pairs. Adult and juvenile anemonefish associated more with, and exhibited higher survival in, *E. quadricolor*. Settlers most often associated with *H. crispa* with no difference in survival rates between the anemone species. In follow-up censuses from 1997 to 2015, sea anemone and anemonefish numbers declined by over 80%, from 87 *E. quadricolor* and 112 *H. crispa* to 15 and 12, respectively. In 2015, every anemone was occupied, with most *E. quadricolor* inhabited by adults. The anemones left at the study site, on average, hosted more fish per anemone than in the original population. This saturated habitat would potentially hinder anemonefish recruits from settling. These results indicate that if the host anemone population does not recover and provide habitat for settling anemonefish and the anemonefish community, the anemonefish could face local extinction.

THERMAL ADAPTATION AND SELECTIVE BREEDING IN CORALS FROM THE WORLD'S HOTTEST REEFS (Abstract ID: 29311)

Corals in the Persian Gulf (PG) have already experienced warming on par with end-of-century projections for most reefs. We characterized traits that enable PG corals to withstand summers of up to 36°C and evaluated their suitability for heat tolerance selective breeding. Firstly, thermal responses in Platygyra daedalea from the PG were compared with conspecifics from the milder Indian Ocean (IO). At 33 and 36°C, PG corals had ~50% higher survival rates in both symbiotic adults and their non-symbiotic larvae. PG hosts had greater antioxidant capacity and their Symbiodinium had better retention of photosynthetic performance. Superior heat tolerance of PG versus IO corals was maintained after acclimation to a common environment and was underpinned by genetic divergence in host and Symbiodinium. These results show that adaptation of both partners enables PG corals to cope with extreme temperatures. Secondly, we cross-bred P. daedalea from the PG and IO and compared heat tolerance of hybrid versus purebred larvae from each region. Fifty families were bred under controlled conditions and the survival of >10,000 non-symbiotic larvae was tracked at ambient and elevated temperatures. The genetic contribution of PG sperm to IO eggs produced hybrids that, on average, had 37% higher survival at 36°C than purebred IO families. This hybrid gain in heat tolerance matched that of purebred PG crosses, thus demonstrating the success of selective breeding. Finally, we genotyped breeding parents and their offspring to reveal important markers and alleles associated with heat tolerance.

ORIGINS AND DIVERSIFICATION PATTERNS OF SCLERACTINIAN CORAL DIVERSITY (Abstract ID: 28136)

Recent accumulation of molecular data and development of phylogenetic models have provided means to test various evolutionary patterns. In particular for scleractinian corals, the resolution of difficult taxonomic issues aided by robust phylogenetic data has opened up opportunities to investigate the origins of global and regional diversity. Here we compare diversification rates between reef and non-reef corals, and test the evolution of the Coral Triangle center of diversity. First, using time-calibrated evolutionary trees of living coral species in conjunction with a dynamic model of speciation, extinction and trait transitions, we show that reef corals have undergone more rapid diversification than non-reef species, supporting the onshore-offshore diversification trend inferred previously for corals and several other marine taxa. However, the most recent common ancestor of all extant scleractinians is most likely an azooxanthellate species, and transitions from non-reef to reef taxa are not insignificant, highlighting the importance of both ecological groups in the evolution of coral diversity. Second, we use a phylogenetic model of biogeographic evolution to show that origination rates within the Coral Triangle are lower than in surrounding regions, refuting the long-standing center of origin hypothesis. Instead, the high diversity of reef corals in the Coral Triangle is due mainly to range expansions into this region of species that evolved elsewhere, strongly supporting the notion that range shifts play a major role in generating species diversity gradients.

STATUS OF CORAL REEFS IN XISHA ISLANDS(PARACEL ISLANDS) (Abstract ID: 28412)

Xisha Islands is mostly the atoll reefs, located about 300 kilometers southeast of Mainland China's Hainan Island, and between the latitude 15 ° 45'N~17 ° 15'N, longitude 111 ° E ~ 113 ° E. It consists of about 44 islands, and most of these islands are belonging to 8 large atolls. The biodiversity in Xisha Islands is quite abundant. Some 210 species of the reef corals were recorded so far. Overfishing and destructive fishing practices have badly damaged coral communities in Xisha Islands, the valuable edible fish and mollusc species are the target, causing most high-value fish species to become locally extinct. In terms of live percent cover of reef corals, coral reefs of the Xisha Islands was in good condition before 2002, when coral cover was >70%. The live cover of reef corals in Yongxing Island (Woody Island), Xisha Islands were 68% , 51% and <1% in 2002, 2006 and 2009 respectively. Comparing to the historical record of the corals in these area, coral reefs are degrading over the last 20 years in a fast pace. The recent survey founds much variation of restoration processes existed between reefs of the Xisha Islands. The reason for this may be due to the recruitment limiting, which is involving hydrodynamics.

SUSTAINABILITY PERFORMANCE ASSESSMENT FOCUSING ON CORAL REEF PROTECTION BY THE TOURISM INDUSTRY IN THE CORAL TRIANGLE REGION (Abstract ID: 28086 | Poster ID: 595)

Tourism is a major industry in the Coral Triangle region, responsible for economic benefits, but also for negative social and environmental impacts. Considering that in this area, tourism is directly dependent upon healthy coral reef ecosystems, and that the vast majority of the reefs are threatened by local human activities, an approach to evaluate this industry's sustainability performance would be particularly valuable. In this study, we selected 10 key indicators, out of 681, that were directly relevant to the impacts of tourist activities on coral reefs in economic, social, environmental, and wildlife aspects of sustainability. Optimization methods were used to develop efficiency, inefficiency and overall models, in three scenarios, to measure sustainability performance focusing on coral reef protection (SPFCRP) by the tourism industry for all six countries in the Coral Triangle region, from 2008 to 2012. Our results showed that Indonesia (IND) had the best relative SPFCRP among countries in the region, followed in descending order by; Papua New Guinea, Malaysia, Philippines, Timor-Leste (TIL), and Solomon Islands (SOI). IND can be considered as an example in most key indicators for other countries in the Coral Triangle. Conversely, SOI and TIL are the ones with the greatest need for improvement. Future plans to achieve higher SPFCRP by the tourism industry in each country can be made if a comprehensive sensitivity analysis is carried out, provided that more data on each key indicator is available.

THE CARBONATE BUDGET OF ST. CROIX REEFS 35 YEARS LATER (Abstract ID: 29407)

In the early 80s, a carbonate budget was determined on NW St. Croix (USVI). On 2 shore-normal profiles, carbonate production (Pg) was determined along >50 chain transects from shore to a depth of 43m. Bioerosion (BioE) was locally determined; sediment export was measured during a spectrum of conditions. Seven cores documented reef structure and accretionary history. Based on these measurements, BioE was ca. half of Pg, and nearly 50% of the sediment was exported, mostly during storms. A recent study repeated these measurements – 3 decades later. Pg was based on similar chain transects and local coral-growth rates. Fish and urchin data provided estimates of BioE due to grazing. These were combined with infaunal losses to compute total BioE. Over the past 3 decades, coral cover declined by ~31% relative to 1980; Pg and BioE have been reduced by ~21%. Lower Pg approximates only part of the lost accretionary potential over 30 yr. Increased storminess will accelerate sediment export. Even small storms (~5/yr) increase fair-weather export by an order of magnitude; transport during Hurricane Hugo was 5 orders of magnitude greater. Considering coral decline across the world ocean, these results suggest that the accretionary potential of coral reefs is declining rapidly. While the absolute rates are insufficient to drown reefs and reef islands

by 2100, the impacts on reef structure, sediment supply and protection from storm waves are profound. Quantifying the balance between reef building and sea-level rise will require studies that consider more than coral cover. Further, sediment export is likely to have a greater impact than either changing Pg or BioE.

THE ROLE OF INVERTEBRATES IN CORAL REEF MICROBIALIZATION (Abstract ID: 28907 | Poster ID: 298)

Microbialization is the process by which microbes replace macro organisms on a coral reef and metabolize the majority of the bioavailable energy. The microbialization score is a practical metric for evaluating and comparing reef health, as there is a direct relationship between the increase in microbial metabolism and the cumulative human impact on the ecosystem. As of now the microbialization score only accounts for the biomass of fish and microbes in coral reefs, neglecting other organisms. Invertebrates are especially known to significantly contribute to trophic dynamics in coral reefs. To further the accuracy of this metric we measured body dimensions of Gastropods and Crustaceans, and applied biometric regressions that convert the length and width of the respective organism to its wet weight. These measurements were then applied to the Metabolic Theory of Ecology, an equation that predicts the organisms metabolic rate based on its body size and temperature. The average abundance of Gastropods and Crustaceans was then assessed by analyzing benthic time lapse images and used to calculate the invertebrate metabolic rate on the reef. The so generated invertebrate metabolic rate was then added to the already existing microbialization score calculations. This addition of reef invertebrates will enable further accuracy of the microbialization score, and allow for a more comprehensive assessment of the status of a coral reef.

TEACHING STYLES IMPACTS STUDENT ACHIEVEMENT IN A RESEARCH-BASED UNDERGRADUATE SCIENCE COURSE (Abstract ID: 28370 | Poster ID: 705)

Inquiry-based instruction in undergraduate science courses connects students to research and prepares them for careers in science, technology, engineering, and mathematics (STEM). Often, graduate Teaching Assistants (TA) with differing experience and teaching methods are responsible for leading hands-on laboratories. This study determined how differences in TA teaching methods and styles impact student achievement in an ecology research course at the University of Hawai'i, Mānoa. In this course, TAs write their own weekly quizzes and teach material according to their personal teaching style. We observed TA teaching style by measuring the number of open and closed questioning, pacing, use of digital media, question wait time, and other indicators that are shown to affect student learning. We measured differences in student responses on concept surveys and analyzed quizzes with Bloom's Taxonomy. Several characteristics of teaching style, including frequency and type of questioning, had positive associations with student scores and survey responses. Students received the lowest quiz scores and had no improvement in homework scores when asked to define or recall concepts on quizzes while students received higher quiz and homework scores when asked to analyze and synthesize concepts. These results indicate that TA teaching methods may have a stronger impact on student achievement than previously known. This research suggests universities should provide training for TAs to develop teaching methods that promote student achievement and encourage students to pursue careers in STEM.

PALEOTEMPERATURE RECORDS FROM CUBAN CORALS (Abstract ID: 30141)

Understanding the long-term patterns of climate variability in the Caribbean region is critical to predicting such changes in the future. Coupled ocean-atmosphere systems including the North Atlantic Oscillation (NAO) can vary on multi-decadal time scales, remaining in sustained positive or negative phase for decades. Previous paleoclimate records from corals in Bermuda and the Red Sea show that multi-decadal NAO variance increased over the past century compared to the preceding 150 years, suggesting high variability will continue in the near future. However, there are also striking differences during the earliest part of the records, potentially due to past changes in NAO stationarity. Additional coral paleoclimate records are needed from the Caribbean region in order to constrain the spatial patterns of past NAO variability. Coral paleoceanographic reconstructions in the Atlantic basin are still relatively uncommon compared to the Pacific, and different coral species must be investigated to determine if geochemical proxies reliably record climate. Here we report on new results from a 227-year drill core obtained from a Siderastrea siderea coral in the Jardines de la Reina off southern Cuba. Coral Sr/Ca data over the past 35 years show a very clear seasonal cycle and strong correlation to monthly sea surface temperature (SST) from satellite observations. The Sr/Ca-SST relationship is also strong over interannual time scales such as winter-season averages, indicating the great potential for constructing paleoclimate records from corals throughout Cuba.

A BRAVE NEW WORLD FOR CARIBBEAN REEFS (Abstract ID: 27913)

Coral reefs face an uncertain future as they continue to respond to pervasive human pressures, particularly overfishing, pollution and climate change. At a time of global crisis, the need to understand how and why reefs are changing has never been greater. Here we document profound long-term shifts in the species composition of Caribbean corals over the past five decades. At a seascape scale spanning 100s of kilometers, no coral species today is as abundant as it was in the 1970s, and consequently all ecological functions performed by them have diminished. Species abundances are lowest today where herbivores are rare, and macroalgae have largely replaced corals. In contrast, where herbivores are more abundant, novel coral assemblages are reassembling on a new trajectory, despite elevated mortality from disease and climate change. Restoration of herbivory to foster recruitment and survival of corals is key to rebuilding ecosystem structure and function of Caribbean reefs in the face of further global change.

THE 2016 CORAL BLEACHING EVENT IN AUSTRALIA (Abstract ID: 30169)

Summer temperatures in February-April 2016 have caused severe and widespread coral bleaching in Australia. On the east coast, this is the third mass bleaching event for the Great Barrier Reef (GBR) and 93% of reefs have been affected. In the remote northern 1000km sector of the GBR, >80% of reefs have been severely bleached with heavy losses of corals, and only 1% are untouched. Compared to earlier mass bleaching in 1998 and 2002, 2016 is much more severe, with 50-80% coral mortality recorded on northern reefs. The geographic footprint of each of the three events has been different, with each one explained by where the hottest temperatures occurred. Based on aerial and underwater surveys of >1000 reefs in 2016 and 650 reefs in 1998 and 2002, we can now identify reefs that have bleached 0, 1, 2 or 3 times, and examine their attributes. Over time progressively fewer GBR reefs have escaped bleaching, and because of the severity of the most recent event, hundreds of reefs have bleached for the first time in 2016. For the Great Barrier Reef and elsewhere, we have already entered an era when the return time of mass bleaching caused by global warming is shorter than the recovery time of long-lived coral assemblages.

CORAL TRIANGLE INITIATIVE ON CORAL REEFS, FISHERIES, AND FOOD SECURITY MARITIME LOCAL GOVERNMENT NETWORK: TO IMPROVE COASTAL AND MARINE RESOURCE GOVERNANCE (Abstract ID: 28133)

There are more than 1000 of local governments across CTI region. Maritime Mayor position plays important roles as a Political, Government, and Community Leader. There are estimated 120 million people living in coastal communities who are directly dependent on the Coral Triangle's resources for their food and livelihoods and are considered the most direct beneficiaries of Coral Triangle Initiatives on Coral reefs, Fisheries and Food security (CTI-CFF)'s coastal and marine resource management programs. Many constituencies that can be targeted at the local level and development partners and international NGOs have directly engaged and worked with coastal communities across the Coral Triangle through their various community-based programs. The CTI-CFF Regional Secretariat, NCCs and Partners are working to expand the participation of local government leaders in CTI-CFF activities, including through a CTI Local Government Network (LGN). The network aims to improve the capacity of local government leaders in addressing various coastal and marine resource sustainability issues in their localities and to recognize their critical role in achieving the goals of the CTI-CFF. The CTI-CFF Maritime LGN was launched in May 2011 by a group of enthusiastic mayors and local leaders from across the CT Countries to promote cooperation between local governments, how the local government and/ or community is managing coastal and marine areas; how coastal law environment is facilitated and implemented; and how the role of tourism is promoting better management of marine and coastal areas.

CHINESE CORAL REEF MANAGEMENT AND RESEARCH: ENHANCING THE SCIENTIFIC FOUNDATION FOR BEST PRACTICE, ADAPTIVE MANAGEMENT IN THE SOUTH CHINA SEA (Abstract ID: 29947)

Chinese coral reef research and scientific knowledge has increased greatly over the last two decades, but the condition of Chinese coral reefs has declined markedly over the same period- as it has in many areas globally. In particular, there has not been sufficient integration between scientific knowledge and management agencies in assessing and responding to changes in condition and management effectiveness. We are adapting best practices in science-based adaptive management to the Chinese context, to assess the condition, pressures, management approaches and resilience of coral reefs in the Sanya area of south China, in turn to provide recommendations for future management planning. Importantly for the effectiveness of these measures, we are simultaneously adapting processes for engagement between scientific agencies and management agencies, to develop effective practices and approaches for building and sustaining partnerships and capacity in coral reef management in southern China.

HIGH IN SITU SETTLEMENT RATES AND EARLY SURVIVORSHIP OF HARD CORALS IN A CARIBBEAN REEF (Abstract ID: 29322 | Poster ID: 170)

Coral settlement and early survivorship are key ecological processes in reef resilience. In this study, we investigated the temporal and spatial variation of coral settlement and post-settlement survivorship in different reefs with high and low coral cover in Los Roques Archipelago, Venezuela. In situ estimations of settlement and post-settlement survivorship were compared between months of expected gamete release for broadcasters, and months when larval supply was expected mainly from brooders. Terracotta tiles were deployed at reefs with high (>50%) or low (<15%) hard coral cover, and recruit survivorship was evaluated during their first 4 months of age by monthly examination of the tiles. Overall, mean (± SD) settlement rates varied between 30 ± 46 and 236 ± 143 individuals $m^{-2}$ $month^{-1}$. At particular reefs and times, settlement rates were up to 7 times higher than previously reported for the Caribbean region. Settlement rates varied between reefs, but were similar between seasons, suggesting that settlement does not increase significantly after a spawning event. Survivorship of settled corals up to 4 months old varied from 22 to 49% between reefs and was higher at reefs with more coral cover. Our results support the theory that preserving reefs with high coral cover (and maintaining the biological and environmental factors that promote this condition) will result in enhanced settlement and survival of coral in its early life-stages, and therefore is a key factor in the conservation of coral reefs.

CUMULATIVE EFFECTS OF SEDIMENTS, ORGANIC NUTRIENT ENRICHMENT AND HIGH TEMPERATURES COMPROMISE THE EARLY LIFE HISTORY STAGES OF THE CORAL ACROPORA TENUIS (Abstract ID: 28460)

Elevated suspended sediment concentrations, nutrient enrichment, and rising seawater temperatures are each known to have detrimental effects on the early life history stages of hard corals. However, studies of the combined effects of these stressors on these vulnerable early life history stages are lacking. We conducted a series of experiments to test the interactive impacts of suspended sediments (up to five levels), organic nutrient enrichment (three levels), and temperature (up to five levels) on gamete fertilization, embryo development, larval settlement and juvenile survival for the common inshore coral *Acropora tenuis*. Fertilization and settlement were significantly reduced by increased levels of suspended sediments and temperature, while abnormal embryo development increased when elevated temperature and nutrients co-occurred. Juvenile survivorship was reduced by suspended sediments and high temperatures together with nutrients. The observed rates of change, and type of interaction (additive vs synergistic effects) depended on the stressor combinations, and also varied between life stages. Overall, gamete and embryo stages were more affected by poor water quality and temperature stress than juveniles. These results demonstrate that the cumulative exposure to suspended sediments, nutrient enrichment and elevated temperatures over all early life history stages is likely to result in a critical failure of larval supply and recruitment for this species.

CORAL SUCCESSIONS IN THE GREAT BARRIER REEF DURING GLACIAL-INTERGLACIAL CYCLES (Abstract ID: 28444)

Tropical coral reef ecosystems have been affected by drastic sea level and environmental changes during Quaternary glacial-interglacial cycles. However, their responses to these perturbations prior to the Holocene are still poorly understood. Recent offshore drilling of the submerged fossil reefs along the shelf edge of the Great Barrier Reef of Australia (GBR) revealed multiple reef sequences formed during the last glacial period and subsequent deglaciation (IODP Expedition 325). A total of 34 boreholes drilled along four transects at three localities (Hydrographers Passage, Noggin Pass, and Ribbon Reef) were used to resolve for the first time the geometry and composition of the GBR during glacial-deglacial conditions when the continental shelf was exposed and reef growth was restricted to the shelf edge. Here we analyse the evolution of reef coral composition in the GBR during glacial-interglacial cycles by comparing the IODP Exp. 325 data set with coral data from two deep boreholes drilled in 1995 in Ribbon Reef 5 (RR5) and Boulder Reef (BR) in the northern GBR (International Consortium for GBR drilling). The RR5 and BR boreholes record a succession of highstand reef sequences formed during late deglacial-interglacial conditions when the shelf was innundated. Our statistical analysis points to a marked difference in coral composition between glacial-early deglacial fringing reefs and late deglacial-interglacial barrier reefs, and highlights the relationships between reef architecture, shelf morphology and coral composition.

ANCESTRAL GENETIC DIVERSITY ASSOCIATED WITH THE RAPID SPREAD OF STRESS-TOLERANT CORAL SYMBIONTS IN RESPONSE TO HOLOCENE CLIMATE CHANGE (Abstract ID: 28361)

Coral communities in the Persian/Arabian Gulf (PAG) withstand unusually high salinity levels and regular summer temperature maxima of up to ~35 °C that kill conspecifics elsewhere. Due to the recent formation of the PAG and its subsequent shift to a hot climate, these corals have had only <6,000 y to adapt to these extreme conditions and can therefore inform on how coral reefs may respond to global warming. One key to coral survival in the world's warmest reefs are symbioses with a newly discovered alga, *Symbiodinium thermophilum*. Currently, it is unknown whether this symbiont originated elsewhere or emerged from unexpectedly fast evolution catalyzed by the extreme environment. Analyzing genetic diversity of symbiotic algae across >5,000 km of the PAG, the Gulf of Oman, and the Red Sea coastline, we show that *S. thermophilum* is a member of a highly diverse, ancient group of symbionts cryptically distributed outside the PAG. We argue that the adjustment to temperature extremes by PAG corals was facilitated by the positive selection of preadapted symbionts. Our findings suggest that maintaining the largest possible pool of potentially stress-tolerant genotypes by protecting existing biodiversity is crucial to promote rapid adaptation to present-day climate change, not only for coral reefs, but for ecosystems in general.

FISHERIES MANAGEMENT MEDIATES ALGAL CONSUMPTION THRESHOLDS ON CORAL REEFS IN KENYA (Abstract ID: 28631)

Herbivory is a key process that mediates the abundance and production of primary producers in both terrestrial and aquatic ecosystems. On tropical coral reefs, the ability to avoid phase shifts from coral to seaweed dominance relies primarily on the balance between grazing intensity and algal production, but also by other losses of algae through physical disturbances and sloughing. In this study, we examine thresholds of herbivory needed to prevent algal accumulation using experimental substrata and underwater video cameras on Kenyan reefs under different fisheries management regimes. Average production rate of algae across six study sites was 2.1 g algae m-2 day-1. Herbivory at older fisheries closures and heavily fished reefs was high enough to prevent algal accumulation, although attributable to different taxa (i.e. sea urchins or fishes). Non-juvenile parrotfishes (> 20 cm) had a particularly important role at fisheries closures.

Consequently, reefs protected from fishing that lack sea urchins and larger-bodied scraping parrotfishes are likely to have grazing intensities below the threshold required to prevent phase shifts, which is approximately 70% of algal production. Where fishing is allowed, we estimate 303.97 g m-2 of sea urchins is needed to prevent algal accumulation, and where fishing is prohibited, 12.28 and 59.04 g m-2 of scraper and grazer biomass is needed, respectively. These empirical results provide a mechanistic basis to estimate thresholds of grazing necessary for preventing algal accumulation and phase shifts on coral reefs.

DEPTH IS A MORE POTENT STRUCTURING FORCE FOR BRACHYURAN CRAB ASSEMBLAGES THAN LATITUDE, GEOGRAPHY, OR HUMAN IMPACT ACROSS THE HAWAIIAN ARCHIPELAGO (Abstract ID: 29599)

Shallow coral reefs are extensively studied, and although scleractinian corals have been recorded to 165 m, little is known about other mesophotic coral reef ecosystem (MCE) inhabitants. Brachyuran crabs fill many ecological and trophic niches on reefs, making them ideal candidates for evaluating species composition among depths. Here we ask if MCEs host the same communities as the shallower reefs spread across the entire 2400 km Hawaiian Archipelago. We deployed Autonomous Reef Monitoring Structures (ARMS) for two years among shallow sites (12 m) across the latitudinal gradient of the Hawaiian Archipelago to compare directly with a depth gradient (12, 30, 60, and 90 m) south of O'ahu island. Over 650 brachyuran crabs representing 130 morphospecies (21 families) were found. Community composition was not significantly different among shallow sites spread across the archipelago, but was significantly different and highly stratified across the depth gradient. We show that 90 m of depth is a more potent determinant of brachyuran community composition than the latitudinal, geographic (high vs low islands), or anthropogenic impact (human population size) gradient across the archipelago. Deeper reefs host significantly different brachyuran communities than shallow ones in Hawai'i, and only 3 of 130 morphospecies (~4%) occurring across the entire depth range (mesophotic to shallow) sampled. Further research on the cryptic reef-dwelling fauna is needed for identifying areas of unique biodiversity, as well as boundaries between depth- stratified reef ecosystems.

IMPLEMENTATION OF EAFM IN INDONESIA, WILL SUSTAIN THE FISHERY? (Abstract ID: 29197 | Poster ID: 257)

Different perception on ecosystem approach to fisheries management (EAFM) drives misleading of EAFM implementation in Indonesia. EAFM perception using existing paradigm (single sector specific) may not consider the impact of fishing to ecosystem. The paper reviews the central paradigm and proposes the extension of the conventional management to achieve better ecosystem consideration. We also discuss the misusing of EAFM as tools to reduce poverty in fishery which may increase fishing pressure leading to unsustainability. As Indonesian fisheries are dominated by small-scale fisheries (SSF) and about 25 % are reef fisheries, promotes conservation should be carefully integrated to SSF. We conclude with comments on the sustainable development: the balance of ecological well-being and human well-being.

PUT FISHERS' KNOWLEDGE IN THE RECONSTRUCTION OF LONG-TERM REEF FISH CATCH DATA (Abstract ID: 28148)

Reef fisheries in Indonesia play an important role, both culturally and as a reliable source of food security, but remain under-reported in the statistics. Reconstructing catch data based on limited data requires lots of works. Fishers'ecogical Knowledge (FEK) is an important source of information about continuity and change in coastal ecosystems. Fishers' continued experience with coastal environments may provide important evidences and facts which unfortunately being ignored in the coastal science and management. Detailed knowledge of resources, environment and fishing practices were collected from coastal fishers by conducting semi structured interview to explore its potential for constructing trends within fisheries. We, therefore, come with a 3 steps model of reconstruction. First, available limited fisheries data statistics were plotted to obtain a basic model of fisher's growth. Second, time-lined from fishers' knowledge was placed to adjust the model of fishers growth. Reconstruction of fishers time-series data was the result of this step. In the third step, fishers time-series data was employed to produce gear and catch time-series data through extrapolation and interpolation data from fishers. The final result of long-term catch data showed a sudden increased of catch in the year of 2007 and followed by gradual reduction of higher trophic group of reef species such as groupers, emperors and snappers. Historical time series data is important for fisheries sustainability and overcasting fisheries management.

CONNECTIVITY OF THE SKUNK CLOWN FISH IN THE INDIAN OCEAN USING A COMBINATION OF MICROSATELLITE AND MITOCHONDRIAL GENETIC MARKERS (Abstract ID: 27864)

Knowledge of connectivity, the exchange of individuals between populations on coral reefs, is vital for a correct spacing of Marine Protected Areas. Dispersal between reefs is limited to a weeks to months-long pelagic larval stage. This study uses the Skunk Clown Fish (Amphiprion akallopisos) as a model species to assess connectivity. It has a disjunct distribution, occurring in the Western Indian Ocean (WIO) and the Eastern Indian Ocean (EIO), separated by more than 4.500 km of open sea. We use a combination of mitochondrial (MtDNA, Control Region) and 15 highly polymorphic microsatellite loci. Fin tissue of 394 individuals from 22 different sites in the WIO (Kenya, Tanzania, Madagascar, and Mozambique) and the EIO (Indonesia) was analysed. Mitochondrial and nuclear markers concurred in detecting strong population structure between the EIO and the WIO populations (AMOVA: $\Phi$ct = 0.63; Fct= 0.10 respectively, P<0.001 both), and panmixia within the EIO. Within the WIO, however, MtDNA did not reveal population structure ($\Phi$st = 0.006; n.s.), whereas microsatellite data indicated genetic differentiation between Northern Kenyan populations and the rest, and, to a lesser extent, between Madagascar and African mainland populations, identifying two zones of restricted gene flow that may be either recent or incomplete barriers to larval dispersal. The Skunk Clown Fish probably originated in the EIO from where it was able to colonize the whole Indian Ocean through stepwise dispersal but later disappeared at stepping stone locations in the Central Indian Ocean due to competition.

MILLENNIAL-SCALE ECOLOGICAL CHANGE IN CARIBBEAN SPONGE COMMUNITIES (Abstract ID: 28921)

The siliceous spicules of sponges preserve exceptionally well in reef sediments after sponges die. Cores of approximately 3 m were extracted from three reefs in Bocas del Toro to explore changes in spicules assemblages over the last 1–3 thousand years. Spicules were extracted every 5 cm along the cores and identified to morphotype using an in-house reference collection. Of the 12 morphotypes observed monoaxial and ellipsoidal spicules dominated. We observe that moving up-core towards the present day, the relative abundance of ellipsoidal spicules increases. This clear pattern occurs in each of the three reefs which are geographically separate, suggesting a region-wide driver. Ellipsoidal spicules in Bocas are only produced by the demosponges Placospongia intermedia, Geodia gibberosa, and Geodia papyracea that have previously been observed to increase in abundance as reefs degrade. Placospongia and Geodia also represent the principal diet of Hawksbill turtles. The increase in ellipsoidal spicules therefore may have been driven by historical declines in spongivory and/or reef deterioration. A comparative study with reef cores from southern Belize is in process to see if patterns are repeated.

TESTING DISPERSAL LIMITS IN THE SEA (Abstract ID: 30099)

Biogeographic provinces provide a framework for understanding the origin, distribution, and evolution of species. Here we present a range-wide phylogeographic study of one of the few marine species distributed across all tropical Indo-Pacific biogeographic provinces: the pronghorn spiny lobster, *Panulirus penicillatus*. This species has a nine-month pelagic larval stage and the broadest species distribution of any spiny lobster, extending from the Red Sea to the East Pacific. A fragment of the mtDNA cytochrome*c* oxidase subunit I gene (COI) was resolved in 774 individuals from 28 locations, plus 55 sequences (10 locations) from public databases. Portions of COI, 12S and 16S mtDNA regions were resolved for phylogenetic analyses on a subset of individuals. Phylogenetic and population-level analyses reveal that the Red Sea and East Pacific provinces comprise distinct phylogenetic lineages, divergent at $d$ = 1.1% and 1.8%, respectively. Additional phylogeographic subdivisions align with Indo-Pacific biogeographic barriers. Tropical and temperate regions in the Pacific are significantly differentiated, potentially

indicating an ecological partition. We compare these results with other species that have broad distributions across the Indo-Pacific. Our synthesis provides insight into the drivers of population differentiation in species with seemingly limitless dispersal potential.

STATUS AND CHANGING TRENDS OF CORAL REEFS IN LAKSHADWEEP ARCHIPELAGO AFTER 1998 MASS BLEACHING EVENT - LONG TERM MONITORING SURVEY (Abstract ID: 27796)

The status of coral health and trends of the coral reef of Lakshadweep islands were not known before the mass bleaching event of 1998. Moreover, the status of the coral reef of Lakshadweep Islands is restricted to qualitative descriptions. Quantitative description on the percentage cover and abundance of the coral species and the benthic substrate composition status of the Lakshadweep reefs are essential for the assessments of reef health and inevitable to create accurate baselines for long-term monitoring. As a preliminary attempt, the status of the coral reefs in 12 atolls of this Archipelago incorporating generic composition and percentage occurrence of different coral species and other benthic substrate types in different atolls have been documented. This baseline information will be of much importance to assess the effect of the natural and anthropogenic alterations in the coral reef ecosystem of these atolls in a long term perspective.

NUTRIENTS DISTRIBUTION AT TWO DIFFERENT CORAL REEF SITES AROUND SESOKO ISLAND OKINAWA, JAPAN (Abstract ID: 29210 | Poster ID: 441)

Coral reefs are facing various threats of global and local stressors such as ocean acidification, coral bleaching and development of coastal area. Nutrient load is one of the risk factors for deteriorating reef environment. Continuous or frequent monitoring of water quality is needed to predict the future state of coral reefs under the global climate change. Nutrients were monitored every month since 2013 at two different sites around Sesoko Island, Okinawa, Japan. Site A, "Sesoko South", is located off southern part of Sesoko Island where Acropora sp. dominate the coral reef. On the other hand, site B, "Ishikawabaru" is located close to river mouth, fish harbor, resort hotels, aquaculture cage and sewage treatment facility, although coral coverage is 56% in average and more heterotrophic organisms exist. Water samples were taken twice a month at both 2 sites to see the site difference and seasonal variability, and also taken twice a year at broader area around the sites to see the source of the nutrients. There was no seasonality of nutrients at both 2 sites. All the samples showed low level that cannot have an effect on coral growth. Most of the samples were slightly higher at site B than at site A. The sources of nutrients around site B were found to be an aquaculture cage (nitrite), river water (nitrate), sewage facility (ammonium) and land adjacent to costal area (phosphate). The results suggested that the increased nutrients from various sources can influence on the structure of coral reef community at site B and differentiate the structure from site A.

PHYSIOLOGICAL TRADE-OFFS AND THE LIMITS OF ACCLIMATION AND ADAPTATION OF REEF CORALS (Abstract ID: 30037)

Climate change and direct anthropogenic insults are degrading coral reefs globally at an unprecedented rate. Considering the fragility of reef corals to elevated temperatures and ocean acidification, it has been postulated that under current climatic trajectories, these ecosystems could disappear within a few decades. On the other hand, there is evidence indicating that not all coral species or individual phenotypes within a species are equally sensitive to elevated temperatures and ocean acidification, suggesting that there is a large biological substrate to accommodate successful acclimatization and/or adaptation to future climatic scenarios. In this context, it is important to determine if corals would be capable of retain reef functionality under future scenarios of climate change and ocean acidification. Reef functionality is largely dependent on the capacity of corals to deposit calcium carbonate at rates that exceed those of erosion. Here, I explore the roles played by several physiological trade-offs and constrains on the capacity of symbiotic corals to retain high calcification rates during thermal acclimation and/or adaptation. I will present several models illustrating the effects of strong selection of thermally robust holobionts on community calcification rates, as well as the effects of selecting robust symbionts on the calcification rates of individual species. I will discuss how the selection of traits that provide thermal tolerance, and therefore increasing fitness under climate change, may also compromise the ability of corals to form coral reefs.

DENSE FISH SCARS AS AN INDICATOR OF PHYSIOLOGICAL VARIATION AMONG MASSIVE PORITES COLONIES (Abstract ID: 28295 | Poster ID: 213)

Grazing by other organisms is considered as one of the important factor that can directly influence coral growth and survival. For example, grazing scar by coral reef fishes in particular has primary influence such as the growth inhibition due to partial mortality of colony while the scar itself can become a potential settlement place for other species. Although one can recognize there are variations among colonies of massive *Porites* in terms of scar density even between two colonies next to each other, there is limited information on the potential cause of such differences. Therefore, in this study, we aimed to elucidate the cause of such variation by conducting field observations as well as experiments. We first conducted field dive survey at 36 sites within Sekisei Lagoon, Okinawa, Japan. During the survey, 48 colonies were measured for their in-situ maximum quantum yield of symbiotic Zooxanthella (maximum photosynthetic efficiency; *Fv/Fm*). Also, each colony was digitally photographed for the calculation of "grazing scar ratio" utilizing ImageJ software. We hypothesized that "grazing by fish is performed randomly but scar healed faster in these colonies with greater growth rate that resulted in fewer grazing scars in certain colonies". To examine the relationship between growth rates versus scar density in the field condition, we conducted series of experiments testing the growth rates of nubbins from massive *Porites* with various scar conditions. Based on the results, we'll discuss potential implication of various scar densities among massive *Porites*.

FISHERY IMPROVEMENT PROJECT (FIP): AN EFFECTIVE DELIVERY MECHANISM OF EAFM PRINCIPLES TO IMPROVE CORAL REEF FISHERIES MANAGEMENT (Abstract ID: 29316)

This paper draws from the experiences and lessons learned in the implementation of Fishery Improvement Projects (FIP) showing the delivery of EAFM principles to improve fisheries management. FIPs advocates a stepwise process to improve the fisheries performance to a level consistent with a conditional pass against the Marine Stewardship Council (MSC) Standard within a prescribed period. Fishery improvements are identified through a pre-assessment of the fishery against three MSC principles of i) stock status, ii) ecosystem impacts of the fishery and iii) the governance system and provides the basis for actions needed and agreed to by stakeholders via a transparent consultation process. Experiences show that addressing the management and governance issues and adherence to a science based policy and decision making processes are the two major challenges of FIP and EAFM. The strategy to overcome these challenges hinges on coordinating and harnessing the full potential of stakeholders while providing economic incentives that ensure participation. FIP as a framework deliver much more than EAFM: provides the flexibility to incorporate the socio cultural and economic aspirations using existing EAFM tools to achieve livelihood retention and improved fishery value. In addition sustainable financing mechanism that harness the power of markets could be built into the design of an FIP. To date there are few examples of FIP applied to coral reefs that are in various stages of development: the Bahamas lobster fishery and the Koon snapper fishery of Indonesia.

USING CONCEPTUAL ECOSYSTEM MODELING TO SUPPORT ECOSYSTEM-BASED MANAGEMENT IN WEST HAWAI'I (Abstract ID: 29542 | Poster ID: 603)

The west coast of Hawai'i Island faces myriad threats related to environmental stress, population increase, and a rapidly changing climate. These compromise the region's capacity to deliver ecosystem goods and services critical to human wellbeing. The problem's complexity and region's ecological and economic importance prompted NOAA's Pacific Islands Fisheries Science Center to initiate an Integrated Ecosystem Assessment (IEA), a program focused on conducting scientific research to support ecosystem-based management. Initial IEA phases involve comprehensively characterizing system components and identifying monitoring indicators that span the social and ecological system. Workshops with resource managers, scientists, and community members from 2014-2016 developed conceptual ecosystem models (CEMs) guided by the Driver-

Pressure-State-Impact-Response framework. The participatory process engaged a broad base of stakeholders, with special emphasis on gathering and synthesizing place-based knowledge. The resulting CEMs identify natural and anthropogenic stressors affecting different ecological states (e.g., reefs, water body), ecosystem services, and relationships among system components. Participants also weighted relationships and assigned indicators. These are the first CEMs for West Hawai'i and will directly inform how we research and manage the region. CEMs can help clarify the decision context, integrate stakeholder values, and reveal gaps in scientific information needed to support decision-making. They constitute an important phase of the IEA.

POTENTIAL AND BOTTLENECKS OF MONITORING CORAL REEFS FROM SENTINEL 2 IMAGES (Abstract ID: 30056 | Poster ID: 541)

Monitoring coral reef ecosystems over large-scale areas and long-term periods can be successfully achieved if remote sensing images, ground truth data and automatic image processing algorithms are available. The increasing availability of Earth observation images acquired by the Sentinel 2 satellites opens attractive opportunities for coral reef monitoring as it provides freely accessible high resolution images with a complete coverage of the Earth's surface every ten days. This huge amount of data acquired by the same sensor under the same view angle enables accurate detection of real changes of the surveyed ecosystem. This paper presents an exploratory approach to monitor coral reefs from Sentinel 2 imagery. The proposed approach exploits deep convolutional networks for mapping a predefined typology of coral reefs on Sentinel 2 images and exploits temporal imagery for monitoring purposes. The approach is validated on Sentinel 2 images of New Caledonia. Results show the capacity of the proposed approach for mapping purposes and highlight the potential of Sentinel 2 imagery for monitoring.

ENGAGING DIVE TOURISM IN SUSTAINABLE FINANCING AND CORAL REEF DATA COLLECTION FOR BETTER MANAGEMENT OF KARIMUNJAWA NATIONAL PARK, INDONESIA (Abstract ID: 28657)

Indonesian coral reefs cover an area of almost 40,000 km2, scattered over thousands of islands. These geographical conditions, compounded by limited marine scientists and funding for coral reef monitoring, create challenges for understanding and management of Indonesian coral reefs. Widespread development of the diving industry presents an opportunity to address these challenges. This study was conducted in Karimunjawa National Park (KJNP) from 2006 to 2013. In 2006, Diponegoro University - Marine Diving Club (MDC), KJNP authorities and partners established Reef Check EcoExpeditions (RCE). These coral reef monitoring expeditions were conducted annually and a significant percentage of the costs were covered by paying dive voluntourists. RCE generated an average of 2,187 USD/year, funds which were critical for covering Reef Check survey activities in the park. In total, 107 divers were certified as Reef Check monitoring personnel and contributed coral reef monitoring data at five sites within the park. Over the seven years data collection, hard coral live coverage increased from 47% to 54%, and declining snapper and grouper populations were recorded. These declines were driven by increased fishing pressure, in part to support demand for reef fish as a result of increased tourism. The coral reef health data served as the primary data guiding KJNP authority management actions. The KJNP study was the pilot site for Reef Check tourist diver certification system in Indonesia, and it has since inspired a number of universities to adopt the same system.

MID-TO-LATE HOLOCENE SEDIMENT DYNAMICS AND DRIVING MECHANISMS IN A MIXED CARBONATE-SILICICLASTIC LAGOON (BORA BORA, FRENCH POLYNESIA, SOUTH PACIFIC) (Abstract ID: 28146)

A multi-proxy approach applied to sediment cores from the mixed carbonate-siliciclastic lagoon of Bora Bora was used to detect palaeoenvironmental changes and to evaluate controlling mechanisms of sediment dynamics during the mid-to-late Holocene. The increase in coarse-grained and clay-sized sediments, productivity, XRF Ca counts and decrease in XRF Cl counts over the past 5 kyrs seem to indicate event deposition and can be correlated with event deposits in nearby Tahaa lagoon explained by higher cyclone activity. Based on this model, intense rainfall during cyclone landfall would enhance erosion and run-off from the volcanic hinterland and lower lagoonal salinity. Reefal sediment would be transported into the lagoon. However, the Ti/Ca proxy for terrigenous input has decreased steadily during that time period. Also, benthic foraminifera assememblages do not indicate reef-to-lagoon transport of sediment. Alternatively, more permanent southeast trade winds during the mid-to-late Holocene could have favored higher hydrodynamic energy conditions, flushed higher amounts of open ocean water and pelagic organisms into the lagoon, enhanced marine productivity and lowered lagoonal salinity. Our alternative model of long-term lagoonal sediment dynamics includes mid-to-late Holocene sea-level change and lagoonward progradation of sand aprons. The observed lagoonal sedimentation patterns during 4.5-0.5 kyrs BP reflect intensified sediment dynamics and gravity-induced slumping at sand apron/lagoon edges due to oversteepening during ongoing progradation. Additional analyses and age dating are in progress and will help to constrain the interpretation summarized here.

CORAL REEF STATUS AND BLEACHING INTENCITY AT ST. MARTIN ISLAND, BANGLADESH. (Abstract ID: 28275)

St. Martin island and adjacent location is only coral habitat in Bangladesh. Although not much rich more than 70 species have so far been identified under 22 genera. The multidimensional threats prevailing in the island coral ecosystem, more due to recent development and tourism initiative rather than island anthropogenic impact. Current manmade major problems are sedimentation, plastic pollution, anchor damage and coral mining. Global worming intensifying coral bleaching along with the entire world tropical coral habitat. Bleaching has been recorded in 1998, 2008 and in last several years with small scale. At least 5-8 large vessel operates during tourist season Oct-April each year with transportation of several thousand each day make huge plastic disposal in the sea that has no control yet in place. The vessels anchor nearshore that create extreme sedimentation. Large number of plastic items and huge sedimentation recorded in Nov-Dec 2015 coral survey. There is no sewage and toilet systems suitable for coral habitat in the island. Marinelife Alliance, research and conservation NGO is trying to establish locally managed MPA at south and west nearshore area with a span of 1200 acres. Annually underwater cleanup and coral habitat protection by community is underway. There is much need of international support both financial and technical to manage the coral habitat of St. Martin island. International volunteers and students are invited to join in annual survey and threat reduction. At least 90% coral coverage has bleached recorded in last Nov 2015 survey.

IMPLICATIONS OF THE ROLE OF HYBRIDIZATION IN SPECIATION OF THE GENUS *ACROPORA*: FEATURES OF REPRODUCTION OF HYBRIDS IN THE INDO-PACIFIC SPECIES (Abstract ID: 28116)

Hybridization of the Indo-Pacific reef-building corals, particularly the most dominant genus *Acropora*, is assumed to have occurred through multi-specific synchronous spawning events. However, natural $F_1$ hybrids have never been documented in the Indo-Pacific corals and the role of hybridization remains unknown. In this study, we succeeded repeatedly to observe the spawning of two $F_1$ hybrid corals, which were produced experimentally from the two Indo-Pacific species, *A. intermedia* and *A. florida*. One colony ("FLOint") is from the egg of *A. florida* and sperm of *A. intermedia* and the other ("INTflo") is from the reciprocal cross. They spawned at the same timing of the parent species. However, their fecundities were clearly different: high in FLOint, but very low in INTflo. In case of FLOint gametes, backcrossing with parent species was successful, but self-fertilization rate was high (>90%). Selfing is plausible to have advantages when available gametes for fertilization are low: hybridization may be one of good strategy to survive in case of low population density. These data suggest that in the Indo-Pacific *Acropora*, $F_1$ hybrid can reproduce via not fragmentation but self-fertilization: However, hybrids may have a risk for re-fusion into another species in future by backcrossing with parent species, depending on the eggs of which species is from.

THE POTENTIAL FOR SUMATRA EARTHQUAKES AND TSUNAMI RECONSTRUCTION USING *PORITES* CORAL SKELETONS FROM SIMEULUE ISLAND, INDONESIA. (Abstract ID: 28550 | Poster ID: 394)

The great (M 7-9) subduction-zone earthquakes have occurred along Sunda megathrust during recent several hundred years. In Sumatra, Indonesia, two earthquakes occurred on 26th Dec 2004 (M 9.2) and 28th Mar 2005 (M 8.7). These earthquakes triggered giant tsunami, coseismic uplift and subsidence in the rupture area. Here we show the potential for reconstruction of the coseismic events (uplift, subsidence and tsunami) using geochemical analysis and skeletal microstructural observation in Porites coral skeletons collected from Simeulue Island, Indonesia. Simeulue Island was reported that the northwest part uplifted max 145 cm in 2004 and the southeast part uplifted max 165 cm in 2005. Coseismic uplift and subsidence would change the light availability for reef corals, which have the relationship with coral skeletal carbon isotope ratio. The tsunami would also have influenced on habitat of reef building corals, it would caused by high turbidity due to fling up sea bottom muddy sand and terrestrial runoff. We collected coral cores at four sites of Simeulue Island in 2010. Coral annual extension rates in pre-earthquake were significantly higher than that in post-earthquakes. At the northwest coral (uplifted 142 cm in 2004), the variation of skeletal carbon isotope ratios was characterized by large amplitude after the earthquakes. Moreover, one of our coral specimens had a characteristic band so-called green band, which corresponded to the timing of tsunami occurrences. We propose that coral skeletons are the potential proxy for earthquake and tsunami during several hundred years.

DIFFERENCES IN CRYPTIC DIVERSITY AND HOST SPECIFICITY OF COPEPODS ASSOCIATED WITH STONY CORALS IN THE RED SEA (Abstract ID: 29154 | Poster ID: 67)

More than 340 species of Scleractinia-associated copepods (Crustacea) have been described so far, but not from the Red Sea. They usually occur in multiple associations and show a high degree of host specificity. We collected symbiotic copepods from 189 colonies of stony corals at 0.5-40 m depth in the south and the middle of the Saudi coast of the Red Sea. We conducted an analysis of nuclear and mitochondrial markers (ITS & COI) of (i) all morphotypes of copepods associated with 13 species in 9 genera of the family Fungiidae and (ii) copepods of the genus Spaniomolgus (Poecilostomatoida) living in association with Seriatopora hystrix and various morphotypes of Stylophora. The results of tests on DNA taxonomy (e.g. GMYC, PTP, and ABGD) will be presented to detect independently evolving lineages that could be considered as representing different species. Moreover, results of exploratory tests on phylogenetic comparative methods will be presented to highlight the levels of association between species of copepods and host corals.

LINKING MANAGEMENT PERFORMANCE TO POSITIVE ECOLOGICAL OUTCOMES IN THE RAJA AMPAT MARINE PROTECTED AREAS, INDONESIA (Abstract ID: 29730 | Poster ID: 656)

An increasing number of Marine Protected Areas (MPAs) has been established in the last decade in response to threats such as overfishing and habitat destruction. However, in order for MPAs to provide the ecological and social benefits they were designed for, there must be effective management in place. Using quantitative methods, this study investigates whether there were significant changes in fish biomass, fish size and percentage of hard coral cover in six MPAs in Raja Ampat, Indonesia. It further investigates the relationship between management strategies and changes in these three ecological indicators. A temporal analysis was carried out using baseline and repeat monitoring data as well as annual management scores using the World Bank Scorecard methodology. Dampier, Missol and Kawe MPAs had significant positive changes in fish biomass, average fish size and percentage of hard coral cover values. Results from the World Bank Scorecard assessments indicate that management of Raja Ampat's MPAs has overall improved from 2012 to 2014. These results indicate that there has been an effort to better manage the MPAs in the BHS, which may be correlated to increasing values of ecological outcomes. The findings of this study may help MPA managers and decision makers developing better strategies and improving MPA management to effectively achieve conservation objectives.

EXPRESSION PATTERN OF CYTOCHROME P450 AROMATASE GENE DURING SPAWNING PERIOD IN *ACROPORA TENUIS* (Abstract ID: 28524 | Poster ID: 177)

Most scleractinians including *Acropora* species accumulate yolk into their oocytes during spawning moon phase. It is considered that yolk accumulation (vitellogenesis) occurs physiologically under stimulation of hormones and neurotransmitters, although it is not fully understood how vitellogenesis is regulated endogenously. Cytochrome P450 aromatase is known as a rate-limiting enzyme converting androgen to estrogen and plays a role in physiological processes in vitellogenesis of oviparous species. The present study aimed to clone and characterize cytochrome P450 aromatase (*atArom*) cDNA of *Acropora tenuis* in Okinawa, Japan, and evaluate its expression during the spawning season (May through July). The isolated cDNA clustered with aromatase of other invertebrates, suggesting that the aromatase of *A. tenuis* was successfully cloned. Monthly collection of *A. tenuis* around the full moon period revealed that this species releases their gametes in May and June. mRNA abundance of *atArom* in the samples from May through October was measured using quantitative polymerase chain reaction, and was higher during the pre-spawning period than during the post-spawning period. This expression pattern of *atArom* mRNA is in agreement with the histological appearance of oocytes laden with yolk in the polyp. It is concluded that estrogen (perhaps estradiol-17b) is closely related to the final stages of oogenesis in *A. tenuis*.

THE IMPORTANCE OF HABITAT CONNECTIVITY AND PROTECTION ON NURSERY REEF FISHES IN THE PHILIPPINES (Abstract ID: 29280)

Several studies on reef-associated fish species show evidence of ontogenetic habitat shifts among seagrass beds, mangroves, and coral reefs during their life stages (nursery species). In the Caribbean region, the availability of mangrove nursery grounds influenced the community structure and biomass of reef fishes in their adult stage. However, information to demonstrate similar ecological processes underlying ontogenetic habitat shift along the mangrove-reef habitat continuum has only started to accumulate in the Indo-Pacific region. Here, we validate ontogenetic habitat shift by some reef fishes in the Philippines based on their proximity to mangrove habitats and, hence, provide additional data for the Indo-Pacific region. It attempts to verify the hypothesis that high biomass with well-defined size structure may be attributed to a highly connected coral reef and mangrove habitats through ontogeny. Further, the study aims to determine if there is difference in community assemblage and biomass of these nursery species between protected and unprotected reefs to show the benefits of protection in biodiversity conservation with value added information as regards the synergism between protection and habitat connectivity. This study therefore highlights the contribution of this connectivity to the coral reef fish species diversity in the Philippines widely acknowledged as the center of high marine biodiversity in the world. Results of the study are discussed along these lines of ecological framework.

GOOD GOVERNANCE INCREASES CORAL REEF RESILIENCE (Abstract ID: 28699)

Reef corals are declining worldwide due to local stressors and global climate change but the ways these different factors interact to reduce coral abundance remain obscure. We analyzed data from more than 35,000 surveys to document ecological changes on reefs throughout the wider Caribbean from 1970 to 2012, and then compared local differences in the status and trends of coral populations in relation to local differences in fishing pressure, human population density, and thermal stress. Average coral cover declined by half by 1990 with little subsequent decline, while macroalgal cover increased more than three fold in the 1980s and early 1990s and has remained high. These early losses were principally due to outbreaks of disease and overfishing a decade before the first regional episodes of sustained thermal stress and coral bleaching. In contrast, more recent losses of corals following extreme thermal stress varied among locations as a function of fishing pressure, the abundance of macroalgae, and concomitant susceptibility to disease. These differences are strongly related to basic socioeconomic indicators with quality of governance, GDP, and fishing regulations the most important factors. Our results support the hypothesis that local protections can increase reef resilience in the short term pending global action on climate change.

METABOLIC SCALING IN COLONIES: THE INFLUENCE OF INTEGRATION (Abstract ID: 29117)

From single celled bacteria to complex multicelled vertebrates, intraspecific variation in metabolism commonly scales allometrically, but with considerable variation. Here, I investigate if and how scaling relationships in colonies vary with the degree of integration. Clones can live in different states: a loosely associated group, a highly integrated colony, and eventually transition into a fully integrated individual. I hypothesized that highly integrated colonies are more likely to exhibit standard metabolic scaling (allometric, with exponent = 3/4), as is observed in fully integrated individuals. Furthermore, loosely associated groups of clones are more likely to scale isometrically (exponent=1) because the addition of new clones should not affect the metabolism of the other group members. The effect of colonial state on metabolic scaling was tested using ~100 taxa, including Arthropods (24), Bacteria (7), Bryozoans (8), Chordates (9), Cnidarians (37), Plants (4), and Protozoa (5). While colonial state and phyla are poor predictors of the scaling exponent, the scaling exponent generally decreases with integration, from 0.97 +/- 0.08 in loosely associated groups, to 0.90 +/- 0.07 in highly integrated colonies, and to 0.85+/-0.06 in fully integrated individuals. Thus, increases in integration are associated with a shift from isometry to allometry. In theory, an increase in integration indicates a transition in individuality, but integration is difficult to quantify. Thus, metabolic scaling exponents can represent a continuous measure of a transition in individuality.

PHAGE THERAPY FOR DISEASED CORALS? POTENTIAL OF A NOVEL GIANT VIRUS AS ANTIMICROBIAL AGENT AGAINST CORAL PATHOGENS (Abstract ID: 29296 | Poster ID: 164)

Coral reefs are amongst the most biologically diverse and productive ecosystems on Earth and provide economic goods and ecosystem services through fisheries and tourism. The health of these fragile ecosystems is severely threatened by the combined effect of anthropogenic pressure and global climate change. The increased surface water temperature and pollution have been associated with the development of diseases leading to the demise of infected coral reefs. Extensive research is currently dedicated to characterizing the causative agents of the coral disease and, in most of the case, the identified pathogens are bacteria. It is however equally important to investigate procedures to cure and prevent these infectious diseases. Over the past 5 years, the use of phages as biocontrol agents to treat bacterial mediated disease has emerged as a promising tool to inhibit the progression of coral infection but also its transmission to healthy counterparts. To further investigate the usefulness of phage therapy, it is nowadays necessary to describe the biological traits and ecological functioning of phages candidates. In this study, we isolated a novel giant phage that specifically kills a causative agent of coral bleaching, Vibrio coralliilyticus. We will present a genomic and functional analysis of this bacteriophage and discuss the effectiveness of these parasites as therapeutic agents for diseased corals.

MORE SHARKS, LESS FINS: ECOLOGICAL SUCCESSES AND SOCIO-ECONOMIC CHALLENGES OF SPATIAL PROTECTION WITHIN THE WORLD'S BIGGEST SHARK FISHERY (Abstract ID: 29472)

Despite the popularity of spatial closures as a tool to address conservation goals, little is known about the effectiveness of shark-specific closures to protect sharks, or their impacts on fisher behavior. Situated within the Coral Triangle, Indonesia's shark fishery contributes more to the international shark fin trade than any other nation. We assessed shark diversity and abundance in an open access zone (OAZ) and two No-Take Zones (NTZs) of a Marine Protected Area within the recently established shark sanctuary in Raja Ampat, eastern Indonesia, where sharks have high monetary value. Shark abundance was significantly higher in the privately managed NTZs than in the OAZ. Across all management zones, neither zone size, depth nor reef complexity explained variations in shark abundance, suggesting that governance is the main driver of successful shark conservation areas. Interviews with shark fishers showed that while most fishers knew that sharks were protected in their former fishing grounds, few felt that the agencies implementing fishing bans understood their livelihood needs. We found that fishers adapted to the loss of fishing grounds by shifting fishing effort to other locations or diversifying their livelihoods, including illegal petrol transport. While conserving sharks for tourism can be effective, it may inadvertently result in displacing fishing effort to unprotected regions. We propose that where shark fisheries support important livelihoods, effective shark conservation should combine strategic spatial protection with support for livelihood diversification.

MANAGING NATURAL RESOURCES THROUGH VULNERABILITY ANALYSIS: AN APPLIED CASE STUDY INTO RECREATIONAL ACTIVITIES AT CORAL REEFS IN PUERTO RICO (Abstract ID: 29683 | Poster ID: 589)

Coral reef related tourism and recreational activities rank among the most important industries by providing jobs, supporting local economies, increasing visitor knowledge of coral reefs, promoting pro-environmental values and helping to create a conservation ethic. However, research has demonstrated that marine recreational activities like snorkeling and diving can also degrade coral reefs when visitors act inappropriately. Damage to the reef is often the result of inappropriate behaviors of individuals and not the industry. Given the current and expected growth in tourism and marine recreational activities, the problem of recreationally-based damage to coral ecosystems can cause significant damage. In Puerto Rico not enough is known about the type of stress recreationalists place on reefs, what management actions are available, or how effective they will be at mitigating impacts. This presentation aims to share knowledge about these areas by presenting a methodology developed to assess the vulnerability of select coral reefs to recreational activities within La Cordillera Reserve, Puerto Rico.

EFFECTS OF ACUTE AND CHRONIC CHANGES IN SALINITY AND LIGHT ON THE BLEACHING AND RECOVERY OF THE STAGHORN CORAL, ACROPORA MILLEPORA (Abstract ID: 29902 | Poster ID: 360)

In this study, both acute and chronic tests were conducted to determine whether light intensity and salinity triggered bleaching of coral, Acropora millepora. Five treatments of light (0, 1000, 3000, 10000, and 30000 lux) and five treatments of salinity (20, 25, 30, 35 and 40 psu) levels were used. The results of the acute light intensity experiment revealed that color of A. millepora reduced significantly within 8 days under the highest light intensity level (30000 lux) compared to other light intensity levels. Similar to light intensity experiment, A. millepora colonies turned into pale colors, and were bleached in 2 days under the highest salinity level (40 psu). In addition, the corals showed signs of tissue slough-off. The results from the chronic tests showed that under light and salinity conditions, corals tended to have more tolerance than that of in the acute experiments. At the end of the experiments, all experimented corals were brought to the normal condition for a recovery. The results showed that bleached corals under the light experiments were able to recover 100% while experimented corals under the salinity experiments were not able to recover or had lower recovery rates. Moreover, from the molecular genetics analysis, zooxanthellae found in all experimented corals both before and after the experiment trials were clad C1. Therefore, zooxanthellae clad may not play an important role on susceptibility of the corals to the bleaching in this study.

DIVERGENT REEF CARBONATE BUDGET TRAJECTORIES FOLLOWING A MAJOR CLIMATIC DISTURBANCE EVENT (Abstract ID: 28538 | Poster ID: 238)

Climate warming and associated increases in the frequency or intensity of stressors is one of the greatest threats to coral-dominated tropical ecosystems. For example, warm water events have caused major coral bleaching and associated mortality events, and are predicted to do so with greater intensity and frequency. While the ecological ramifications of such events have been widely explored, to date the geological and geomorphological implications are poorly understood. Here, using a census based technique, we track the biological carbonate budget of 21 reefs of the inner Seychelles from 1994 to 2014, across the impact of the 1998 bleaching event, where up to 90% of coral cover was lost. All reefs had a positive carbonate budget in 1994, but by 2005 all reefs had a negative budget. Reefs then followed two distinct trajectories: 14 reefs remained in an erosional condition despite some increases in coral cover, while 7 reefs regained a net positive budgetary state within 10 years of bleaching, and a similar budget to pre-bleaching reefs by 2014. Using boosted regression trees, we identified that reefs with no macroalgae, higher massive coral cover, low wave exposure and lower excavating parrotfish biomass (< 90kg/hectare) in 1994 were more likely to recover to a positive budgetary state. While in 2014 the recovering reefs attained a similar positive budget to 1994, the present overall greater biomass of excavating parrotfish, increased macroalgal cover and lower massive coral cover makes it unlikely that similar recovery trajectories will occur after future bleaching events.

RELOCATION OF CORALS AND ASSOCIATED FAUNA LOCATED IN THE DREDGING AREA OF THE ACCESS CHANNEL TO CARTAGENA BAY (Abstract ID: 29764 | Poster ID: 437)

In order to mitigate the environmental impacts due to the implementation of deepening dredge in the access channel to Cartagena bay (Colombia), the Environmental Management Plan approved involved the relocation of 8,725 individuals belonging to 15 marine species of ecological importance in the area. Among the relocated species, it was found corals, antipatharians, sponges, sea urchins and fish. Within six months of moving the fauna and by the repeated measures analysis of variance, it was established that the areas where the fauna was entered have not suffered a statistically significant change in biotic and abiotic cover ($p > 0.05$) but it does have for algal cover and density of invertebrates and fish ($p < 0.05$). This significance was given by the increase in density at the six months monitoring compared to that found at the one month monitoring after the relocation. This pattern in density may be related to the increased availability of food, since most of the observed organisms feed on algae, which increased their coverage. In addition, within six months of the relocating process the corals and sponges have a survival percentage of 86% for the former and 57% for the latter. The results obtained indicate that the actions implemented to mitigate the impact of dredging on this ecosystem in the area were appropriate, ensuring the survival of more than 50% of individuals that were moved without alter in an ecological way the habitats to which they were entered.

AN ASSESSMENT OF THE DIVERSITY OF ZOANTHARIANS FROM ECUADOR USING AN INTEGRATIVE APPROACH. (Abstract ID: 29442 | Poster ID: 58)

Zoantharians (Cnidaria, Order Zoantharia) represent a group of marine invertebrates that are distributed from shallow waters to the deep sea worldwide. They are especially diverse and abundant in the rocky reefs of the Pacific Ocean and, as such, they are key elements of the marine biodiversity shaping ecosystems in these areas. Few reports on the diversity present of the mainland coast of South America and especially of the coast of Ecuador exist despite its high interest as a zone of confluence of two main Pacific currents. The taxonomy of zoantharians is highly challenging due to a lack of clear morphological characters and in recent years, molecular techniques have helped clarify high level-taxonomic relationships within the order. However, many issues remain at species level due to the limited resolution of the DNA markers commonly used. In this context, the use of a metabolomics approach shows promise to help distinguish closely related morphotypes in related temperate zoantharians and especially amongst Zoanthus spp. We applied an integrative approach to classify Ecuadorian species and here we will present preliminary data on the diversity of zoantharians present in the Marine Protected Area "El Pelado" in the province of Santa Elena, Ecuador. Importantly a metabolomics approach involving UHPLC-HRMS proved to be useful as a complementary tool for their classification. A global comparison with well-known species of the Western part of the Pacific (Okinawa) revealed very few similarities between zoantharians present in both parts of this Ocean.

MOLECULAR PHYLOGEOGRAPHY AND POPULATION STRUCTURE OF BELIZEAN SEA CUCUMBERS (Abstract ID: 29693 | Poster ID: 54)

Sea cucumbers are fairly inconspicuous animals that live on the ocean floor and gain nutrition from diatoms, bacteria, and detritus associated with the sediment they ingest. Sea cucumbers perform vital ecosystem services by recycling nutrients and aerating the upper sediment layers. The biology, ecology, and taxonomy of commercially exploited sea cucumber species are poorly understood in Caribbean and Central American countries where the bêche-de-mere fishery is fairly new and inconsistently regulated. We report preliminary findings of sea cucumber species diversity and within species genetic variation along the Belize Barrier Reef. We wish to determine the extent of genetic variation in these exploited sea cucumber populations and the role MPA's may play in maintaining genetic diversity on the reef.

THE 26 YEARS OLD CAPTIVE REEF KEPT AT THE MONACO'S OCEANOGRAPHIC MUSEUM (Abstract ID: 29443 | Poster ID: 480)

The Monaco's Oceanographic Museum harbors one of the (and perhaps the) oldest captive reefs in the world. This reef was set up in 1989. It was made of live stones, live sand and live corals as well as fishes collected in the Gulf of Tajoura (Djibouti, Indian Ocean), shipped to Monaco and used to stock a 40,000 liters semi-closed aquarium. The aquarium is almost entirely ecologically balanced (JAUBERT NNR SYSTEM). The hard corals (massive, branching and foliose species) have built a life size patch. The patch, which is still thriving today after 26 years of uninterrupted development, is as beautiful as the most beautiful coral patch that one can see in nature. Therefore, while coral reefs are under heavy pressures because of overexploitation, pollution, global warming and ocean acidification, this successful experiment opens interesting prospects of ex situ conservation. By multiplying examples of this kind in public aquariums one might contribute to make an increasing number of people undoubtedly sensitive to the importance and beauty of coral reefs and to the need to conserve them.

TWO NMFS CONSULTATION CASE STUDIES IN PACIFIC AND CARIBBEAN CORAL REEF ECOSYSTEMS TO AVOID AND MINIMIZE CORAL REEF IMPACTS (Abstract ID: 30114)

In both the U.S. Pacific Islands and the Caribbean, natural resource agencies review water resource development projects proposed along the coast. A growing interest in renewable energy production and telecommunication installations in the Pacific and Caribbean Islands has led to a number of permit applications for new types of projects that include construction offshore. The first case study, the Honolulu Air Conditioning Project, is an example of an innovative renewable energy project that proposes to draw cold water from deep offshore waters and pipe it to land to help generate air conditioning for buildings in downtown Honolulu. Resource agencies were concerned about the associated proposed discharge of very large amounts of the cold, nutrient-rich return water to the nearshore coral reef environment. Through early consultation with the permitting entities and natural resource agencies the applicant redesigned the project to discharge return water in deep waters outside the depth range of coral reef habitat. The second case study focuses on two sites in San Juan, Puerto Rico, that are hubs for submarine cable projects connecting the Caribbean, South America, and the continental U.S. NOAA Fisheries has worked with the U.S. Army Corps of Engineers to create standard conditions for submarine cable projects due to the increase in submarine cable projects in the U.S. Caribbean over the last 15 years, the listing of 7 Atlantic coral species

under the Endangered Species Act, and the importance of shallow and mesophotic reef systems as fishery and coral habitat along many cable routes. Standard conditions related to survey methods to establish temporary anchorage areas and site the cable routes in shallow and deep water and cable laying requirements to minimize potential coral impacts have been developed. The outcomes of these consultations have led to a reduction in damage to coral resources, while allowing economic growth to continue in the U.S. Caribbean and Pacific.

EMPLOYING SOFTWARE ENGINEERING PRINCIPLES TO ENHANCE ANALYSIS OF CORAL REEF DATABASES (Abstract ID: 29768)

In order to answer questions in a coral reef context, we have created a framework that reduces the overhead of continual data preparation and allows more time and resources for scientific inquiry. Directly employing software engineering principles, this framework improves data access, connectivity, and scalability with consideration for privacy and security by introducing an abstraction between the data management layer and the application layer. Using the software repository pattern, this solution offers a decentralized data service for use with minimal up-front data processing. In our presentation we will use this framework to analyze a complex data set consisting of twenty corals and seventeen environmental factors collected at fifty reef sites over a span of four years. One goal is to determine if the presence of a particular coral facilitates growth of other coral species and recruits. Using our software framework we are able to look at the incomplete data and expose how much of the picture is missing. Furthermore, this platform allows us to exhaustively search the space of coral associations and test all relationships. This yields statistically significant evidence that one coral species is conducive to growth and recruitment of other species in the Caribbean. We argue that much of the success in answering this and other complex ecological questions stems from our robust data management framework which will allow us to evaluate the potential implications of species and environmental associations on a larger scale to address coral resilience.

FUSION OF CORAL EMBRYOS: A POTENTIAL AND UNEXPECTED SHORTCUT TO COLONY FORMATION (Abstract ID: 28590)

Juvenile coral colonies originate either from the asexual budding of the primary polyp, or fusion of gregariously settling larvae and adjoining recruits. Here, we observed for the first time the inborn juvenile colonies resulting from fusion of embryos and the following settlement of conjoined larvae in a broadcast spawning reef coral Platygyra daedalea. We hypothesize that fusion of coral embryos might be a potential and unexpected shortcut to colony formation, and meanwhile an adaptive strategy to form pre-metamorphic chimeric larvae and larger recruits in reef corals, thereby promoting early survival. Future studies are required to explore whether fusion of embryos is common in broadcast spawning corals and occurs in the field, and fully evaluate its implications.

MEASUREMENTS OF UNDERWATER CARBONATE CHEMISTRY USING A PROTOTYPE HYBRID AUV/ROV AND AUTOMATIC SENSORS: A DEMONSTRATION PROJECT (Abstract ID: 29903)

Knowledge of deep-water carbonate chemistry remains limited, largely due to the limitations of observational capabilities. Here we present results from a 6-day (Aug. 8-13, 2015) survey along the east coast of Florida using a new hybrid AUV/ROV U-4000 outfitted with state of the art biochemical sensors, and a high-definition imaging system. The U-4000 is a flat rectangular platform designed to operate in an autonomous mode or a supervised autonomy mode using a self-spooling, fiber-optic tether. In this project, the vehicle was outfitted with CTD, SAMI-pH, HydroC pCO2, and DO sensors to characterize the carbonate chemistry and water conditions. The pCO2 and pH sensors sampled at 1 and 5 min. interval, respectively. The vehicle was deployed 11 times at 6 dive sites from nearshore (~15 m) to shelf edge (~75m). Nine CTD casts were made with a mini-rosette to collect water samples for measurements of total CO2, alkalinity, and other parameters. The U-4000 performed reasonably well on various operations such as diving, climbing and mosaicking at sites with weak currents (<0.5 m/sec), but having difficulty of moving against strong currents. Further enhancements of the vehicle are ongoing. A preliminary analysis indicates that the sensor data were in good agreement with sample data. For the two shelf edge sites in the vicinity of the Oculina HAPC and within the Gulf Stream frontal zone, the pH, pCO2, and aragonite saturation state (omega) all show a wide range of values with pH from 8.07 to 7.96, pCO2 from 300 to 600 µatm, and the omega from 4.0 to 2.4 from surface to bottom.

A GALNAC-BINDING LECTIN COULD BE INVOLVED IN ACQUISITION OF *SYMIODINIUM* BY *ACROPORA TENUIS* (Abstract ID: 29382 | Poster ID: 118)

Many corals often harbor symbiotic dinoflagellates, *Symbiodinium* spp., and their symbiosis is indispensable for the survival of corals. However, they often acquire *Symbiodinium* around their environment, and this acquisition was inhibited by some carbohydrates, suggesting that a carbohydrate binding proteins may play a role in this step. So we purified a lectin using a hard coral *Acropora tenuis*. The juvenile polyps of *A. tenuis* acquire *Symbiodinium* strain NBRC102920, and this acquisition was inhibited by galactose, *N*-acetylgalactosamine (GalNAc), and *N*-acetyl-glucosamine. By GalNAc-affinity chromatography, two components at 29.0 kDa and 14.6 kDa were purified. *De novo* sequencing by MALDI-TOF MS spectrometry suggests that 29.0 kDa component is similar to a GalNAc/GlcNAc binding lectin tachylectin-2 (TL-2) purified from a horseshoe crab, which is involved in immunity. Based on the sequence, the corresponding cDNA was cloned. The deduced amino acid sequence was composed of 267 amino acids, and had a similarity to TL-2 and some putative proteins from *A. digitifera* genome database, so the protein was named to AtTL-2. Immunohistochemistry of *A. tenuis* tissue suggests that AtTL-2 distributed a kind of nematosysts. Moreover, Anti-TL-2 antibody inhibited *Symbiodinium* acquisition by juvenile polyps. These results let us to hypothesize that *A. tenuis* may acquire *Symbiodinium* near themselves by releasing AtTL-2 from nematocysts.

UNUSUAL FEATURES OF A MESOPHOTIC HARD CORAL ASSEMBLAGE IN A LAGOON ENVIRONMENT DOMINATED BY HEAVY TERRIGENOUS SEDIMENTATION: THE BANC GAIL (SW NEW CALEDONIA). (Abstract ID: 28630)

Mesophotic coral assemblages are most often developed on the deep fore reef slopes exposed to oceanic conditions. Less common are the mesophotic assemblages which occasionally occur within the confines of large lagoons where environmental conditions impart specific and unusual characters to the scleractinian community. Situated in the SW lagoon of the New Caledonian barrier reef system, the Banc Gail is an example of such uncommon mesophotic environment. There, between 35 and 45m deep, the lagoon floor is subjected to input in the form of periodical pulses of fine terrigenous mud originating from the nearby rivers. The terrigenous silts and clays are trapped in an eddy of the general water circulation and settle on the seabed. Such a turbid environment favours the settlement of oysters forming banks that tends to create ridges up to 3 m high on which corals settle, separated by muddy gullies Although high levels of fine particle sedimentation are proven to be detrimental to the development of scleractinians, a number of corals have adapted to such peculiar conditions, principally low light levels and high rates of fine sediment deposition. The composition of the scleractinian assemblage is examined. Although the suite of species is a subset of the general scleractinian mesophotic fauna, some key components such as the Agariciidae or species of the *Acropora elegans* group are uncommon or absent. Further, most species show unusual growth forms in response to the high and periodic muddy particle ingress and a high incidence of natural fluorescence has also been observed

JUVENILE HAWKSBILL AND GREEN SEA TURTLE MOVEMENT BETWEEN SEAGRASS BEDS, CORAL REEFS AND ARTIFICIAL REEFS IN BREWERS BAY, US VIRGIN ISLAND (Abstract ID: 29801)

The movement patterns of juvenile sea turtle is one of the largest gaps in our understanding of these endangered/threatened animals. Movement patterns of juvenile

hawksbill Eretmochelys imbricata and green sea turtles Chelonia mydas were analyzed for a period from Aug 1, 2015 to Nov 1, 2015 as part of the UVI's Mare Nostrum project. The project deployed 37 Vemco acoustic receivers in Brewers Bay St Thomas, Virgin Islands. Five hawksbills, 1.4–28.2kg, and five green sea turtles, 9.5-16.4kg, were tagged with external Vemco sonic transmitters. The green sea turtles showed remarkably consistent circadian movement patterns, with days spent in S. filiforme dominated seagrass beds and nights spent in both artificial and coral reefs. The high degree of site fidelity suggests that individuals have specific resting areas where they overnight. All green sea turtles stayed within the approximate 1 km2 area covered by the acoustic array, suggesting home ranges of less than 1 km2. No significant correlation between mass and home range was found in Green sea turtles. Hawksbills showed no obvious circadian movement patterns. Larger Hawksbills had wider movement patterns, suggestive of a correlation between size and home range. Both Hawksbill and Green sea turtles spent more time associated with the artificial reef, extension of St Thomas airport runway, then with natural coral reefs in the Brewers Bay. This data suggest that home ranges of juvenile Hawksbill and Green sea turtles are smaller than that of adult sea turtles reported in the literature.

FLUCTUATIONS IN ORNAMENTAL FISH POPULATIONS AFTER THE MASSIVE DIE-OFF OF CORAL IN 1997 ON THE PADANG SHELF REEF SYSTEM, INDONESIA (Abstract ID: 29257)

Ornamental fish communities are part of the reef fish community associated with coral reef ecosystems. They are exported from Indonesia for the aquarium trade. Surveys of reef fish has been conducted continuously on the reefs off Padang, West Sumatra, Indonesia before and after the occurrence of massive die off of coral in 1997. Surveys were conducted again in May 2014 to see the change in fish populations at permanent transects at 3 Islands (Pulau Pieh, P. Pisang, P. Pandan) and on 3 patchreefs (Gabuo, Air and Sipakal). This report concentrates on changes in the ornamental fish populations since the die off. The species and number of individuals per species were recorded 2.5 m either side of three 30 m transects at each site. Twenty four families of ornamental fish from the low to the high demand, were recorded which the highest demand including Chaetodontidae, Pomacanthidae, Achanturidae Balistidae Achanturus Leucosternon Pomacentridae and 7 species. The following species were the most abundant: 3,17% of Pomacentrus alleni on the high demand, 58,57% of Odonus niger on the middle demand and 8,42 of Abudefduf vaigiensis on the low demand. The results obtained by the average number of species of fish as much as 41,5 and the average number of population of 682,92 individual fish. The number of species and number of individuals of ornamental fish was higher in 2014 than in 2007 and lower than in 2001. The mass death of corals impacts the number of species and individuals of ornamental fish or reef fish in the waters of the Municipality of Padang and surrounding areas. Keywords: Ornamental fish, reef fish communities, fluctuations, mass death of corals

LARGE PREDATORY CORAL TROUT SPECIES UNLIKELY TO MEET INCREASING ENERGETIC DEMANDS IN A WARMING OCEAN (Abstract ID: 28362)

Increased ocean temperature due to climate change is raising metabolic demands and energy requirements of marine ectotherms. If productivity of marine systems and fisheries are to persist, individual species must compensate for this demand through increasing energy acquisition or decreasing energy expenditure. Here we reveal that the most important coral reef fishery species in the Indo-west Pacific, the large predatory coral trout *Plectropomus leopardus* (Serranidae), can behaviourally adjust food intake to maintain body-condition under present day (24-30˚C) and elevated (+3˚C) temperatures, and acclimate over time to consume larger meals. However, 3˚C elevated temperatures also caused a 55% reduction in spontaneous swimming speeds and doubled the time individuals spend resting motionless on the bottom. Given that movement and activity patterns of large mobile species are directly related to prey encounter rates and ability to capture prey, any reductions in activity patterns are likely to reduce foraging opportunity and limit the energy available for growth, reproduction and fitness. Additionally, increased energetic demands are unlikely to be met by adequate production at lower trophic levels, as smaller prey species are often the first to decline in response to climate-induced loss of live coral and structural complexity. Consequently, ubiquitous increases in energy demand combined with reduced foraging opportunity due to climate change will increase top-down competition for a dwindling biomass of prey, and potentially distort entire food webs and associated fisheries.

SAVING THE "CRITTER CAPITAL" THROUGH SUSTAINABLE LIVELIHOOD INITIATIVES (Abstract ID: 29611 | Poster ID: 685)

St. Vincent and the Grenadines(SVG) is promoted to dive enthusiasts as the 'Critter Capital' of the world and is home to the smallest coral reef creatures. Since the lionfish invaded SVG's waters in 2010, fishers and divers noted the negative impact on coral reef fish; a problem that may lead to a critter crisis. SVG is currently establishing a second marine park and the possible disenfranchisement of fishers is of critical concern since the majority of the population depends on the marine environment for their income and diet. In order to address the lionfish invasion and provide fishers with supplementary livelihoods options, a sustainable livelihoods initiative was implemented by the Climate Resilient Eastern Caribbean Marine Managed Areas Network (ECMMAN) project. The project was implemented jointly by two dive shops and two fisher organizations. The project outcomes included the certification of 25 fishers in diving and training in lion fish culling methodologies with permission to catch lionfish within the proposed MMA; the establishment of a tackle shop with lionfish culling equipment; the promotion of lionfish consumption; and stable markets for lionfish sales. The project has recorded many benefits including (i) reduction in lionfish populations, (ii) rebounded populations of reef critters, (iii) establishment of a secure lionfish market through restaurants and hotels, (iv) improved partnerships and communication among dive shops and fisher organizations, and (v) the demonstration of a successful sustainable livelihood initiative in a small island state.

HIERARCHICAL EFFECTS OF THE ENVIRONMENT ON THE DISTRIBUTION AND SIZE OF PARROTFISH ON THE NORTHERN GREAT BARRIER REEF. (Abstract ID: 30024 | Poster ID: 247)

Scarine labrids (parrotfishes) are critical to the resistance of reefs from shifting to a macroalgal dominated state on reefs worldwide. Despite their importance, few studies have investigated the community structure of parrotfishes on the Great Barrier Reef at large spatial scales. The distribution of 25 parrotfish species was examined at 82 sites on the Northern Great Barrier Reef from north of Cape Tribulation to Cairns, representing spatial scales both cross-shelf and along a 6 degree longitudinal gradient. Parrotfish and predator abundance was recorded using stereovideo cameras to facilitate consistently accurate length measurements for all species encountered. Total predator biomass (kg / Ha) and parrotfish biomass (kg /Ha) were calculated at each site. To investigate their role in parrotfish community structure, coral cover, slope and rugsoty were also quantified at each site. Similarly to previous studies (Hoey & Bellwood 2008), clear patterns emerged in abundance and biomass of parrotfish on a cross-shelf gradient. As distance from shore increased parrotfish densities increased, while total parrotfish biomass increased. Patterns of variation in community structure were difficult to distinguish at a larger 6 degree longitude spatial scale. Despite the increase in biomass of parrotfish from inshore to the outer shelf, the majority of biomass is represented by a smaller diversity of species.

SUCCESSES, CHALLENGES, AND LESSONS LEARNED FROM A DECADE OF CAPACITY BUILDING FOR IMPROVING THE MANAGEMENT OF MARINE PROTECTED AREAS (Abstract ID: 29753)

With some 9,000 Marine Protected Areas (MPAs) designated globally (Spalding et al, 2013), only a small fraction of these are considered effectively protected. At the same time with the array of capacity development programs offered around the globe, there is now more than ever the need to assess the progress made by marine resource managers in meeting their management objectives; establish and set staff competency standards; and communicate results in terms of the return on these investments. NOAA's International MPA Capacity Building Team strives to improve marine and coastal resource management by bring together different MPA management models from around the world and sharing experiences and lessons learned amongst marine and coastal re-

source managers. After a over a decade of work, we have developed a successful model for improving the capacity of coastal and marine area managers to ensure successful management. As part of this, we recognize a key element in comparing the success of capacity building program is ensuring there's a standardized means for defining what are we trying to achieve as well as outlining common benchmarks for "success". Additionally, we need to consider standardizing indicators of success. A systematized set of standards and indicators for results-based capacity development would provide a means to measure and compare the effectiveness of capacity development efforts across a region and globally in moving towards effective marine and coastal area management.

CORAL COMMUNITY CHANGE ON A TURBID-ZONE REEF COMPLEX: DEVELOPING BASELINE RECORDS FOR THE CENTRAL GREAT BARRIER REEF'S NEARSHORE CORAL REEFS (Abstract ID: 27950)

Understanding past coral community development and reef growth is crucial for placing contemporary ecological and environmental change within appropriate reef-building timescales. Coral reefs located within coastal inner-shelf zones are widely perceived to be most susceptible to declining water quality due to their proximity to modified river catchments. On the inner-shelf of Australia's Great Barrier Reef (GBR) the impacts and magnitude of declining water quality since European settlement (c. 1850 A.D.) still remain unclear. This relates to ongoing debates concerning the significance of increased sediment yields against the naturally high background sedimentary regimes and the paucity of long-term (>decadal) ecological datasets. To provide baseline records for interpreting coral community change within the turbid inner-shelf waters of the GBR, 21 cores were recovered from five nearshore reefs spanning an evolutionary spectrum of reef development. Discrete intervals pre- and post-dating European settlement, but deposited at equivalent water depths, were identified by radiocarbon dating, enabling the discrimination of extrinsic and intrinsic driven shifts within the coral palaeo-record. We report no discernible evidence of anthropogenically-driven disturbance on the coral community records at these sites. Instead, significant transitions in coral community assemblages relating to water depth and vertical reef accretion were observed. We suggest that these records may be used to contextualise observed contemporary ecological change within similar environments on the GBR.

VULNERABILITY OF PACIFIC REEF-DEPENDENT COMMUNITIES TO OCEAN ACIDIFICATION: FOOD SECURITY AND LIVELIHOOD IMPLICATIONS (Abstract ID: 28429)

In the Pacific region, coral reefs provide critical goods and services for coastal communities, particularly food security, livelihoods and coastal protection. The implications of ocean acidification (OA) are significant due to the expected impacts of OA on reef structure and fish productivity. Combined, these impacts present a major challenge for reef-dependent communities. Here we present the results of an assessment of vulnerability of reef-dependent communities in 22 Pacific island countries and territories (PICTs) that focused on the projected impacts of OA in 2050 on reefs and their goods and services. In particular, we examined fisheries production for food security, livelihood income, employment and reef area as a proxy for coastal protection. The semi-quantitative assessment used indicators to score and rank communities based on their: (i) exposure to reef habitat degradation, (ii) sensitivity to declines in reef goods and services, and (iii) adaptive capacity as measured by social indicators of health, education, economy size and governance. The PICTs assessed with the highest relative vulnerability were: Solomon Islands, Kiribati, PNG, FSM, Tonga and Tuvalu. The PICTs with the lowest relative vulnerability were: Niue, Northern Mariana Islands, Tokelau, New Caledonia and Guam. Key factors contributing to high vulnerability were large reef to land area ratio, a high percentage of household earnings from coastal fisheries, and education as a driver of low adaptive capacity. In contrast, PICTs with low relative vulnerability consistently had high adaptive capacity and generally low reef to land ratios. These results are informing future adaptation planning.

CONNECTIVITY AMONG POPULATIONS OF THE INVASIVE LIONFISH (*PTEROIS VOLITANS*) IN THE ATLANTIC, CARIBBEAN AND GULF OF MEXICO. (Abstract ID: 28211)

Lionfish have recently invaded Atlantic waters beginning in the North Atlantic in the late 1980s progressing into the Caribbean in 2006 and into the Gulf of Mexico (GOM) as of 2010. We investigated the population genetic connectivity of the invasion across these three regions. Previous studies found that there are 9 mitochondrial control region (d-loop) haplotypes found in samples from the North Atlantic region (ATL) and that the Caribbean (CAR) region has only a subset of those haplotypes (n = 4). Our samples from the Gulf of Mexico contain only three haplotypes. It is clear from these samples that there were founder effects within each region as they were successively colonized and possible slight barriers to dispersal among the three regions (ATL, CAR, GOM). It is clear from our data that the GOM was colonized by dispersers from the CAR rather than the ATL as there is no evidence of the ATL only haplotypes in the Gulf samples. Understanding the genetic composition and patterns of connectivity of lionfish will help aid in multi-agency management efforts to control lionfish populations and the further spread of lionfish.

A SUSTAINABLE REPOSITORY FOR CORAL REEF HISTORICAL IMAGERY (Abstract ID: 29369)

Underwater photographs of known reef sites are valuable sources of historical data. As part of a new initiative to create a sustainable, open-access repository of historical reef imagery and associated data, a collection of 1480 images made by Eileen Graham in the mid 1960s near Discovery Bay Jamaica are available for download at http://data.nhm.ac.uk. Images have precise location and date information, and they record the state of reefs prior to their decline in the 1980s and before well-established monitoring surveys in the Caribbean. Images range from detailed close-ups to reefscapes, and are a rich source of ecological data including benthic community composition and habitat complexity. Ecological change on coral reefs shows great variability at local scales, thus we aim to establish a network of image repositories from reefs worldwide to help define local baselines that better inform decision-makers. The time is right because the first generation of SCUBA-enabled scientists are retired and should be considering the future disposition of their photographs. Our experience with assembling this collection indicates that it is critical to work closely with photographers to capture information on dive sites and dates. Furthermore, we would like to highlight the role of natural history museums as sustainable repositories of historical archives. In contrast to short-term projects, museums are better able to guarantee future availability of reef imagery because they have the long-term commitment and resources required for the curation and dissemination of scientific data.

TURFS OF THE FUTURE: GLOBAL CHANGE IMPACTS ON BIOLOGICAL AND COMMUNITY RESPONSES OF CORAL REEF TURF ALGAE (Abstract ID: 28860)

Coral reef algae are critically important for organic and inorganic production in tropical systems, yet they are markedly understudied in the context of global change. Within the algae, even less is known about the response of turf algae communities to environmental stressors. We conducted a mesocosm experiment in Moorea, French Polynesia to test the combined effects of $CO_2$ enrichment and warming temperatures on turf growth, physiology, community structure and endolithic growth. These metrics relate to the roles of turf algae in production, competition, and as a resource for herbivores. Carbonate plugs covered by turf were collected from the reef and exposed to ambient and elevated $CO_2$ (1,000 µatm) conditions for three weeks. Each $CO_2$ treatment was replicated across six temperatures, ranging from 24-31.5°C. OA and warming had complex, and sometimes interactive, effects on turf algae response. OA stimulated growth of both turf algae and the endolithic community, but more so at warmer temperatures. Conversely, temperature alone stimulated photosynthetic production and respiration. OA and warming also altered community structure, with a shift towards dominance by cyanobacteria in warmer and more acidic conditions. These results indicate that global change impacts could enhance the competitive ability of turf algae over other slower growing taxa such as reef-building corals. The complex and differing effects of $CO_2$ enrichment and warming across a suite of algal responses demonstrate how multiple stressors have diverse and unexpected biological effects.

TEN YEARS OF LARGE SCALE CORAL BLEACHING MONITORING ACROSS THE FLORIDA REEF TRACT (Abstract ID: 28876)

The Florida Reef Resilience Program (FRRP) is a collaborative effort among managers, scientists, conservation organizations and reef users to develop resilience based management strategies for coping with climate change and other stresses on Florida's coral reefs. Since 2005, The Nature Conservancy has coordinated a Disturbance Response Monitoring (DRM) effort, consisting of a probabilistic sampling design and a stony coral condition monitoring protocol, implemented during peak thermal stress across the entire Florida Reef Tract that extends from Martin County to the Dry Tortugas. Each year, 13 teams from federal, state, and local government agencies, non-profit organizations, and universities completed surveys across the entire South Florida reef tract within a six to eight week period. Sites were stratified randomly, allowing information gathered on the coral population's size frequency, size structure, and bleaching prevalence to be extrapolated for different sub-regions and zones. From 2005 to 2015, 2,200 surveys were completed. Results from these ten years of surveys show spatial and temporal patterns in coral bleaching and colony size frequency distribution, indicating that some reef areas or coral species may be more resilient to stress than others. While the causes of this variability remain poorly quantified, projected increases in coral bleaching due to climate change makes identification of these resilient reef areas and species important for long-term coral reef conservation and future management strategies.

3D PHOTOGRAMMETRY FOR MEASURING REEF PRODUCTIVITY: ADVANCES IN LIGHT PROPAGATION AND SELF-OCCLUSION (Abstract ID: 28381)

With recent advances in photographic 3D benthic mapping, it is now possible to build high-resolution 3D maps of benthic ecosystems over large spatial areas that will allow us to address the importance of 3D reef structure for community metabolism. Using stereoscopic photogrammetry and scene reconstruction, the distribution and approximate surface areas of most stationary members of the community can be obtained. As light is the major short-term control on reef productivity, we propose to generate a model of received light over the surface of the reconstructed community. The key technical advance proposed here in underwater 3D reconstruction is the use of multi-view stereo to improve both the spatial density and accuracy of the 3D structure of the structural models, building on previously developed 2-view methods. This multi-view formulation, in conjunction with more sophisticated models for light propagation through water, will enable us to both measure light in its capacity as a driver for reef metabolism and generate more accurate 3D models of the reefs for all manner of study. Results will be displayed on real data gathered from a mixed coral-algal reef in the Florida Keys.

ROOTING THE TREE; PHYLOGENOMIC ANALYSIS OF POCILLOPORA CORALS PROVIDES EVOLUTIONARY INSIGHTS INTO RECENT DIVERSIFICATION. (Abstract ID: 28840)

Pocillopora corals are notoriously difficult to identify and recent work has found more cryptic species and plasticity than preciously thought, motivating a reorganization of the genus. Here, we analyze the phylogenetic relationships within the scleractinian genus Pocillopora using RAD-seq. We examined 15 coral holobiont libraries and found strong concordance in both the phylogenetic analyses of the entire holobiont dataset and reads that mapped to transcribed coral genes. We further assembled nearly complete mitochondrial genomes (18 kb), a 5 kb segment of histone gene sequence, and 430 unlinked, biallelic SNPs, which also show general concordance with previously published clustering of the mitochondrial clades rather than the currently recognized morphospecies. This analysis expands on previous genetic, morphologic, and ecological studies and corroborates that Pocillopora have more variable and convergent morphology than previously appreciated. Our data provide unprecedented phylogenetic resolution into the recent radiation of species within this genus, with general concordance between mitochondrial and nuclear datasets indicating that there is not rampant hybridization or introgression between mitochondrial lineages.

VALIDATION OF REEF-SCALE THERMAL STRESS SATELLITE PRODUCTS FOR CORAL BLEACHING MONITORING (Abstract ID: 28114)

Satellite monitoring of thermal stress on coral reefs has become an essential component of reef management practice around the world. A recent development by the U.S. National Oceanic and Atmospheric Administration's Coral Reef Watch (NOAA CRW) program provides daily global monitoring at 5 km resolution—at or near the scale of most coral reefs. This and other novel CRW products may provide crucial information in support of local monitoring and management activities prior to, during, and after thermal stress events. Using in situ survey data collected during the 2014 thermal stress event across the Northern Mariana Islands, we undertook the first quantitative comparison between 5 km satellite monitoring products and coral bleaching observations. Observed bleaching at 62 sites across seven islands ranged from 0%–94% of live coral cover. Analysis of coral community characteristics, historical temperature conditions, and current thermal stress revealed a strong influence of coral biodiversity on the patterns of observed bleaching. This resulted in a model based on thermal stress and generic richness that explained 97% of the variance in bleaching. These findings illustrate the importance of using local benthic community characteristics to predict and interpret the level of impact from thermal stress exposure. In an era of continuing climate change, accurate monitoring of thermal stress and prediction of coral bleaching and resilience are essential for managers to utilize resources effectively and conserve coral reefs.

LONG-TERM MONITORING OF CORAL ASSEMBLAGES IN FLOWER GARDEN BANKS NATIONAL MARINE SANCTUARY, GULF OF MEXICO (Abstract ID: 28368 | Poster ID: 13)

The Flower Garden Banks National Marine Sanctuary, consisting of East Flower Garden Bank (EFGB), West Flower Garden Bank (WFGB), and Stetson Bank, contains coral reefs and coral communities in the northwestern Gulf of Mexico. Long-term monitoring programs have been conducted at EFGB and WFGB since 1989 and at Stetson Bank since 1993. We examined 27 years of shallow (<33.5 m) benthic percent cover data at EFGB and WFGB, providing a long-term trend analysis of the community structure. Although percent macroalgae cover has increased significantly, mean coral cover averaged above 50%. In contrast to many other phase shifting reefs in the Caribbean region, the increase in macroalgae cover has not resulted in coral decline at EFGB and WFGB. Conversely, benthic monitoring at Stetson Bank has documented three community shifts (2000, 2006, and 2015). In this 23 year time frame, both sponge and coral cover declined, macroalgae cover varied widely, and the reef has been impacted by bleaching, hurricane damage, and land-based runoff. The highly variable environmental conditions at Stetson Bank differ drastically in comparison to the relatively stable conditions at EFGB and WFGB. This is largely due to Stetson's more northern latitude and closer proximity to shore. Continued long-term monitoring documents changes in the reef communities at the marine sanctuary, enabling resource managers to make decisions regarding management and research activities focused on the dynamics of the benthic communities and the megafauna they support.

GENETIC AND BIOPHYSICAL MODELING ASSESSMENT OF CONNECTIVITY IN THE RED GROUPER, EPINEPHELUS MORIO (Abstract ID: 29516)

Understanding connectivity of reef organisms is important to aid the conservation of biological diversity and facilitate sustainable fisheries. Common methods to assess reef connectivity include genetics, modeling, and tagging. Individually, these techniques can offer insight into population structure; however, the information acquired by a singular analysis is often subject to inherent limitations of the chosen method. Thus combining approaches may allow for better resolution of population structure and the biophysical factors driving it. We utilized both genetic analysis and biophysical modeling to assess connectivity dynamics and linkages of the red grouper (Epinephelus morio), a major reef fishery species found throughout the Gulf of Mexico (GOM) and southeastern USA (SE-USA). First, we used a model to incorporate ocean conditions and biotic traits of the grouper to deliver a spatial forecast of 'source' and 'sink' populations in the GOM and SE-USA spanning ten years. Next, using a suite of 13 polymorphic microsatellite markers we assessed the genetic population structure of red grouper across this same spatial scale to directly compare levels of connectivity between methods. Our population genetic survey of groupers suggested high connectivity and the presence of a single genetic population. Similarly, modelling the fish over ten years suggested panmixia over generations. Using a dual empirical and theoretical approach lessens error over one method alone and is important validation of both the genetic and biophysical modeling techniques used in this study.

KANEOHE BAY, OAHU, HAWAII: CENTURIES OF HUMAN IMPACT AND REEF RECOVERY WITH PROJECTIONS TO 2050 (Abstract ID: 27908)

Kaneohe Bay has endured a long history of anthropogenic disturbance and recovery. The bay is currently experiencing increasing episodes of coral bleaching due to global warming. The long-term outcome is in doubt, so a review of past reef resilience can be informative. The first contact by Polynesians occurred over 1500 years ago. Expanding population led to exploitation of marine resources, clearing of land for agriculture, introduction of alien species, construction of massive shoreline fish pond enclosures and extensive terraces in the valleys that were used for taro culture. The arrival by the first Europeans in 1778 led to development of a plantation agricultural system accompanied by increased human immigration, population growth and an end to traditional management practices. During 1930-1940 the reefs were devastated by extensive dredge and fill operations. Human population increases led to extensive urbanization of the watershed. By the 1960's the bay was severely impacted by sewage discharge along with increased sedimentation due to improper grading practices and stream diversion-channelization that led to extensive loss of coral cover. Management action corrected many of these problems and the reefs recovered. Increasing global temperature is now impacting these reefs with the first "bleaching event" in 1996 and more severe events in 2014 and 2015. The reefs of Kaneohe Bay developed and have persisted under severe natural and anthropogenic perturbations. To date, these reefs have proved to be very resilient, but a major question remains as to their limits in the face of future global climate change.

COMMUNITY PARTICIPATION IN MARINE RESOURCES MANAGEMENT: A CASE STUDY OF THE PROPOSED TUN MUSTAPHA PARK, SABAH (Abstract ID: 29161)

In March 2003, the Government of Sabah approved the intention to gazette the proposed Tun Mustapha Park (TMP), an almost one million hectares marine area located at the northern part of Sabah. Located within the Coral Triangle, TMP harbors one of the richest marine flora and fauna complexes in the world and is also home to more than 80,000 coastal dwellers that depend on a healthy continuous supply of marine resources. TMP will be the largest marine protected area in Malaysia once it is formally gazetted. Because of its size and the commercial activities that occur in the region, it requires a multidisciplinary and collaborative management system. Increasingly, community support and participation in the establishment of a Marine Protected Area (MPA) is seen very important to ensure the success of the MPA. However, little attention has been given to how communities respond to MPA, particularly how they can actively participate in the management of their marine resources, following the establishment of a restrictive collaborative management regime. In this paper, we explore the early effects of a MPA geared towards the management of marine resources as well as possibilities of combining Ecosystem Approach to Fisheries Management to communities current fisheries management practice. To illustrate our case, we draw upon our research experience in social, fisheries and biological assessment and our experience in establishing marine protection in the TMP. Keywords: Marine Protected Area, Ecosystem Approach to Fisheries Management, Community based Marine Resources Management

DEGRADATION OF INDONESIAN CORAL REEFS: SCIENTIFIC AND MANAGEMENT CHALLENGES AND SOME SOLUTIONS… (Abstract ID: 29973)

Coral reefs of Indonesia, at the center of Coral Triangle biodiversity hotspot, have suffered from long term pressures, including destructive fishing practices, overfishing, coral mining, sedimentation, pollution, eutrophication, anchoring, and recently from coral diseases and global warming. Global warming has caused serious coral mortality due to mass bleaching around the globe in the last decades. Emerging diseases and more frequent outbreaks of coral predators such as Crown of Thorn star fish have also occurred in many reefs. Due to long-term destruction and decreased population of herbivores and increase of nutrient inputs, many reefs have experienced phase shift from coral to rubble, sand, or algal dominated reefs. Combinations of these factors have contributed to coral reef degradation in Indonesia, where only around 6% of coral reefs remain in very good condition. Science based adaptive and effective management strategies have to find the delicate balance among and between the people and the reefs to create more resilient and productive coral reef ecosystems. Contemporary strategies include: introducing Marine Protected Area Networks, ecosystem approach for reef management, community based and co-management, strong and effective regulations and proactive coral restoration. Can all of these solve the increasing and alarming pressures on the reefs, with potential benefits to people and ecosystems? We illustrate some of these challenges, and the potential solutions, with examples from around Indonesia, especially Sulawesi and the Birds-Head Seascape.

ENHANCING MULTI-STAKEHOLDER FISHERIES MANAGEMENT IN POHNPEI, FSM (Abstract ID: 30131)

Over the last two years, the Conservation Society of Pohnpei embarked on a comprehensive coral reef fisheries program to reverse the decline of food fish populations and to establish sustainable management efforts. The program focuses on the integration of strong partnerships, biophysical and socio-economic research, new management interventions, good governance, and behavior change strategies to promote the long-term viability of fish harvesting, compliance, and retail practices among the stakeholders. Fish life history, standing stock, harvest, and market data from research provided information for managers, resource users, and the general public to understand the status and trends of highly targeted species – much of which indicated harvest levels beyond biological capacity, spawning declines, and undermining commercial marketing. To address these concerns, a multi-sectorial Fisheries Support Group helped to identify threats and opportunities for sustainability, introduced new policy, assisted with strategies to enhance compliance and fish retail. Additionally, a Marine Advisory Council provided recommendations to traditional and community leaders on community engagement and culturally appropriate management innovations. As a result of the increased public awareness state, municipal, and traditional and religious leaders have taken concrete steps to strengthen fisheries management. Specifically a number of new regulations and co-management approaches have been adopted including size-based regulations for key herbivores, along with enhanced multi-agency cooperation.

THE REEF SULPHUR CYCLE: INFLUENCE ON CLIMATE AND ECOSYSTEM SERIVICES (Abstract ID: 27784)

Research in the western Pacific over the last fifteen years has shown that hard corals contain exceptionally high concentrations of a sulphur substance called dimethylsulphoniopropionate or DMSP which can produce a volatile sulphur substance called

dimethylsulphide or DMS. Of all the different coral species, staghorn coral or Acropora species produce the greatest amounts of atmospheric DMS. Oxidation of atmospheric DMS produces a sulphate aerosol which can potentially form cloud condensation nuclei leading to low level cloud development. An increasing amount of evidence now suggests that DMS emitted from coral reefs could keep sea surface temperatures (SSTs) cooler in the western Pacific, including the Great Barrier Reef, through this reef produced low level cloud climate feedback. However, recent research on the effect of coral bleaching on this climate feedback indicates that enhanced solar radiation could reflect increased DMS emissions from reefs increasing SSTs and causing this feedback to shut down, exacerbating the bleaching response. The production of these natural sulphur substances from coral reefs; their effect on regional climate, bird, bacterial and fish behaviour, and possible use as Polynesian navigational aids are reviewed, providing evidence of a very valuable and important ecosystem service not previously described. Research on the effect of coral bleaching on this coral reef climate feedback indicates that increasing SSTs cause this feedback to shut down, exacerbating the bleaching response.

EXAMINING RECOVERY RATES AMONG FISHES INSIDE A NO-TAKE MPA IN BELIZE. (Abstract ID: 29772 | Poster ID: 643)

As pressures mount to protect the economic and ecological benefits of its coral reefs and associated fisheries, the Caribbean nation of Belize has increased the area of its territorial sea under no-take protection as well as issued nation-wide harvest bans on herbivorous fishes. In 2011, we set up a long term monitoring program at the onset of the newly enforced no-take area within the South Water Caye Marine Reserve (SWCMR), with 12 permanent transects inside the reserve boundary and 12 outside. An aggressive protocol assesses hard corals and fishes for abundance, diversity, size distribution and condition while generating benthic composition photoquadrats. After five years of bi-annual surveys, we found that coral cover and community composition differ between habitats, but are similar inside and outside the no-take area. The abundances of several fish species, however, are significantly higher inside the no-take area, a pattern that presumably existed prior to no-take enforcement. After five years of monitoring, we expect that fish species with nation-wide harvest bans (scarids and acanthurids) should show no difference in abundance or biomass inside the SWCMR when compared to outside the reserve. However, for long-lived species of commercial interest, trajectories of abundance or biomass should differ inside the no-take area.

LANDSCAPE PATTERNS OF SYMBIODINIUM COMMUNITY DYNAMICS IN ORBICELLA FAVEOLATA DURING AND AFTER THE CONSECUTIVE MASS BLEACHING EVENTS OF 2014 AND 2015 (Abstract ID: 29588)

Despite the high level of concern regarding coral bleaching, and the expectation that bleaching events will increase in both severity and frequency, little is known about how *Symbiodinium* dynamics correlate with landscape patterns of bleaching and recovery. To this end, we tagged 150 colonies of *Orbicella faveolata* at six separate sites at Cheeca Rocks, an inshore patch reef in the upper Florida Keys, and took tissue samples from the same colonies during: 1) peak bleaching in 2014, 2) recovery in early 2015, and 3) recovery from the 2015 mass bleaching in early 2016. Landscape patterns of bleaching and recovery were investigated by taking > 2000 high resolution photographs from 1-2 m above the seabed at each of the same six sites before, during and after the two bleaching events. The photos were then stitched together to generate a composite mosaic image approximately 10m by 10m. Tissue samples were analyzed using quantitative-PCR to determine the relative abundance of *Symbiodinium* from clades A-D in each of the corals. Plots (pie charts and bar graphs) depicting symbiont community structure in each of the tagged colonies were layered over the landscape mosaics using ArcGIS to assess linkages between symbiont types, mortality (partial and full), and recovery. These data will provide insight into landscape patterns of bleaching and recovery, providing managers with information about bleaching patterns at the reef-scale and the role that *Symbiodinium* play in these trends.

MANGING DREDGING NEAR CORAL REEFS (Abstract ID: 28779)

Maintenance and capital dredging represents a potential risk to tropical environments, especially in turbidity-sensitive environments such as coral reefs. There is a need to develop water quality thresholds for dredging near coral reefs that can relate physical pressures to biological responses and define exposure conditions above which effects could occur. These thresholds can then be used for day-to-day management purposes. Water quality characteristics during dredging have, however, not been well described and this information is needed to test realistic exposure scenarios, to better understand the seawater-quality implications of dredging, and ultimately to better predict and manage impacts of future projects. Using water quality information from three recent major capital dredging programs in North Western Australia, we describe sediment particle sizes in the water column and seabed, suspended sediment concentrations at different temporal and spatial scales during natural and dredging-related turbidity events, and changes in light quantity/quality underneath plumes. These conditions differ considerably from those used in past laboratory studies of the effects of sediments on corals. Other problems associated with using information from past studies for developing thresholds include the existence of multiple different and inter-connected cause-effect pathways (which can confuse/confound interpretations), the use of sediment proxies, and the reliance on information from sediment traps to justify exposure regimes in sedimentation experiments.

TRANSBOUNDARY CORAL REEF MONITORING FOR THE GRENADINES NETWORK OF MARINE PROTECTED AREAS (Abstract ID: 28356)

The establishment of GNMPA was led by local transboundary NGO the Sustainable Grenadines Inc SusGren. In 2011, SusGren established the GNMPA in order to strengthen MPA management on the Grenada Bank. At a meeting in June 2014, the GNMPA set short-term goals to train at least one staff member from each of the six participating MPAs in coral reef monitoring, and to establish one long-term coral reef monitoring site in each of the MPAs in the coming year (2014-2015). The Network selected the Atlantic and Gulf Rapid Reef Assessment (AGRRA) protocol for reef ecosystem monitoring. Small grants under a U.S. National Fish and Wildlife Foundation project were used to sponsor an AGRRA coral reef monitoring training workshop and the first Grenadines-wide field work expedition by and for members of the Grenadines Network of Marine Protected Areas. We will present findings about the condition of coral reefs across two countries and six biologically-connected MPAs and highlight lessons learned for MPA management in this and other locations in the Caribbean. All except for one site exhibited high coral cover and low fleshy macro algal cover relative to the Caribbean regional averages reported by AGRRA. Several MPAs have the potential to tip the balance back towards coral dominated reefs if herbivores are brought back (eg. by protecting parrot and other fish). Fish biomass, particularly of commercially important species such as groupers and snappers, was found to be significantly lower in the Grenadines MPAs than Caribbean regional averages, indicating strategic directions for education and outreach, enforcement and ongoing monitoring.

INTEGRATED INSTRUMENTATION FOR MARINE ENVIRONMENTAL MONITORING (Abstract ID: 30127)

Persistent environmental monitoring can offer unparalleled information about marine ecosystems but presents several challenges for instrumentation and data processing. Here we describe two novel systems to enhance capabilities and reduce costs for environmental monitoring: 1) an Intelligent Adaptable Monitoring Package (iAMP) that integrates a flexible suite of instrumentation into a single, streamlined body and 2) the infrastructure allowing an inspection class ROV and custom tool skid to deploy the iAMP to a cabled docking station. The monitoring capabilities supported by the iAMP can provide real-time visual and acoustic data of the surrounding marine environment for multi-month deployments. Instrumentation supported by the iAMP prototype includes a hybrid stereo-optical and acoustical camera system, a multi-beam sonar, a localizing hydrophone array, fish tag receiver, and an acoustic Doppler wave and current profiler. The adaptable design of this platform allows researchers to customize the instrument

configuration to address evolving research goals. The iAMP software integrates the data streams from all instruments to achieve situational awareness through sensor fusion. This allows the iAMP to continuously monitor all sensors, but only archive events of significance for post-processing. Integration also minimizes interference between active acoustic instruments. While motivated by marine energy applications, the iAMP can provide researchers with new information about a range of marine ecosystems.

## DISENTANGLING THE ROLE OF HUMAN AND NATURAL DRIVERS OF MULTIPLE REEF REGIMES ACROSS THE HAWAIIAN ARCHIPELAGO (Abstract ID: 29800)

In the face of global change and increasing anthropogenic impacts, there is an urgent need to understand the human and natural drivers that support or undermine different reef regimes. A key challenge for coral reef management is to understand how these different drivers combine and interact to affect coral reef systems. Here, we use one of the most extensive natural and human driver dataset ever put together for the main Hawaiian Islands, in conjunction with the recent identification and mapping of five distinct ecological reef regimes occurring across the archipelago. We draw on a combination of machine learning methods to identify non-linear relationships, quantify the thresholds, and characterize the interaction patterns that explain the occurrence of the different regimes. The study provides novel insights into the multi-scale dynamics of Hawaiian reef regimes and allows a comprehensive assessment of what drives them. Results should aid practitioners and managers to move towards practical implementation of ecosystem-based management by helping them understand the combined influence of key anthropogenic (fishing pressure, sedimentation, effluent, habitat modification, invasive species) and oceanographic (wave energy, chlorophyll-a, irradiance, temperature) drivers.

## REMOTELY PILOTED AIRCRAFT SYSTEMS: BRIDGING THE SCALE GAP BETWEEN FIELDWORK AND REMOTE SENSING FOR CORAL REEF MONITORING (Abstract ID: 28105)

Remote sensing plays a critical role in understanding reef spatial patterns related to habitat distribution, productivity, geomorphic zonation, bathymetry, water quality, and water temperature at scales of square meters to square kilometers. Yet while satellites provide large area coverage at moderate to high spatial resolutions, there is a considerable scale gap between space-based and in-situ ground-based observations. Manned aircraft can be used as suitable intermediaries, but are expensive. Enter remotely piloted aircraft systems (RPAS, or drones). Recent technological advances have allowed RPAS to progress from initially providing highly detailed pictures, to producing highly detailed maps. Quality sensor miniaturisation also means that RPAS are becoming increasingly capable of carrying thermal and even hyperspectral sensors, providing a complete image acquisition package. Here we detail the development two systems providing niche capabilities with pilot study data presented from Heron and Orpheus Reefs, Great Barrier Reef. Using a combination of off-the-shelf (3DR Solo + FLIR Vue Pro + Go Pro), and research systems (Aeronavics Icon + Headwall NanoHyperspec + FLIR A65 + Sony a7R), we'll present both thermal and optical data used to assess water temperature variability, as well as benthos type at temporal and spatial scales not previously possible. We document the accuracy and benefits of the systems and their resultant data, and also assess the practical, logistical, and administrative challenges associated with developing the capability for coral reef monitoring.

## NON-DESTRUCTIVE METHOD FOR COLLECTING INVERTEBRATE SPECIMENS INHABITING CORAL COMMUNITIES USING IMPROVED LIGHT TRAP (Abstract ID: 29118 | Poster ID: 297)

Coral communities providing various micro-habitats and food source for many parasitic or symbiotic invertebrates showed higher biodiversity index and have been known as one of the most important habitats than others communities. However, many coral species are in need of effort for the global conservation and registered in the Red List of IUCN (International Union for Conservation of Nature and Natural Resources). For the preparing efficient management method for conservation of coral communities, it is necessary to generalize overall information about the other parasitic or symbiotic invertebrates including present condition of distribution and interaction between them, but many existing methods of taxonomical and ecological researches have been induced disruptions of coral community habitats. In this study, we improve the existing trap using light source for the development collecting methods of various invertebrate specimens without destruction or disturbance in coral communities. The example researches have been performed from soft coral communities in Jeju Is, South Korea, and can be secure various small crustaceans, as a result. Considering only amphipods, 46 species assigned from 41 genera of 30 families are identified, and 13 gammaridean and 10 hyperiid species can be candidated in new to Korea or new to science among them. Therefore, it is useful tool to acquire various invertebrate specimens inhabiting coral communities without damages to habitats and specimens itself.

## HOW TO HAVE YOUR FISH AND EAT THEM TOO: MANAGING PERIODICALLY HARVESTED CLOSURES FOR LONG-TERM SUSTAINABILITY (Abstract ID: 27899)

Periodically harvested closures (PHCs) are small fisheries closures that vary in temporal duration and harvest regime and are the most common management strategy in locally-managed marine areas throughout the Pacific. The main motivations for employing PHCs are to sustain fisheries and increase catch efficiency, which presents a tradeoff. We present an analytical framework that informed our research to assess whether PHCs can effectively achieve multiple objectives. We found on average that pre-harvest protection benefits were greater with: high compliance; bigger, older closures; and high fishing pressure outside of PHCs. Reduced wariness in targeted fish was more likely to be observed before increases in abundance or biomass, though harvest events resulted in a rapid increase in fish wariness. Our theoretical model suggests that when fish behavior is considered, PHCs can be a more efficient strategy for achieving multiple objectives than permanent no-take areas or non-spatial management. A literature review revealed that there were insufficient data to evaluate more complex questions of recovery potential and whether PHCs can maintain absolute yields. Empirical data from Fiji one year after harvests show PHCs did not recover to pre-harvest levels or provide post-harvest recovery benefits for targeted fish. Questions regarding long-term sustainability of PHC practice are being addressed using simulated fisheries models calibrated with empirical data to provide guidance on what harvest regimes and relative sizes of PHCs are most effective for achieving multiple objectives.

SEASONAL VARIATION IN CORAL THERMAL PERFORMANCE ON THE GREAT BARRIER REEF (Abstract ID: 28957)

Thermal performance curves (TPCs) describe the relation between temperature and the rate of physiological processes, such as growth and photosynthesis. These relationships are species-specific and depend on environmental conditions. Previous studies have shown seasonal variation in coral bleaching thresholds, but it is unknown if this is driven by a change in the shape of the TPC. This study aimed to quantify differences in TPCs between winter and summer for a bleaching tolerant coral species, Porites cylindrica, and a bleaching sensitive coral species, Acropora valenciennesi, from the Great Barrier Reef. Photosynthesis rates, respiration rates and photosynthetic efficiency (Fv/Fm) were measured in winter and summer on coral fragments exposed to an acute temperature increase and decrease up to 5 degrees C above and below the average seawater temperature (24 degrees C in winter and 29 degrees C in summer). In winter, photosynthesis rates were highest around 24 degrees C, suggesting physiological acclimation that maximises performance at the average temperature of the environment. However, respiration rates and Fv/Fm were linearly related to temperature suggesting that thermal acclimation does not occur. TPCs measured in summer will be compared with those measured in winter to assess the magnitude of seasonal acclimation and whether the capacity for acclimation differs between species. Quantification of TPCs will improve our ability to project responses of coral populations to climate change by identifying the physiological processes that underlie thermal acclimation.

THE HERITIBILITY OF CORAL TOLERANCES TO OCEAN ACIDIFICATION (Abstract ID: 29299 | Poster ID: 41)

The release of carbon dioxide due to human activities is leading to ocean acidification, which is expected to reduce coral growth rates, but the magnitude of such responses vary from study to study. Corals upregulate pH at their site of calcification, and some of the variation reported for coral responses to reduced pH may be the result of differing capacity to regulate internal chemistry. Heritable variation underlies the potential for evolution over time, but the degree of variation in pH tolerances among corals, as well as the heritability of any such variation, is unknown. Here we examine the heritable variation among eight of the dominant, Hawaiian coral species to ocean acidification (n = 15 colonies per species). Coral colonies were sampled across natural gradients in seawater chemistry from a total of six different locations around O'ahu, Hawai'i. Corals were allowed to acclimate in a common garden for at least 2 months, and then assessed for their sensitivity to reduced pH in an aquarium experiment.

LOCAL ADAPTATION DRIVES CORAL RESILIENCE TO OCEAN ACIDIFICATION AND CLIMATE CHANGE (Abstract ID: 29277)

Mass coral bleaching events are expected to become more common as the climate warms, but the long-term trajectories of bleached and non-bleached corals may be impacted by ocean acidification. In response to a mass bleaching event during September 2014 in Hawai'i, bleached and non-bleached colonies of the corals Montipora capitata and Porites compressa were sampled from a low-pH, high-temperature environment in Kane'ohe Bay, and from a nearby, normal-pH, normal-temperature environment off Waimanalo. To examine the effects of ocean acidification on bleaching recovery, corals were exposed to two levels of pH in an aquarium experiment for 12 months using flow-through, Kane'ohe Bay seawater, and the parent colonies sampled in Kane'ohe Bay were tagged and monitored for recovery under natural, field conditions (n = 6 colonies for each set of conditions). A second mass bleaching event occurred in September 2015, allowing us to examine the influences of both fixed and plastic responses by corals to repeated temperature stress. Corals from the low-pH, high-temperature site, Kane'ohe Bay, showed higher tolerances to low pH and elevated temperature as compared to those from Waimanalo. Likewise, bleaching responses were consistent across years among coral colonies from Kane'ohe Bay, both in the field and in the aquariums. Together these results show that pH and temperature tolerances in these two coral species depend strongly on fixed, heritable traits, and suggest that reef-scale resilience to global change can be driven by rapid, local adaptation among corals.

BUILDING LOCAL CAPACITY BY INCORPORATING REEF CHECK AMERICAN SAMOA INTO ELEMENTARY SCHOOLS IN THE TERRITORY. (Abstract ID: 29741 | Poster ID: 560)

Our reefs provide a home to a vast assortment of marine life while also supporting a diverse array of consumptive and non-consumptive human uses. Village communities in American Samoa have for many years managed their reef areas and enforced their village rules and regulations. As a tradition, villagers have practiced their traditional fishing methods when utilizing their reef areas. These safe and effective traditional fishing practices were often used and the results were plenty of fish and shellfish caught for family consumption. As the years passed by, the American Samoa has gone through major changes over the century, as change is inevitable. These changes include new and advanced fishing methods, rapid growth of population, coastal development, pollution and overfishing. As a result, increasing demands on have been placed on our near shore resources that have altered the approaches and perceptions of the local people on using marine resources to earn more and live better. This project aims to empower youth to appreciate coral reefs and the marine organisms it supports. Incorporating Reef Check American Samoa (RCAS) into the Department of Education helped to achieve some of the objectives stated in the standards and benchmarks for marine science classes. RCAS helped to teach students in their early age about the importance of coral reefs, different roles played by different organisms in the reef and carried out simple scientific survey methods on selected reef fishes, invertebrates and substrates. Students also looked into some of the human activities that are currently affecting local reefs and participated in hands-on activities in order to help the community, collecting trash to prevent it from polluting the water and speaking on the radio about what needs to be done by the community to help save their coral reefs. RCAS aided in the perception of ownership of reefs, help intensify local management capacity within the communities, and provide a broade

'UKU 'AKO'AKO'A: KIN RELATIONSHIP BETWEEN THE CORAL AND PEOPLE IN NATIVE HAWAIIAN EPISTEMOLOGY (Abstract ID: 28875)

As the indigenous people of an island chain surrounded by coral reefs in the center of the Pacific Ocean, Native Hawaiians have profound ancestral and spiritual connections to the coral. Oli (chants), hula (dances), mele (poetry), and mo'olelo (mythology) of Hawai'i are vessels of scientific knowledge acquired through observations and test of time over generations. Many of these forms of knowledge speak to the kin relationship between the coral, among other organisms, and people. For example, the Kumulipo, a chant that traced the genealogy of the chief Lonoikamakahiki to the environmental deities, describe the coral as the first-born organism in the Hawaiian universe. Another chant 'Uku 'Ākoʻakoʻa further expands this ancestral presence of coral to growth of coral reefs as metaphors of personal growth. A hula, I Kanaloa 'o Kanaloa, speak of primordial presence of the ocean in Hawaiian people's psyche that is embodied by the coral. The four cohorts of students of a class called "Kū'ula: Integrated Science" at the University of Hawai'i at Hilo have developed ways to integrate Native Hawaiian and Western sciences to understand the environment of Hawai'i to manage it in ways that integrate natural and human dimensions. We will present a Native Hawaiian understanding of the intersection of natural and human dimensions pertaining to the coral in the hula and chant formats.

TAGGING BONEFISH IN HAWAII: EMPOWERING ANGLERS IN SCIENCE (Abstract ID: 29269)

'Ō'io (bonefish) were important to early Hawaiian culture and are one of the most highly sought after recreational fisheries species in modern day Hawaii. Two species of 'ō'io inhabit Hawaiian waters and are targeted by a mix of commercial and recreational fisheries. The 'Ō'io Tagging Project arose from a consensus that collecting biological and fisheries data on 'ō'io is essential to properly manage this resource, while engaging resource users and disseminating this knowledge back to them is equally as important for long-term sustainability of these fisheries. Outreach events allow for interaction with anglers and the project's mission is manifest through magazine articles, social media, scientific publications, and an interactive website. Since 2003, more than 870 anglers have recorded over 11,000 fishing hours, while tagging 3,500 and recapturing 85 'ō'io. Tagged

ʻōʻio exhibited extremely high site fidelity, with 80% recaptured less than 1 km from their original tagging location. Angler participation and collaboration has extended the project to provide the opportunity to study diet, age, growth, and reproduction. This project serves as an excellent vehicle to include resource users in collecting species-specific life history information and fisheries data that can be used in population assessments and management decisions.

HIGH-ENERGY WINDOW IN MODERN REEFS: AN EXAMPLE FROM MULTI-BEAM BATHYMETRIC MAPPING OF REEF GEOMORPHOLOGY AROUND THE RYUKYU ISLANDS (Abstract ID: 28111)

Accurate descriptions of coral reef geomorphology improve our understanding of reef environments. Since 2010 we have been conducting high-resolution multibeam bathymetric surveys around the Ryukyu Islands, southern Japan, and mapping the coral reef geomorphology with a horizontal grid size of 1–2 m. Here, we introduce our mapping project, which covers of a total of 39 surveyed areas across five islands, and present an example illustrating the barrier reef and island shelf geomorphology of eastern Kume Island (1.8 × 6.5 km bathymetric area, with a depth range of 0.4–161.3 m) combined with SCUBA and VTR observations. The bathymetric area comprises two contrasting reef edge formations: a double reef in the western area, and a deep breakwater reef in the eastern area. The latter shows the high-energy window condition which is accompanied by spur and groove formation in the lagoon, formation of circular spits or bowl-shaped depressions behind the lagoon patch reefs, and traces of movement of coral boulders in the lagoon following typhoon storm surges. These observations enable us to understand and reconstruct the paleo-geomorphology and sedimentology in reefs associated with the Holocene high-energy window, and can also contribute to predictions of coastal environmental change associated with future sea level rise. On the island shelf, we observed five reef terraces at depths between 80 and 95 m, and isolated patch reefs at 135 m depth. The discovery of these features may contribute to reconstructions of past sea level and reef growth in the northwestern Pacific.

CORALSPEQ AND PHOTOSYNQ: AN OPEN, FIELD-DISTRIBUTABLE PLATFORM FOR PROBING CORAL HEALTH ON LOCAL AND GLOBAL SCALES (Abstract ID: 29910)

We have developed an inexpensive but sophisticated field-portable instrument, called CoralspeQ, that dramatically lowers the entry barriers making detailed phenotypic measurements of coral host and its symbiotic algae (as well as other marine photosynthetic organisms) to enable researchers, park rangers and citizen scientists all over the world to probe coral health and the factors that may affect bleaching. CoralspeQ measures spectroscopic properties (both reflectance and fluorescence) under a range of excitation conditions to estimate pigment composition and photosynthetic properties. CoralspeQ is open-source, highly affordable, easy to use and highly expandable. Data from field sites are instantly uploaded to PhotosynQ for both local and global data analyses to reveal new trends that can be used to assess the progress of coral bleaching, test mechanistic hypotheses, and ultimately lead to new coral conservation approaches. Tests in the field and laboratory showed that we could use the signals generated by CoralspeQ to distinguish between "stressed" and healthy corals (See presentation by Ralph et al.). This presentation will describe demonstrations, opportunities to test the platform live and discuss how researchers can gain access to both CoralspeQ and PhotosynQ.

SPONGES AS A MICROHABITAT FOR MACROFAUNA AND MICROBES ACROSS ECOLOGICAL GRADIENTS IN THE CENTRAL RED SEA (Abstract ID: 29140)

Sponges act as important microhabitats and promote biodiversity by harboring a wide variety of macrofauna and microbiota, but little is known about the relationships between the sponges and their symbionts. This study uses DNA barcoding to examine the macrofaunal communities associated with sponges of the central Saudi Arabian Red Sea, an understudied ecosystem with high biodiversity and endemism. In total, 185 epifaunal and infaunal operational taxonomic units (OTUs) were distinguished from the 1399 successfully-sequenced macrofauna individuals from 129 sponges representing seven sponge species, one of which (*Stylissa carteri*) was intensively studied. A significant difference was found in the macrofaunal community composition of *Stylissa carteri* along a cross-shelf gradient, and sponge abundance increased with proximity to shore. The difference in macrofaunal communities of several species of sponges sampled from one location was found to be significant as well, using OTU presence (binary Jaccard diversity index). Four of the seven sponge species collected were dominated by a single annelid OTU, each unique to one sponge species. A fifth was dominated by four arthropod OTUs, all species-specific as well. Results will also be presented based on the diversity of the microbial communities found in the sponge samples. As climate change and ocean acidification continue to modify coral reef ecosystems, understanding the ecology of sponges and their role as microhabitats may become more important.

EVALUATING POTENTIAL MECHANISMS UNDERLYING TROPHIC ASSEMBLAGE SHIFTS IN REEF FISHES FROM SHALLOW TO MESOPHOTIC DEPTHS IN HAWAII. (Abstract ID: 28224)

Herbivorous reef fishes are considered integral components of healthy coral reef ecosystems, yet initial studies of mesophotic coral reefs (>30m) indicate vast reductions in herbivorous reef fish communities compared to their shallow congeners despite observations of high algal abundance at mesophotic depths. Preliminary hypotheses regarding the reduction in herbivorous fishes with depth propose that 1) decreased light levels may reduce habitat quality, 2) reductions in water temperature inhibits fishes' digestion of algal tissues, and 3) algal abundances are reduced or chemically defended on deep reefs. We conducted surveys along stratified depth gradients in West Hawaii to assess variability in reef fish trophic assemblages, temperature, and habitat metrics with depth. We then conducted choice experiments to determine the palatability of common algal species in mesophotic depths. Our findings support previous studies of reduced herbivorous reef fish abundances with depth, yet the absence of herbivores at depth does not appear to be associated with variations in temperature, habitat complexity or turf algal cover. Instead, herbivore reductions were positively associated with reductions in coral cover and negatively associated with increasing macroalgal cover with depth. Algal choice experiments revealed that deep algal species are edible and quickly consumed by shallow herbivorous fishes. These findings suggest changes in herbivore populations with depth are more complex than habitat quality, temperature, or food availability previously hypothesized.

UNWINDING THE MYSTERY OF CORAL BROADCAST MASS SPAWNING, SIGNALING CASCADES AND THE IMPORTANCE OF MOONLIGHT (Abstract ID: 28571)

The geophysical cycles in our planet Earth are mirrored in evolving endogenous clocks allowing organisms to anticipate daily and seasonal rhythms and to adjust their biochemical, physiological and behavioural processes accordingly. Many corals participate in a yearly cycle known as the mass-spawning event. This reproductive event is one of earth's most prominent examples of synchronised behaviour and coral reproductive success is vital to the persistence of coral reef ecosystems. Although several environmental cues have been implicated in the timing of mass spawning, the specific sensory cues that function together with endogenous clock mechanisms to ensure accurate timing of gamete release are largely unknown. Recently we have characterized the transcriptomes of two coral species A. millepora and A. digitifera by sampling colonies at different timelines; before, during and post spawning. Our finding show that moonlight is an important external stimulus for mass spawning synchrony and describe the potential mechanisms for the signalling cascades that ultimately result in gamete release. We identify transcripts

that vary only on the spawning night, with upregulation of light-sensing molecules and rhodopsin-like receptors that initiate different signaling cascades such as the glutamate pathway, SMAD signaling pathway, WNT signaling pathway, neuroactive ligand-receptor interaction and calcium signaling. These signaling pathways are involved in cell cycling, cell movement, tissue polarity, focal adhesion and cytoskeleton reorganization, which together, lead to gamete release.

RECOVERY AND REORGANISATIONS OF CORAL REEFS DUE TO THE COMBINED EFFECT OF OCEAN WARMING AND ACIDIFICATION IN THE GULF OF MANNAR AND PALK BAY, INDIA (Abstract ID: 29414)

Episodic bleaching phenomena occurred around the globe since 1998 recurrently including India. Recurrent bleaching incidences resulted in the loss of live coral cover along with the changes in the coral community structure of the reefs. After the 1998 and 2002 massive bleaching phenomena in the Gulf of Mannar and the adjacent Palk Bay, significant recovery of live coral cover was observed. Conversely, after the 2005, 2006, 2010 and 2013 bleaching incidences, coral cover has continued to decline in response to multiple smaller bleaching events in the Palk bay reefs and Gulf of Mannar. Despite the severity of bleaching, recovery of coral species belongs to the families such as Porites, Favites, Montastrea, Favia, Platygyra, Symphillia and Goniastrea have been recorded. However, significant decline was also observed among the dominant reef builders belong to the families viz., Acropora, Montipora, Pocillopora and Galaxea in the reefs of Palk bay and some reefs in the Gulf of Mannar after successive bleaching events. In spite of the catastrophic bleaching events and associated triggering factors such as ocean acidification, data sets of the biophysical status of corals from 1996 to till date revealed that the transition of coral reef ecosystem with slight changes in the ecosystem functions in the reefs of Gulf of Mannar and Palk Bay is evident. The study also stressed the need for strong commitment and management towards maintain ecosystem services of the coral reef ecosystem of the Gulf of Mannar Marine Biosphere Reserve and Palk Bay resilience by restoring healthy levels of herbivory, macroalgal cover, streamlining the fishing practices and monitor the coral recruitment.

THREE CORAL HEALTH PROJECTS IN COLLABORATION WITH NOAA EDUCATIONAL PARTNERSHIP PROGRAM (Abstract ID: 28168 | Poster ID: 684)

NOAA's Office of Education has several programs, one is the Educational Partnership Program (EPP) where NOAA scientists submit proposed opportunities for students participation in various projects. If selected, the NOAA opportunity is circulated among students associated with four focused centers and corresponding NOAA line offices; the Environmental Cooperative Science Center (ECSC) / NOS, the NOAA Center for Atmospheric Science (NCAS) / NWS, the Cooperative Remote Sensing Science and Technology (CREST) / NESDIS, and the Living Marine Resources Cooperative Science Center (LMRCSC) / NMFS. We present three examples of the successful partnerships between NOAA coral science projects in Hawai'i and Puerto Rico and students provided via the EPP and how these projects address the goals of bridging science to management and policy.

CORAL REEF SOUNDSCAPES MAY NOT BE DETECTABLE FAR FROM THE REEF (Abstract ID: 28064)

Biological sounds produced on coral reefs may help pelagic larvae identify suitable settlement habitat. Evidence that reef sound may play such a role has been unearthed in several studies. Some coral reefs may also be high amplitude sources, suggesting that this sound could be a long-range settlement cue. To date there have only been a small number of studies that have explored how far sound pressure might propagate. In addition to pressure, sound fields are composed of particle motion, which is the vibratory back and forth movement of acoustic particles and the component of the sound field that most fishes and invertebrates are able to detect. However, there are no field measurements of particle motion propagation. To address this deficiency, both sound pressure and particle motion were recorded at a range of distances from one Hawaiian reef at dawn (to capture fish choruses) and mid-morning (as a comparison) on three separate days. Sound pressure attenuated with distance from the reef at dawn but not during the mid-morning. Similar trends were apparent for particle velocity but with more variability. Average levels were low and perhaps too faint to be used as an orientation cue over long distances. However, individual transient sounds, which exceeded the mean values by up to an order of magnitude, might be detectable at greater distances from the reef, depending on their attributes and the hearing abilities of the larva. If sound is not being used as a long-range cue, it might still be useful for near-reef orientation at night or for habitat selection within a reef.

VISUALIZING THE 3D SPATIAL DYNAMICS OF CHEMICAL AND MICROBIAL SIGNATURES ON CORALS (Abstract ID: 28380 | Poster ID: 108)

Coral reefs are one of the planet's most threatened marine ecosystems. Similar to other animals, corals possess a highly complex microbial community that facilitates optimal physiological function for both themselves and their surrounding environment. Unexpected microbial and chemical shifts can have severe consequences on the survival of corals, and thus the entire ecosystem. The development and implementation of innovative macro- and micro-scale imaging mass spectrometry tools has allowed for rapid identification of chemical signatures from organisms. This technology has been combined with emerging photogrammetric techniques to provide, for the first time, 3D spatial visualization of coral molecular features. Molecular profiles were obtained from the interaction among several species of Hawaiian corals. Distinct diurnal metabolic patterns were observed in the Montipora capitata coral affected with tumor-like lesions. Using open-sourced metabolomic profiling tools, such as Global Natural Product Social molecular network (GNPS.ucsd.edu), several coral associated specialized metabolites were identified. Furthermore, by combining imaging mass spectrometry and 16s microbial profiling, correlations between coral metabolites and the spatial distribution of bacterial communities throughout the coral colony surface were characterized in 3D space. By implementing a highly interdisciplinary analytical workflow in chemistry, biology and virtual reality technologies, this study provides an innovative platform to better understand the molecular space of complex coral ecosystems.

WORKING TOGETHER TO UNDERSTAND, QUANTIFY AND MANAGE FOR TIPPING POINTS ON THE REEFS OF HAWAII (Abstract ID: 30096 | Poster ID: 590)

Tipping points occur when small shifts in human pressures or environmental conditions bring about large, sometimes abrupt changes in a system – whether in a human society, an ecosystem or our planet's climate. This talk introduces the Ocean Tipping Points project, a multi-year, multi-organization effort to advance our understanding of abrupt shifts in marine ecosystems and improve ocean management. We present results of our research on ecosystem shifts on reefs of Hawaii and discuss implications for reef management and the benefits of collaborative engagement between scientists and practitioners. In this multi-sector, interdisciplinary collaboration, scientists and governmental and non-governmental experts are working together to better understand complex reef ecosystems and develop management tools to sustain them. By integrating an unprecedented body of newly synthesized benthic and fish community data and novel, spatially explicit datasets representing environmental and anthropogenic drivers, we provide evidence for the existence of multiple reef regimes across the Main Hawaiian Islands and nonlinear relationships between regimes and their drivers. These quantified threshold responses of reef state to multiple stressors provide a useful set of reference points to inform targets for reef protection and restoration. Using tradeoff models we examine costs and benefits of different management actions aimed at reaching those targets. We

conclude by demonstrating how these analyses are supporting efforts to mitigate local stresses and enhance resilience of Hawaiian reefs.

PREDICTING CLIMATE IMPACTS ON HAWAIIAN CORAL REEF FISHERIES: ARE CONTEMPORARY SPATIAL MANAGEMENT STRATEGIES SUSTAINABLE? (Abstract ID: 28214)

Simulation models of coral reef ecosystems predict severe negative ecological responses to climate change. We evaluate the potential consequences of spatial harvesting strategies for tropical reef fisheries of the Hawaiian Islands under two IPCC climate scenarios that accounted for spatial heterogeneity in environmental forcing functions, including climate change-mediated disturbances and nutrification from terrestrial run-off. We simulated a suite of scenarios to test the interaction between the proportion of marine habitat area closed to fishing (as no-take MPAs) at 0%, 10%, or 20%, habitat loss from coral bleaching, and the effect of elevated nutrients on interference competition between benthic functional groups, at a 100 year time horizon. We found that the establishment of MPAs increased both biomass and catch of reef fish across all functional groups (herbivorous, small piscivorous, and large piscivorous) for all scenarios as a shift from coral-dominated to algae-dominated habitats drove a lagged increase in herbivorous fish populations and their predators. However, heightened nutrification of the same reefs protected from fishing resulted in a diminished protection effect, rendering coral and macroalgal cover in high-nutrient, high MPA proportion scenarios similar to low-nutrient scenarios with far less fishing protection. A future wherein reefs retain low coral cover and a functional biomass of herbivores is demonstrated as possible in the context of spatial fishery management under climate change.

THE EVOLUTION OF BEST PRACTICES TO PREVENT, ASSESS, AND MITIGATE CORAL REEF IMPACTS IN THE ATLANTIC/CARIBBEAN (Abstract ID: 29655)

Large-scale coastal development and infrastructure projects have and will continue to result in considerable loss of coral reef habitats world-wide. Best practices for coral reef impact avoidance, assessment, and mitigation options have evolved considerably in recent years in the Atlantic/Caribbean. However, caution is needed in applying impact assessment design achievements from one project to others as regional and local differences in oceanographic conditions and habitat types may require adjustments in order to replicate the initial success. Effectively capturing lessons from planned projects and socializing the lessons learned with participants involved in the planning process is also essential to ensuring projects are designed in a manner that prevents and minimizes coral reef impacts to the extent possible. The progress made in these areas in the Atlantic/Caribbean is applicable to other coral reef regions.

SHOULD ENVIRONMENTAL POLICY AND ADVOCACY FOCUS ON THRESHOLDS OR DEGRADATION? (Abstract ID: 30148)

Uncertainty is unavoidable when addressing the threats posed by everything from greenhouse gas emissions, to nutrient pollution, to ocean acidification. Unfortunately that uncertainty can be used as an excuse for not taking action. Inspired by some game theoretic results, we examine several case studies to determine whether focusing on degradation with uncertainty about its magnitude or focusing on thresholds with uncertainty about where those thresholds lie differ in their ability to promote action and appropriate policy responses. While our case studies are drawn from a wide variety of systems, they apply to how we approach the management and conservation of coral reefs.

COPING WITH CATASTROPHE: BEHAVIORAL FLEXIBILITY ENABLES A LONG-LIVED BENTHIC PISCIVORE TO SURVIVE IN RAPIDLY DEGRADING REEFS (Abstract ID: 28636)

Coral reefs have rapidly lost their architectural complexity in the last two decades from repeated mass-bleaching catastrophes. Understanding the ability of species to cope with this change is critical to determine winners and losers in the face of climate change. To understand which species are surviving in degrading coral reefs, we studied the distribution of a guild of structure-dependent, long-lived predators (groupers) in the Lakshadweep archipelago, along a gradient of reef structure, which has declined with repeated disturbances since 1998. Three of the six most abundant grouper species were seen only in reefs which had a structural canopy of >60 cm. However, the peacock grouper (Cephalopholis argus) dominated species assemblage across the gradient. We explored mechanisms of behavioral flexibility that enables C. argus to survive in degraded reefs. Where potentially less flexible species drop out, C. argus shows a dramatic switch in foraging behavior beyond the 60 cm structural threshold. Territory sizes increase exponentially as prey and competitor densities decline. But C. argus maintains a highly selective diet even in the most degraded reefs, by modifying its foraging mode from a structure-dependent 'ambush' to a structure-independent 'widely- foraging' mode. The ability to maintain trophic position with behavioral flexibility may be a key trait, allowing species to adapt to structurally declining reefs. With rapid environmental change, these adaptable species may perform important predatory functions, maintaining the overall resilience of reefs.

CHARACTERIZING CHEMICAL COMPOSITION OF SIZE-FRACTIONATED PARTICULATE ORGANIC MATTER IN A FRINGING CORAL REEF OF MALAYSIA (Abstract ID: 29146 | Poster ID: 218)

Particulate organic matter (POM) is comprised of microplankton, nanoplankton and picoplankton depending on its size definition. It is assumable that each fraction has different compositions of organisms such as phytoplankton, flagellates and bacteria due to their size ranges. Our goal of this study is to characterize the size-fractionated POM by chemical compositions, especially organic compounds and stable isotopes. Seawater samples were collected at Bidong Island, Malaysia (tropical), Sesoko Island (subtropical) and Sagami Bay (temperate), Japan in 2014 and 2015. Seawater was filtered through nylon meshes with different pore sizes: 2, 20, 100 and 180 μm. POM in each size fraction was collected on GF/F filters. Organic compounds were detected and identified by pyrolysis gas chromatography/mass spectrometer, and stable isotopes were measured by elemental analyzer/isotopic ratio mass spectrometer. The concentration of chlorophyll-a (chl-a) was measured by a fluorometer. In all the studied sites, the smallest size fraction indicated the highest chl-a concentrations, implying a large contribution of cyanobacteria. In Bidong Island, there were no significant differences in stable carbon isotopic values among the size fractions. On the other hand, the stable carbon isotopic values values in Sesoko Island and Sagami Bay were significantly different between the fractions larger and smaller than 20 μm. Our results implied that the difference in organic matter composition of POM could be well characterized by the abundance of micro- and nano-plankton.

CORAL TRANSPLANT SUITABILITY STUDY OF OKINOTORISHIMA BY THE SUPERPOSITION OF CORAL DISTRIBUTION AND HABITAT CONDITION. (Abstract ID: 28533 | Poster ID: 487)

In the aim of enlarging coral distribution, a coral transplantation suitability study was conducted at the inner reef of Okinotorishima,which is located at the southernmost end of Japan. The study was carried out by superimposing the coral distribution on the habitat conditions in the coral reef by using GIS (Geographic Information System). The following four conditions are ideal for selecting transplantation. (A) Suitable locations for coral to habit. These locations were selected from high coral coverage places, places of less high water temperature frequency, and low stress places counted by Shields numbers which indicate the movement of gravel. (B) Locations where the coral coverage temporarily declined. These were selected from places where the coral coverage temporarily declined according to secular-change comparison by satellite image analysis. (C) Locations where transplanted corals could work as a source of coral larvae. These were selected by using larvae diffusion simulation. (D) Locations where ideal substrates for coral exist. These were selected from places where there are knolls that are higher than 50cm from the seafloor, which is higher than the inhabit height of the likes of Acropora tenuis – the objectives of the transplantation. Based on a result of the study, the coral transplantation has been conducted from 2014 once year. Transplantations for 400 colonies have been carried out and the survival rate maintains high state. Monitoring after the transplantation and adaptive management will continue into the future.

COMMUNITY AND ECOSYSTEM ASPECTS OF THE RECOVERY OF ATLANTIC ACROPORID CORALS: SCIENCE IN SUPPORT OF STEPWISE STEWARDSHIP GOALS (Abstract ID: 28926)

The science of species recovery for the Caribbean acroporid corals has focused largely on propagation and survival of individual coral colonies, leaving to later the process of restoring and maintaining the coral reef community as a whole. Later is now. We detail a recovery process that begins with acroporid restoration and culminates in the restoration of west Atlantic coral reef ecosystem services in an era of anthropogenic climate change momentum. The steps in this process are: (1) restoration of self-sustaining populations of the two acroporid species and their hybrid; (2) acroporid restoration triggers reassembly of a web of ecological interactions similar to reef surface dynamics prior to 1980; (3) resumption of framework construction sufficient to keep pace with sea level rise, by acroporids in concert with other framework-builders; and (4) ensurance that restored reef surface framework-building communities and their suite of associated species can sustain and renew themselves spontaneously through an at least several century-long climate recovery period. We critically examine the field interventions and science required to achieve each of these four milestones, assess potentially acceptable alternative outcomes, and consider the enabling environment of laws and actions essential for any of this to occur.

SURVIVORS OF ACROPORA MURICATA COLONIES IMPACTED BY DRUPELLA CORNUS OCCURRING UNDERNEATH PADINA BORYANA: IMPLICATIONS FOR MULTIPLE STRESSORS MANAGEMENT (Abstract ID: 29579 | Poster ID: 419)

The density of the corallivorous marine snail *Drupella cornus* and the percentage of *Acropora muricata* colonies in the coastal zone covered by the macroalga *Padina boryana* were studied over summer (March) and winter (August) months of the years 1998 and 2010-2014 at Flic-en-Flac, Mauritius. In 1998, the mean density of *D. cornus* was <1.00 $m^{-2}$ for both months and the percentage of coral colonies out of 15 covered by *P. boryana* were 11.11% and 8.89% for March and August, respectively. In 2010-2014, the density of *D. cornus* and the percentage of coral colonies covered by *P. boryana* were significantly higher in summer (17.00-30.60 $m^{-2}$; 62.22-93.33%) than in winter (0.40-5.20 $m^{-2}$; 15.56-26.67%), on account of the higher rainfall, nutrient levels and temperatures. The density of *D. cornus* and the percentage of coral colonies covered by *P. boryana* varied throughout the study period, with higher density of *D. cornus* occurring on *A. muricata* colonies covered by *P. boryana*, especially in summer. Although the coastal coral colonies have been reported to be less prone to thermal bleaching than the reef flat ones, the occurrence of *D. cornus* on colonies covered by *P. boryana* indicates that the coral might be prone to predation. This might have repercussions for multiple stressors management in terms of damage caused by *D. cornus* on*A. muricata* in Mauritian waters, especially under a globally changing ocean climate.

POLICY DEVELOPMENT ON IMPLEMENTING AN ECOSYSTEM APPROACH TO FISHERIES MANAGEMENT IN MALAYSIA IN FULFILLING OBLIGATIONS UNDER THE CORAL TRIANGLE INITIATIVE (Abstract ID: 28374)

Increased understanding of the interactions among different marine ecosystem components such as fish, people, habitats, and climate has led to the recognition and adoption of the Ecosystem Approach to Fisheries Management (EAFM) in the Coral Triangle Initiative (CTI). EAFM extends beyond fish in the seas and people in boats, to a marine environment that includes coral reefs and mangroves, and human activities covering fishers, fishing communities, and coastal development. Target 1 of Goal 2 under CTI stresses on implementation of EAFM through the adoption and implementation of strong legislative, policy, and regulatory frameworks. While Malaysia has generally been proactive in integrating EAFM into the country's natural resource regime, beginning with initiatives in Sabah, progress has been generally slow in incorporating the required changes into national policies and regulations. The experience however shows that EAFM can be scaled-up from existing pilot sites or localized management to a broader implementation strategy. Although EAFM implementation is usually deemed the responsibility of fishery agencies, its full implementation at the national level requires coordination and cooperation with other agencies and stakeholders responsible for managing related activities that impact on the marine ecosystem. Successful EAFM fisheries management initiatives in Malaysia are to be further raised by studying the dynamics of marine ecosystems, developing indices of ecosystem health, and setting management targets as a way forward.

A COMPARATIVE STUDY OF MOLECULAR PHYLOGENY AND SEXUAL REPRODUCTIVE CHARACTERISTICS IN *ZOANTHUS KUROSHIO*(HEXACORALLIA, ZOANTHARIA, ZOANTHIDAE) (Abstract ID: 28757 | Poster ID: 70)

Genus *Zoanthus* (Hexacorallia, Zoantharia, Zoanthidae) spp. are widespread, zooxanthellate, colonial benthos. In coral reefs, they are common from intertidal zone to 30 m offshore. Occasionally, they have large influence on neighboring benthos by limiting space availability. Research on *Zoanthus*spp. sexual and asexual reproduction is only fragmentary, and more work is needed to understand their dynamics within coral reef ecosystems.*Zoanthus kuroshio* is abundant in the intertidal zone of Okinawa island, Japan. Basic information such as sexuality and spawning timing is unknown. So we examine the sexual reproductive characteristics of tagged*Z. kuroshio* colonies, specifically colony sexuality, gametogenesis periods, and spawning timing in Okinawa island. Results showed the gametogenesis period of *Z. kuroshio* is from May to July, and oogenesis sets in earlier than spermatogenesis. *Z. kuroshio* is partially protogynous simultaneous hermaphrodites, and we observed colonies of three different sexualities; males, females and hermaphrodites. Spawning timing did not overlap between the colonies of each sexuality, and hence it can be thought that there was reproductive isolation between colonies. This leads to the possibility that *Z. kuroshio* contains more than one species. Accordingly, we conducted phylogenetic analyses of nuclear ribosomal ITS and 18S and mitochondrial 16S sequences. We discuss how the molecular phylogeny reflects sexual reproductive characteristics in the tagged colonies.

MODELS OF CORAL DEMOGRAPHY DURING REEF RECOVERY PROVIDE QUANTITATIVE PROJECTIONS OF CORAL COMMUNITY TRAJECTORIES AND ESTIMATES OF REEF RESILIENCE (Abstract ID: 28487)

Coral reefs are inherently resilient to perturbations. Yet coral populations are declining in many places. The question why is this so has focused much attention on identifying underlying drivers of reef resilience. How coral communities respond to disturbance appears to depend on complex interactions of abiotic and biotic processes acting at multiple scales. Understanding these processes quantitatively requires an approach that integrates empirical individual-level demography with population simulations designed to elucidate community dynamics. We used an Integral Projection Model (IPM) framework to investigate the drivers of coral community recovery in Moorea, French Polynesia. Reefs there are recovering from disturbances that decimated coral populations, providing an excellent model system to evaluate mechanisms influencing early-stage community recovery and longer-term resilience. We quantified recruitment, growth and survival of the three dominant coral genera over multiple spatial scales during the first 5 years of reef recovery. We used estimates of coral performance to construct an IPM that predicts community trajectories based on the population dynamics of the three genera. Our results indicate that spatial variability in coral recruitment, species' life histories, density-dependent regulation and local reef environment interact at different scales to influence recovery. Our approach provides the foundation to quantitatively evaluate the degree to which coral communities are resilient, and to predict the effects of future disturbances such as mass bleaching events.

ECO-TECHNOLOGICAL MANAGEMENT OF ATOLL ISLANDS AGAINST SEA LEVEL RISE (Abstract ID: 28577)

Atoll countries occupy low, narrow islands and are very vulnerable to sea level rise. However, the current problems of inundation and beach erosion reported to occur in atoll island countries result mainly either from natural processed or from local problems associated with concentration of the population to the capital islands. Atoll islands are formed by geo-ecological processes of coral and foraminifer production and their sedimentation. Deterioration of coral reef ecosystem has lead to degradation of reef formation potential to keep up with the rising sea and reduction of sand production to form the islands. Causeways between islands and jetties constructed perpendicular to coastlines prohibit sand transportation. Vertical seawalls do not enhance but inhibit sand sedimentation. These local problems decrease geo-ecological resilience to future accelerating sea level rise. For wise management of atoll island countries against sea level rise, ecosystem-based management including rehabilitation of the damaged coral reefs and minimum control of wave and current to enhance accumulation of sediment above high water level is fundamental together with grey (concrete) technology. Any grey countermeasure plans must not contradict the natural production, transportation and

sedimentation processes. The measures must be instituted with appropriate governance that incorporates traditional forms in the context of the globalized economy and society.

DIFFERENT LEVELS OF ANTRHOPOGENIC IMPACT INFLUENCE CORAL LARVAE SETTLEMENT AND RELATED BACTERIAL BIOFILM COMMUNITIES IN THE SPERMONDE ARCHIPELAGO, INDONESIA (Abstract ID: 29399)

Recruitment of coral larvae is one of the key factors for coral reef recovery. Settlement cues emitted from bacterial biofilms play a vital part in larval settlement and metamorphosis. These cues depend largely on the community composition of the biofilms, which can change drastically with altered environmental conditions and in turn may affect larval settlement behavior. This study investigated bacterial community composition and coral larvae settlement at three sites with differing distance from shore, and thus different levels of human impact and water quality, in the Spermonde Archipelago, Indonesia. Bacteria and coral larvae were investigated on natural reef substrate and artificial ceramic tiles. Bacterial communities were comprised largely of *Gammaproteobacteria, Alphaproteobacteria, Cyanobacteria* and *Flavobacteria* and were strongly correlated with water quality and benthic community composition. No coral recruits were found at the inshore site with the highest anthropogenic impact. Between the other two sites coral recruitment was similar. Path analysis modelling revealed that coral recruitment was influenced directly by water quality and the bacterial community composition, as well as indirectly due to the influence of water quality on the bacterial community. This study shows that negative anthropogenic influences on water quality affect bacterial community compositions and in turn coral larvae recruitment. It also highlights the importance of taking these often neglected factors into account in evaluating the recovery potential of coral reefs.

CAN COMPETITION MAINTAIN BIOGEOGRAPHIC BORDERS? (Abstract ID: 28349)

The role for species interactions in the generation and maintenance of biogeographic borders, where multiple species range edges meet, is unclear. Progress has been hindered by an over-reliance on indirect inference and the use of low-resolution, opportunistic data. To determine the role of competition more explicitly, we are collecting small grain behavioural data across a large geographic extent at biogeographic borders. We target these locations because sister species that have evolved allopatrically in adjacent biogeographical provinces are hypothesised to compete strongly on secondary contact, potentially explaining why these species do not further expand their ranges. Moreover, we might also expect these species to be more aggressive at range boundaries compared with widespread species that traverse biogeographic regions. We test these ideas with Indo-Pacific butterflyfishes (Chaetodontidae). Butterflyfish sister species typically have one species in each of two major biogeographic provinces - the Indian Ocean and the Pacific Ocean - and co-occur at contact zones around a few small islands between these provinces. We visited three contact zones within the central Indo-Pacific (Christmas Island, Bali, Iriomote) and one central control region (Philippines) and recorded >3000 interactions between species pairs. Here, I present preliminary data from these locations at the start of a larger project to determine whether competition could be a significant force in the maintenance of biogeographic boundaries.

`IKE KAI: AN INNOVATIVE AND ENGAGING CURRICULUM FOR THE DIVISION OF AQUATIC RESOURCES (Abstract ID: 29885)

The State of Hawai'i Makai Watch (MW) Program is a collaborative statewide program whereby citizens and NGOs systematically assist the Department of Land and Natural Resources (DLNR) in its mandate to manage marine and coastal resources. A gap was recently identified that is preventing the MW program from fully achieving its mission of building capacity for community stewardship - a lack of foundational training for MW volunteers in marine science and resource management. The goal of the 'Ike Kai curriculum project was to fill this gap by increasing MW volunteers' baseline knowledge of marine science and marine resource management, including traditional and modern use and stewardship. The term "'Ike Kai" means "to know, feel, experience, be aware, and comprehend the ocean". The 'Ike Kai curriculum was designed to inform monitoring projects, outreach activities, and marine fishery and habitat conservation projects being undertaken by these communities while strengthening the relationship with resource management agencies. To make the curriculum training relevant to each unique community, place-based material including a field kit to support outreach and monitoring activities were provided to each group. Future uses include creating an online version as a tool Environmental Court judges can use when sentencing first time resource violators in Environmental Court.

VISUAL DECISION TOOLS: AN INNOVATIVE TECHNIQUE FOR BUILDING OCEAN LITERACY (Abstract ID: 28519)

Visual Decision Tools are interrogated via a visual index rather than read - think Visual Hyperlinking - and can be in digital or print form. They have the potential to empower individuals to rapidly interrogate factual information and solve complex problems without the need for formal knowledge or prior training. Applications include marine identification and capacity building for reef monitoring and conservation. Following 6-years of testing by the Coral Identification Capacity Building Program, we demonstrate how Visual Decision Tools achieve dramatic improvements in a user's capacity to identify corals using the Coral Finder. Results from workshops in the Indo-Pacific show how this approach instantly empowers non-coral specialists with minimal training. Coral-specialists also benefited from the process. Key learnings were used in the design of the Reef Finder - a Visual Decision Tool that enables the user to put any reef organism into a taxonomic group and give visible reasons why. Results are presented showing how the Reef Finder's visual approach dramatically builds the capacity of individuals to recognise a broad range of fish and invertebrate groups with little training or formal knowledge. Visual Decision Tools can unlock existing technical tomes and datasets: e.g. retro-fitting a visual index can be a powerful way to add ease-of-use to information arranged in traditional alphabetical or hierarchical structures. Users of Visual Decision Tools are enthused by the instant success they can achieve. Design guidelines are presented for implementation in print, web and app.

MODELING MARINE METAPOPULATION CONNECTIVITY: UNDERSTANDING OCEANOGRAPHIC AND LIFE HISTORY INTERACTIONS ACROSS MULTIPLE SPATIAL SCALES (Abstract ID: 29805 | Poster ID: 520)

Assessing the degree of connectivity within and among reef sites in a metapopulation is central to understanding persistence of species that inhabit patchy ecosystems. Larval dispersal is determined by numerous oceanographic and biological processes that operate at multiple spatial and temporal scales. Therefore, the probability of successful dispersal, both locally and regionally, may not be simply a function of distance from natal site. This relationship is examined by analyzing the degree of connectivity of the Orange clownfish *Amphiprion percula* at two spatial scales (around-island and bay-wide) in Kimbe Bay, Papua New Guinea. Comparing the observed natal-to-settlement events to all possible anemone-to-anemone connections reveals that there is bias towards shorter dispersal distances at the local around-island (up to 1 km) scale in three different years despite potentially variable oceanographic conditions. Bay-wide (up to 100 km) connectivity is also a regular occurrence, with exchange of larvae across some of the more distant anemones. These observations of larval dispersal across coral reef habitats are compared to oceanographic transport estimates from a biophysical model that examines the interplay of ocean circulation and life history. Temporal and spatial variability of oceanographic transport can generate directional and episodic patterns of connectivity even in systems that appear well mixed by eddies. Larval survival and pelagic larval duration also play a critical role in marine metapopulation dynamics of organisms with a bipartite life cycle.

BIOGEOGRAPHIC COMPARISON OF *LOPHELIA*-ASSOCIATED BACTERIAL COMMUNITIES IN THE WESTERN ATLANTIC (Abstract ID: 28338)

Over the last decade, publications on deep-sea corals have tripled. Most attention has been paid to *Lophelia pertusa*, a globally distributed scleractinian coral that creates critical three-dimensional habitat in the deep ocean. The bacterial community associated with *L. pertusa* has been previously described by a number of studies at sites in the Mediterranean Sea, Norwegian fjords, off Great Britain, and in the Gulf of Mexico

(GOM). However, use of different methodologies prevents direct comparisons in most cases. Our objectives were to address intra-regional variation and to describe the conserved bacterial core community. We collected samples from three distinct colonies of *L. pertusa* at each of four locations within the western Atlantic: three sites within the GOM and one off the east coast of the United States. Amplicon libraries of 16S rRNA genes were generated using V4-V5 primers and 454 pyrosequencing. The dominant phylum was Proteobacteria (75–96%). At the family level, 80–95% of each sample was comprised of five groups: Pirellulaceae, Pseudonocardiaceae, Rhodobacteraceae, Sphingomonadaceae, and unclassified Oceanospirillales. Principal coordinate analysis based on a weighted unifrac distance showed a clear distinction between the GOM and Atlantic samples. Interestingly, the replicate samples from each location did not always cluster together, indicating there is not a strong site-specific influence. A core bacterial community, conserved in 100% of the samples, was dominated by the alphaproteobacterial genus *Novosphingobium*.

BALANCING THE BUDGET: A NEW WAY TO ASSESS HERBIVORE FUNCTION ON FISHED AND UNFISHED REEFS ACROSS MAUI, HAWAII (Abstract ID: 29951)

Herbivore grazing pressure on coral reefs is considered a major driver in the maintenance of coral dominance over algae in competition for space. However few studies have attempted to quantify and compare rates of consumption by herbivores with production of new biomass by the algal community. Here, we calculate a budget for herbivore consumption and algal growth on Hawaiian coral reefs by multiplying bootstrapped distributions of field-measured variables. Data were collected at reefs around Maui including Kahekili Herbivore Fisheries Management Area, a near-shore reef impacted by nutrient pollution and fishing and established in 2009 to prohibit take of herbivores. At Kahekili, our results show that despite herbivore protection, algal production currently exceeds the grazing capacity of the herbivorous fish community by three to four times. While some of this production is likely consumed by urchins or converted to detritus, increased herbivore biomass will be required to effectively reduce algal abundance. Despite the gap, larger size classes of herbivores, particularly of the scraper/excavator feeding guild, are contributing more to consumption in recent years, which could have additional feedbacks that promote reef-building taxa. Island-wide, we found that net algal biomass production was lowest at reefs with high coral cover even when fish biomass at these reefs was comparable or less than on low coral cover reefs. The results of this study suggest lower herbivore biomass is required to maintain a healthy reef than to restore a degraded reef.

EXTREME FUNCTIONAL DIFFERENCES AMOUNG PALAUAN REEF CORALS AND THEIR SYMBIOTIC ALGAE (Abstract ID: 29651)

The inshore coral reef habitats of Palau resemble temperature and pH conditions similar to those projected by 2100 AD. We compared the trophic dynamics and niche width of eight species of Scleractinia found in both inshore and offshore reefs. Stable isotopes ($\delta^{13}C$ and $\delta^{15}N$) were used to deduce the relative importance of photosynthesis and heterotrophy to corals living in each habitat. Coral from inshore habitats were found to associate with *Symbiodinium trenchii* (type D1a). Isotopic values of the animal's tissue, symbiotic algae, and skeleton revealed that these corals relied on zooplankton and particulate organic matter (POM) for metabolism considerably more than conspecifics from offshore reefs. Offshore corals depended more on autotrophy and harbored different species of symbiont. As expected, thermal experiments revealed offshore corals were more negatively impacted by increased temperature. However, comparisons of nutrient allocation under normal and stressful conditions indicated little, or no, significant tradeoffs in the physiological performance of some stress-tolerant host-symbiont pairings, contrary to prevailing assumptions. These findings indicate that while inshore corals rely more on a combination of energy sources to acclimatize to stressful environments, their symbioses are maintained with minimal cost to animal growth. Our findings show how coral metabolism may need to shift to cope with increased ocean warming.

ETIOLOGICAL AGENTS OR SECONDARY OPPORTUNISTS? FREQUENT MONITORING AIDS IN ASSESSING THE ROLE OF *VIBRIO* BACTERIA IN DISEASE OF *ACROPORA PALMATA* (Abstract ID: 28074 | Poster ID: 156)

*Vibrio* bacteria are frequently associated with disturbed states of the coral microbiome due to disease or thermal stress. We examined the seasonal dynamics and association of *Vibrio* with disease lesions on the Caribbean coral, *Acropora palmata* in the Florida Keys, USA. We found ~4X the concentration of cultivable *Vibrio* on *A. palmata* lesions compared to intact tissue. It is often difficult to establish the role of particular microbial taxa, such as *Vibrio*, in coral disease because samples are collected after disease signs are already apparent and lesion age is unknown. *Vibrio* may be primary etiological agents of coral disease or part of secondary opportunistic infections. To further investigate the association of *Vibrio*with *A. palmata* lesions and examine potential community-level successional patterns, we monitored Looe Key Reef for new lesion outbreaks 3-5 days per week during July 2015. Samples from new lesions <24 h old and 3, 6, and 8+ day-old lesions were processed for 16S rRNA sequencing and qPCR. To examine the diversity of *Vibrio* associated with lesioned and intact tissue of *A. palmata*, we processed more than 170 *Vibrio* isolates for phylogenetic analysis. Unique isolates were chosen for further analyses with the aim to provide new insights into metabolic and virulence capabilities of coral-associated *Vibrio*. This study highlights the importance of frequent monitoring during disease outbreaks to attribute lesion causality.

PHYSICAL MECHANISMS OF ISLAND BUILDING – THE IMPLICATIONS OF OVERWASH FOR ISLAND MAINTENANCE (Abstract ID: 28506)

The future stability and continued persistence of low-lying coral reef islands has generated global concern in recent decades as sea levels rise and the frequency of storms increases. Increased shoreline erosion and wave-induced flooding are widely accepted impacts of such environmental changes. However, such assertions are commonly based on an assumption that the island shoreline is static. Recent studies have indicated that islands have the potential to migrate in planform on their reef surfaces, indicating that islands are dynamic features that can adjust their shape and position in response to changing boundary conditions. The three-dimensional nature of island dynamics have not been well quantified. This paper adds to understanding of island responses to elevated sea level by examining additional physical processes that enable islands to build vertically. The magnitude and temporal and spatial dimensions of vertical aggradation of islands are explored and implications for future persistence discussed.

REEF-BUILDING CORALS AS A NATURAL MODEL FOR EVOLUTIONARY TRANSITIONS IN SYMBIONT TRANSMISSION MODE (Abstract ID: 28094)

Symbiosis has played a fundamental role in the evolution of life, and in the case of reef-building corals, constitutes the foundation of one of the most biodiverse and productive ecosystems on the planet. However, surprisingly little is known about how inter-species mutualisms evolve from cooperative partnerships to integrated organisms, though symbiont transmission mode is predicted to be important. A transition from horizontal (symbionts sourced from the environment) to vertical (direct transfer from parent to offspring) transmission aligns the reproductive interests of partners and should optimize resource sharing to maximize whole organism fitness. We quantified resource sharing and evaluated changes in fitness between horizontal and vertical transmitters using three pairs of closely related coral species with different strategies. Two out of three vertical transmitters exhibited phenotypes consistent with predictions: both Porites lobata and Montipora aequituberculata exhibited higher growth and enhanced bleaching tolerance compared to their horizontally transmitting counterparts. Surprisingly, all hosts and symbionts continued to share carbon in spite of thermal stress, suggesting that a breakdown in host-symbiont cooperation is a consequence rather than a cause of coral bleaching. We discuss possible explanations for trait variation among vertical transmitters and argue that future investigations using this framework could provide novel insights into the coral-algal symbiosis.

REEF CARBONATE BUDGET RESPONSES TO CLIMATE CHANGE AND THE USE OF CORALLINE ALGAE AS A RESILIENCE INDICATOR FOR OCEAN ACIDIFICATION (Abstract ID: 28963)

Ocean acidification (and warming) are known to negatively influence calcification rates of marine organisms, with crustose coralline algae (CCA) – which use high-mg calcite to

build skeletons – believed to be particularly vulnerable to changes in seawater chemistry. Despite this, little is known about 'normal' calcification rates of corallines along the Great Barrier Reef (GBR), and their relative contribution to reef structural growth. Our project set out to describe variability in CCA calcification rate, spatially (along the length and breadth of the GBR) and temporally (between seasons). Determining in situ calcification rates provided a baseline for future monitoring efforts aimed specifically at tracking climate change (ocean acidification) impacts on Australian reefs. We augmented our CCA calcification data by placing it into the wider context of reef structural growth, developing the first comprehensive set of census-based coral reef carbonate budgets for the GBR. Reef carbonate budgets, which take into account both biomineralisation (by CCA and corals) and bioerosion processes, describe the ability of a reef to maintain both their structural integrity and vertical reef growth capacity. Data on each reef's carbonate budget status, as well as providing an assessment of reef health, will be further used to inform predictive models that will examine the point of reef functional collapse under future climate scenarios. As CCA play key roles in reef stabilisation and recovery, documenting natural variability in coralline calcification rates in the context of reef carbonate budgets will support research into environmental thresholds for healthy reef structural growth.

THE ROLE OF TABULAR STRUCTURE IN THE ECOLOGY OF LARGE REEF FISHES (Abstract ID: 27788)

Although prior studies had hypothesised that declines in the abundance and diversity of large reef fishes might be seen following the loss of tabular structures, no studies had experimentally demonstrated this relationship. We therefore examined this outcome by excluding access of large reef fishes to the understory of tabular structures. The exclusion of large reef fishes from tabular structures using mesh wire had a significant effect on the distribution of large reef fishes, even though these structures only constituted a small fraction (4%) of the benthic cover. Reduction in the availability of tabular structures at this spatial scale (200 m2) shifted activity spaces of fishes away from these localities. To examine why some species of large reef fishes demonstrate such a strong attachment to tabular structure, we sought to test two hypotheses to explain sheltering behaviour: avoidance of predation or avoidance of solar irradiance. Patterns of shelter use offered minimal evidence in support of the predation avoidance hypothesis, with usage of tabular structures being low during the sunset period when predators of large reef fishes were likely to be most active. However, tabular structure usage reached a peak during the middle of the day when incident solar irradiance would reach its zenith. As such, the data suggest that large reef fishes are primarily sheltering to protect themselves from harmful UV irradiance. Given the significant costs of producing UV-blocking mycosporine-like amino acids, fishes may achieve considerable energetic savings by sheltering.

MARINE PROTECTED AREA PRIORITY SITES FOR FISHERIES AND BIODIVERSITY OBJECTIVES IN THE CENTRAL SAUDI ARABIAN RED SEA (Abstract ID: 28607)

Spatial prioritization is an important step for making sound decisions regarding sustainable management of marine resources. Ideally, such management should protect biodiversity while also achieving sustainable fisheries objectives, but these two contrasting objectives are rarely combined in systematic conservation planning. Here, we prioritize reefs for inclusion in local marine protected area (MPA) networks near Thuwal in the central Saudi Arabian Red Sea, aiming to achieve either fisheries or biodiversity objectives. We then compare the outputs of these spatial prioritization exercises. Within each type of objective, minimum and maximum recommended levels of protection (up to 10 and 30% of available resources, respectively) were considered, leading to a total of four scenarios. The scenarios for fisheries objectives integrated spatial patterns of the abundances of 11 commercially targeted fish species, while those for biodiversity integrated 7 fish species and 5 benthic categories that are endemic and/or representative of different local reef communities. Results showed considerable spatial overlap between MPAs produced for fisheries and those produced for biodiversity objectives; however, MPAs for fisheries were generally larger, and thus, likely to be more expensive. Overall, results suggest that implementing a local MPA network that can achieve both fisheries and biodiversity objectives simultaneously may be possible in the presence of adequate species information.

WHEN DO ADULT REEF FISHES DIE? (Abstract ID: 28956)

Mortality is considered to be critically important in shaping reef fish communities, however, we currently know remarkably little about the nature of mortality in adult coral reef fishes. Mortality on coral reefs is intrinsically linked with predation, with most evidence suggesting that key predators are usually on the hunt during dawn and dusk. We tested this 'crepuscular predation' hypothesis using passive acoustic telemetry movement data to determine the time of day of potential mortality events of adult herbivorous reef fishes. Furthermore, we identified five types of potential mortality events based on the nature of change in signal detections from tagged fishes. We found that the majority of the potential mortality events were characterised by an abrupt stop in detections, possibly as a result of a large, mobile predators such as a carangids or reef sharks. Mortality in adult herbivorous reef fishes is higher during the day than previously expected. The time of day of the potential mortality events suggest that predation was highest during the day and crepuscular periods, and lowest at night, offering only partial support for the crepuscular predation hypothesis. Visually-oriented, diurnal and crepuscular predators appear to be more important than their nocturnal counterparts in terms of predation on adult reef fishes. By revealing the timing of potential mortality events, passive acoustic telemetry may offer an important new tool for investigating the nature of predation on coral reefs.

LONG-TERM MONITORING OF CORAL HEALTH IN BOCAS DEL TORO, PANAMA FOLLOWING THE 2005, 2010, AND 2015 MASS BLEACHING EVENTS (Abstract ID: 28247)

Coral reefs are declining worldwide due to climate change and other local and global environmental stressors. However, most research on coral reef health does not track the corals for sufficient time after a disturbance to determine the long-term effects. For this project, we observed the bleaching response, mortality, and recovery of over 300 tagged coral colonies in Bocas del Toro, Panama by photographing them approximately annually between 2005 and 2015. There was a Caribbean-wide mass bleaching event in 2005, followed by additional bleaching events in 2010 and 2015. We measured the areas of bleached, partially bleached, and live and dead tissue on individual tagged corals of 7 dominant Caribbean reef species using image segmentation to calculate growth and decline rates. We found that there were significant differences between species and that by 2013, all corals had declined in live area. Moreover, field observations from 2015 and preliminary analyses show that previously resistant species such as *Siderastrea siderea*were more affected by the 2015 bleaching event than previously vulnerable species such as *Stephanocoenia michelini* and *Orbicella franksi*. This indicates that coral recovery is a complex process that is likely dependent on multiple factors; therefore, time series are important because they allow us to consider recovery on a longer time scale. By continuing to monitor bleaching and assessing reef health, we can better understand how coral reefs will respond to a warmer future and try to develop effective management strategies.

SISTER SANCTUARIES LINK CORAL REEF SCIENCE AND STEWARDSHIP IN CUBA AND THE U.S. TO ENHANCE PLACE-BASED MANAGEMENT (Abstract ID: 28181)

The currents that flow from the Caribbean through the Gulf of Mexico and into the Atlantic physically connect the coral reefs of Cuba and the SE U.S. Collaboration in marine science and management between Cuba and the U.S. is therefore essential to strengthening and protecting the ecological integrity of coral reefs in the Gulf of Mexico and South Florida. As part of the cooperation on MPA science, management and education programs recently established by Cuba and the U.S., joint marine conservation and research programs at Guanahacabibes National Park's Banco de San Antonio and Flower Garden Banks National Marine Sanctuary are being designed. Flower Garden Banks National

Marine Sanctuary has comparable physical and biological features to the coral reefs at Banco de San Antonio. The sister sanctuary designation allows direct evaluation of the influences on ecosystem functions and changes at the two sites. It also allows the U.S. and Cuba to share their technical expertise in characterizing the physical and biological features within the sister sites, understanding the migratory and reproductive connections of species between the sites, investigating the mechanisms that spread invasive species, pathogens and pollution in the region, and evaluating how human activities are impacting marine resources in both countries. These and other programs developed in this sister sanctuary relationship are establishing unprecedented cooperation between the U.S. and Cuba at a time when their marine resources and societies urgently need it.

CORAL HEALTH & DISEASE IN URBAN VERSUS RURAL AREAS OF TIMOR-LESTE (Abstract ID: 29046 | Poster ID: 157)

Coral disease and other signs of compromised health (i.e. macroalgal overgrowth, invertebrate overgrowth etc.) are expected to be an increasing threat to coral reefs in a warming and acidifying ocean. Timor-Leste became a sovereign state in 2002 and is located in the Lesser Sunda Islands in the southern Indo-Pacific. Line intercept transects for benthic cover and 15 x 2 m belt transects quantifying coral health and disease were conducted in November 2015 at two urban and two rural sites and revealed varying levels of coral cover and low levels of disease. Beloi Barrier Reef, a rural site, in the channel 25 km off the coast had the highest coral cover and diversity compared to the remaining rural and urban sites onshore, but also had the highest level of coral disease at 1.6%; however, the sites had higher levels of compromised health such as tunicate overgrowth and flatworm infestation. Additional sediment and macroalgal samples were collected at all sites for analysis of heavy metals and stable isotope analysis respectively to determine any potential links with coral disease and compromised health.

JEJU ISLAND, SOUTH KOREA SOFT CORAL COMMUNITY STRUCTURE ANALYSIS (Abstract ID: 29331 | Poster ID: 65)

Anthozoa recorded that inhabit total seven Order, 19 Family, 43 species in Munseom, Beomseom, train rocks, Jeju-do, Korea to march and june in 2011. Munseom recorded that 27 species and 30.8% mean coverage to high diversity and dominant rate in june. Beomseom and train rocks almost similar leveled that each species number(23 and 22 species) and dominant rate(21.2%, 25.4%). Anaysis of similarity of anthozoa between communities that Beomseom and train rocks had the highest similarity. Munseom and Beomseom had the lowest similarity. But statistically three areas appeared a similar community structure. This study compare with Seoul National University (2009) study of survey results of research region(munseom, beomseom, trains rocks) that were almost the same level species number, mean coverage, diversity index. Anthozoa dominant species composition showed a similar trend. and recently anthozoa community is expected that stable populations are being maintained. Legal management species of this research appeare in total seven species Myriopathes lata, Dendronephthya suensoni, Dendrophthya putteri Kukenthal, Euplexaura crassa, Dendronephthya castanea, Dendronephthya mollis, Tubastraea coccinea.

FILLING THE GAPS: IMPUTATION OF CORAL TRAIT DATABASE AND FUNCTIONAL BIOGEOGRAPHY OF CORALS (Abstract ID: 28289)

Variability in functional traits and their responses to environmental filters provide raw material for a variety of research areas from population and community ecology to conservation. However, compilation of trait information on a global scale requires prohibitively extensive fieldwork. Consequently, global trait databases for many organisms, including corals, remain largely sparse, and understanding the spatial distribution of corals' functional diversity is challenging. A common practice in other taxonomic groups for missing values is to disregard the missing values and characterise functional groups only using the known values despite the fact that such reduction in datasets may result in erroneous or biased projections. Here we show that missing values in global trait databases can be imputed using statistical tools. Functional biogeography of corals based on the resultant comprehensive dataset reveals spatial heterogeneity in trait combinations, and the correlation between biodiversity indicators (species richness and phylogenetic diversity metrics) and functional diversity indices (functional richness, evenness, and divergence).

TERRESTRIAL POLLUTION VERSUS GLOBAL WARMING: WHAT DRIVES CORAL ANNUAL EXTENSION IN THE ANTHROPOCENE ERA? - A CASE STUDY IN CHUUK LAGOON, MICRONESIA - (Abstract ID: 29228 | Poster ID: 442)

Terrestrial pollution and CO2-driven global warming are main threats to coral reefs ecosystems. Previous studies revealed the contrasting responses of reef building coral species to human-led changes. Increased sea surface temperature (SST) reduced coral annual extension in the Red Sea, whereas, terrestrial pollution increased extension in Indonesia. These two concurrent threats raise some questions about coral annual extension in the Anthropocene. Coral reefs in Chuuk lagoon have suffered from high anthropogenic impacts through the WWII and subsequent population growth, additionally, the SST increased by about 0.5 °C over the same period. To assess the relative importance of these two factors in coral annual extension, we collected two coral cores of Porites sp. at Newman and Nepukos which are located at Weno island in Chuuk lagoon, Federated States of Micronesia. Age estimation based on band counts of x-radiograph indicated the first core encompasses the time-period 1938-2013 and the second core is estimated to include the entire 20th century. According to correlation analyses, coral annual extension showed no correlation with SST and population density, however, significantly correlated with precipitation on the most recent half of the record. While the second core is still being analyzed, the preliminary results indicate increased human population and concomitant deforestation caused an influx of terrestrial pollutants and subsequently affect coral annual extension rather than global warming nearshore reef.

NOAA'S NATIONAL CORAL REEF MONITORING PROGRAM: INTEGRATED ECOSYSTEM MONITORING AND REPORTING IN U.S. CORAL REEF AREAS TO INFORM CONSERVATION AND MANAGEMENT (Abstract ID: 29448)

The National Oceanic Atmospheric Administration's Coral Reef Conservation Program (CRCP) strives to protect, conserve, and restore coral reef resources by maintaining healthy ecosystem function. Since 2013, CRCP has supported the National Coral Reef Monitoring Program (NCRMP) to collect biological, physical, and socioeconomic data

throughout the U.S. Pacific, Atlantic, and Caribbean coral reef areas. The overarching goal of this effort is to collect the information needed to gauge the changing conditions of U.S. coral reef ecosystems and support well-informed ecosystem-based conservation and management. NCRMP is a long-term approach to provide an ecosystem prospective via monitoring benthic, fish, climate, and socioeconomic variables in a consistent and integrated manner, to provide information supporting NOAA and our State, Territorial, and other Federal partners efforts to more effectively manage and conserve our nation's coral reefs. We will present on the development and implementation of the general themes and core indicators of NCRMP, as well as the partnership with the University of Maryland Center for Environmental Science, to develop pilot status and trends reports (Report Cards) synthesizing the monitoring data on coral reef ecosystems, including benthic, fish, climate, and socioeconomic data streams.

PROTECTED AREAS NETWORK (PAN) – NATIONAL SYSTEM FOR THE PROTECTION OF THE CORAL REEF ECOSYSTEMS IN PALAU (Abstract ID: 28772)

The Protected Area Network (PAN) is a national mechanism to protect the critical biodiversity and ecosystems in Palau. The PAN was established in 2003 under the national low for enhancing the state governments to conserve the national network of protected areas. State governments may apply for membership to register their protected areas as PAN sites through the PAN Office that handle all the activities regarding to PAN. PAN Office provides technical resources, advices, guidelines and trainings to the members for better management of the PAN sites. This national system also includes Green Fees, a fee paid by all visitors leaving Palau. These fees go into a restricted PAN Fund, which is used for management of PAN member sites. A five year Science and Technology Research Partnership for Sustainable Development (SATREPS) project has been conducted for the Sustainable Management of Coral Reef and Island Ecosystems: Responding to the Threat of Climate Change since 2013 to provide scientific data and information for conservation of Palau's Island ecosystems focusing on climate changes, biodiversity conservation and protected area management. The project has also supported capacity building for state governments on monitoring and management of the PAN sites to enhance conservation of the biodiversity of entire islands ecosystems of Palau. This presentation shows the processes and mechanisms of the project to support capacity building of PAN.

INVASIVE MARINE PREDATOR ALTERS COMPETITION BETWEEN NATIVE CORAL-REEF FISHES (Abstract ID: 28866)

Our understanding about the mechanistic ability of invasive predators to influence native communities and ecosystems is limited. We tested whether the invasive Pacific red lionfish (*Pterois volitans*) alters interspecific competition between native species on Atlantic reefs: fairy and blackcap basslets (*Gramma loreto* and *Gramma melacara*). We conducted a manipulative experiment in The Bahamas to measure the response of each prey species in local populations under isolated reef ledges in both the presence and absence of its competitor cross-factored with the presence and absence of the invasive predator. Lionfish significantly affected the density of juvenile fairy basslet through time ($p=0.012$), causing substantial declines in prey by the sixth week of manipulation. Lionfish indirectly enhanced the feeding position and individual growth rate of juvenile blackcap basslet: these fish exhibited shifts towards coveted feeding positions and higher growth rates that were comparable to the response in populations where fairy basslet had been experimentally removed. Additionally, the effects of competition on these parameters were significant in low-lionfish reefs (position: $p=0.043$; growth: $p=0.046$), but were not significant in high-lionfish reefs (position: $p=0.201$; growth: $p=0.680$). Lionfish did not alter any effects of competition on fairy basslet. These results indicate that predation by invasive lionfish differentially affects fairy basslet, which tips the balance of competition from symmetrical to asymmetrical in favor of blackcap basslet.

LARVAL BEHAVIOR AND LONGEVITY OF FISHES INFLUENCES THE GENETIC RESILIENCE OF REEF-BASED POPULATIONS (Abstract ID: 27863)

The persistence of reef fish populations depends on reproductive output, larval behaviour and survival, pathways of connectivity and postsettlement processes. A surprisingly high percentage of many fishes recruit to their natal reefs and recent studies have indicated that connectivity may be so limited that genetic differences may persist at small spatial scales (kilometres to tens of kilometres). Key elements of such differences include larval dispersal and behaviour and post settlement longevity. We show that larval behaviour that can assist in the persistence of genotypes while very short lives, for some common fishes, could weaken genetic resilience.

REPRODUCTIVE BIOLOGY OF THE BRAIN CORAL, PLATYGYRA SINENSIS AT MU KO SAMAE SAN, CHON BURI PROVINCE IN THE UPPER GULF OF THAILAND (Abstract ID: 29709 | Poster ID: 167)

Platygyra sinensis is one of the most common species in Mu Ko Samae San, Chon Buri Province, the upper Gulf of Thailand. In this study, gamete development and post-fertilization development of the brain coral Platygyra sinensis, were investigated. From the field observations, the results showed that the development of gametes started from February to March of each year, and the spawning occurred later from March to April within 4 to 5 days after the full moon. After the spawning, gametes were collected and brought back to the coral hatchery for fertilization. Fertilization rates of the gametes in the coral hatchery were more than 95%, and the settlement rates of planulae varied from 15 to 30%. This finding can be a baseline data for further use of sexual propagation of corals in Thailand.

TEMPORAL PATTERNS OF GENE EXPRESSION IN RESPONSE TO HEAT AND SALINITY STRESS IN *PLATYGYRA DAEDALEA* FROM THE PERSIAN GULF (Abstract ID: 29774)

Scleractinian corals are severely threatened by rising ocean temperatures and some coral populations possess heritable genetic variation in thermal tolerance, providing potential for adaptation to climate change. High seawater temperatures (reaching 36°C) and salinity (up to 45 ppt) in the Persian/Arabian Gulf have likely selected for environmental stress tolerance in the local populations, presenting a unique resource for the study of corals' adaptive potential in a warming climate. To investigate thermal tolerance phenotypes in these populations, we focused on aposymbiotic larval stages of *Platygyra daedalea*. Thermal tolerance (survival during heat stress) was measured in 55 controlled crosses generated from 13 parental colonies. We documented moderate genetic variation in thermal tolerance ($h2=0.33$), and identified families with contrasting tolerance phenotypes. To investigate the functional basis for these differences, larvae were exposed to factorial combinations of elevated temperature and salinity. Transcriptional responses were examined using RNA-Seq, which revealed greater upregulation of putative stress response genes in susceptible than resistant families. To investigate the dynamics of gene expression more directly, we conducted 10 additional crosses in a subsequent season and profiled changes in gene expression during a time-course thermal stress experiment. This study provides insights into the mechanisms through which stress tolerant corals persist in the Gulf, and ultimately into possible mechanisms through which corals may adapt to climate change.

PHYLOGENETIC RELATIONSHIPS BETWEEN ZOANTHARIAN *EPIZOANTHUS* SPP. (ANTHOZOA: HEXACORALLIA) AND HOST *EUNICE* SPP. TUBE WORMS (EUNICIDAE) (Abstract ID: 28015 | Poster ID: 82)

Examples of co-speciation between hosts and their associates based on phylogenetic molecular analyses have become common in recent years. However, there are few marine invertebrate examples due to taxonomic uncertainty in many taxa hindering such analyses. In this research, we investigated the phylogenetic relationships among three species of epibiotic zoantharians (*Epizoanthus* spp.) and their host eunicid worms (*Eunice* spp.). Freshly collected and museum Pacific Ocean specimens of *Eunice* spp. with *Epizoanthus* colonies on their zig-zag tubes were examined. Molecular and morphological analyses were conducted to estimate phylogenetic congruence between the zoantharians and eunicid worms. The phylogenetic relationships were conducted using sequences from multiple molecular markers (nuclear 18S ribosomal DNA and internal transcribed spacer region of ribosomal DNA; mitochondrial 16S ribosomal DNA and cytochrome oxidase subunit I) for both hosts and epibionts. Phylogenetic congruence was tested by topology-based, distance-based, and data-based methods. The combined data set

indicates co-speciation and duplication between*Epizoanthus* species and eunicid worms. In this presentation, we discuss the phylogenetic relationships between *Epizoanthus* and *Eunice*, showing the existence of previously unknown cryptic diversity.

SPECIES AND GENOTYPE DISTIBUTION OF POCILLOPORA DAMICORNIS-LIKE CORAL ACROSS SUBTROPICAL TO TEMPERATE REGION IN JAPAN (Abstract ID: 29997 | Poster ID: 51)

Rising sea surface temperature is expected to have impacts on distribution of corals. Therefore it is necessary to study the current distribution of species and genetic structure for future prediction of coral reef ecosystem. We investigated the distribution of *Pocillopora damicornis* and *P. acuta*, which had long been treated as a junior synonym of *P. damicornis* across subtropical to temperate region of Japan. Both species were distinguished by genetic analysis based on the mitochondrial open reading frame (ORF) sequences although morphological identification is difficult especially in field. We found that *P. acuta* distributes only subtropical region (northern limit, 30°28'N), while *P. damicornis* distributes in all regions but is dominant in temperate region. Similar distribution of both species has been observed in other region of Indo-Pacific. We also found two haplotypes in Japanese *P. damicornis*; one of them is the major one widely shared in the tropical Pacific reefs, and the other one is a novel one that is dominated in the temperate region. We obtained similar result by genetic analysis using polymorphic nuclear microsatellite markers that showed clear genetic break between subtropical and temperate regions. Such limited gene flow among the regions implies the adaptation of the populations to the peculiar environment in each region. Distribution of genotypes of *P. damicornis* appears to correlate with sea surface temperature in winter.

FAILURE TO SPAWN: A SELF-CRITIQUE OF PARTNERSHIP SUCCESSES AND SINKHOLES (Abstract ID: 29537)

It's easy to take a victory lap when effective partnerships lead to successful implementation; it's less fun to admit when these efforts fail to ignite sustainable, long-term action. Why does one watershed or marine conservation area get more traction than another? What absentee partner is critical to sustaining implementation enthusiasm? Who is maintaining those restoration projects? Where did that management plan go? After a decade of providing technical assistance, training, and partnership support for addressing land-based sources of pollution in the US coral reef jurisdictions, we have had plenty of time to reflect on the factors contributing to our successes and sinkholes. Through live, interactive audience polling, this session will encourage you to critique your own partnerships and projects and identify mechanisms for improving your chances of long-term success. Lessons-learned and laughter, not finger-pointing and criticism, will help to remind us that there is always room for improvement, particularly when our goal of coral conservation is so high.

HYPERTHERMAL STRESS ALTERS TRANSCRIPTOMIC RESPONSE OF CORAL LARVAE AT THE ONSET OF SYMBIOSIS (Abstract ID: 29494)

Cnidarian-dinoflagellate partnerships collapse under prolonged thermal stress associated with climate change. We are beginning to understand the physiological and molecular consequences of bleaching events on host-symbiont associations in adult corals; however, few studies have addressed the effects of thermal stress during onset of symbiosis in coral larvae. The capacity of larvae to buffer climate-induced stress while undergoing symbiosis comes with physiological trade-offs altering behavior, development, settlement and survivorship. Understanding the mechanisms that underlie the formation of symbiosis during early developmental stages is critical to predicting coral resilience and resistance to stress and overall reef ecosystem health in the future. Here we examined the effects of both thermal stress and onset of symbiosis together on symbiont colonization, survival, and host global gene expression in *Acropora digitifera* larvae. The combined stress increased mortality, decreased symbiont colonization by half and algal density by 98.5% after two weeks. Using RNASeq, we identified 232 differentially expressed genes with the interaction of olonization and thermal stress. The combination of events changed expression of genes linked to immune, cytoskeletal, oxidative stress and lipid metabolism pathways. In addition, we used co-expression networks to isolate temperature and symbiosis transcriptional patterns. These findings expand our understanding of how the physical environment, biotic pressures and molecular coral stress-response mediate pre-settlement events in corals.

FROM REEF TO TABLE: SOCIAL AND ECOLOGICAL FACTORS AFFECTING CORAL REEF FISHERIES, ARTISANAL SEAFOOD SUPPLY CHAINS, AND SEAFOOD SECURITY (Abstract ID: 28249)

Ocean and coastal ecosystems provide critical fisheries, coastal protection, and cultural benefits to communities worldwide, but these services are diminishing due to local and global threats. In response, place-based strategies involve communities and resource users in management have proliferated. Here, we present a transferable community-based approach to assess the social and ecological factors affecting resource sustainability and food security in a small-scale, coral reef fishery. Our results show that this small-scale fishery provides large-scale benefits to communities, including 7,353 ± 1547 kg yr-1 (mean ± SE) of seafood per year, equating to >30,000 meals with an economic value of $78,432. The vast majority of the catch is used for subsistence, contributing to community food security: 58% is kept, 33.5% is given away, and 8.5% is sold. Our spatial analysis assesses the geographic distribution of community beneficiaries from the fishery (the "food shed" for the fishery), and we document that 20% of seafood procured from the fishery is used for sociocultural events that are important for social cohesion. This approach provides a method for assessing social, economic, and cultural values provided by small-scale food systems, as well as important contributions to food security, with significant implications for conservation and management. This interdisciplinary effort aims to demonstrate a transferable participatory research approach useful for resource-dependent communities as they cope with socioeconomic, cultural, and environmental change.

IDENTIFICATION OF PRIORITIES FOR THE EXPANSION OF THE MARINE PROTECTED AREA ESTATE OF REPUBLIC OF SEYCHELLES (INDIAN OCEAN) (Abstract ID: 29514 | Poster ID: 527)

The Republic of Seychelles is responsible for a vast Exclusive Economic Zone (EEZ) and 155 islands covering 1.35 million km$^2$. The Government of Seychelles (GoS) has declared a large number of protected areas (PAs). The existing marine PA estate only covers <1% of the EEZ. In 2011, the GoS made a bold new commitment to expand the PA estate beyond the Aichi Targets set by the Convention on Biological Diversity - Strategic Plan for Biodiversity 2011–2020. The goal set by GoS was 50% of all terrestrial areas, and 30% of the Seychelles EEZ, 15% of which would be identified as 'no-take' areas. The GoS recognised the need to assess the existing estate and the potential benefit of using spatial decision-support tools to identify priority gaps for the future expansion of the national network. With the support of a GoS-UNDP-GEF project, the Seychelles Systematic Conservation Planning (SEY-SCP) process was launched. The SEY-SCP process established new procedures to promote the sharing of data, which facilitated the release and compilation of previously unavailable datasets from national, regional and international sources. Through a series of workshops and MARXAN modelling of these datasets, a provisional set of PAs was delineated for further consultation. These included larger areas proposed as "Sustainable Use" areas, which are closely compatible with the existing "Fisheries Exclusion Zones" that subdivide national and international fishing grounds. The key steps in the SEY-SCP process will be presented with the main results and recommended follow-up actions.

LONG TERM CHANGES IN THE STATUS OF THE CORAL REEF OF ALDABRA ATOLL (SEYCHELLES): A GLOBALLY SIGNIFICANT CORAL REEF OBSERVATORY (Abstract ID: 29804)

Aldabra, the world's second largest atoll, situated away from the main populated Seychelles islands, provides an ideal benchmark for assessing long-term changes in coral reef health. This remote atoll only narrowly avoided becoming a military base in the 1960's due to an intervention by the Royal Society and David Stoddart. Managed by the Seychelles Islands Foundation (SIF) since independence, the atoll was inscribed as a UNESCO World Heritage (WH) site in 1982 and is still one of only two marine WH sites in the entire Indian Ocean. Marine research has been limited compared to terrestrial studies due to operational challenges. After the mass coral bleaching event in 1997/1998, an external group of researchers established the Aldabra Monitoring Programme (AMP) to help SIF assess the condition of the reefs. The AMP completed surveys in 1999, 2001- 2006 and 2008. In 2012, SIF recognised the need to build internal capacity for marine monitoring. With support from a GOS-UNDP-GEF funded project, the protocol was revised to create a more practical scalable solution: existing sites at 10m and 20m depth were resurveyed and repositioned to 15m and 5m and new video and photographic survey technologies were introduced for benthos and fish. The results of the new programme demonstrate the recovery of the reef since 1998, but also highlight new concerns, including the presence of *Terpios hoshinota*, the furthest western reported occurrence of this coral-killing sponge in the Indian Ocean, which together with the anticipated coral bleaching in 2016 pose a threat to this legacy site.

THE TIMELINE OF THERMAL ACCLIMATIZATION IN AMERICAN SAMOAN CORALS: HOW LONG DOES IT TAKE TO GAIN BLEACHING RESISTANCE? (Abstract ID: 28559)

Corals native to variable thermal environments often resist bleaching temperatures and survive exposures that typically bleach conspecifics from cooler environments; providing promising evidence for the persistence of reefs under projected global climate change. This bleaching resistance is attributed to acclamatory or adaptive conditioning to brief, but frequent high water temperatures. Acclimatization plays an important role in modifying thermal thresholds and has been observed within 1 week and up to 2 years. However, it is not known what acclimatory potential happens during the first year and how many species are capable of acclimation gains in bleaching resistance. This study transplanted populations of Porites lobata and Goniastrea retiformis from three contrasting backreef environments in Ofu Island, American Samoa into a highly variable pool known to elicit increased bleaching tolerance. Following one week and six months, transplanted and native coral nubbins were subjected to a controlled thermal exposure. Physiological responses to bleaching – zooxanthellae density, chlorophyll a, and photosynthetic efficiency – were quantified to elucidate the level of bleaching resistance attributed to acclimatization. One week of conditioning was not enough time to elicit enhanced bleaching resistance for these species, in contrast to previous studies using Acropora. Comparative results following 6 months of exposure are being collected and will be presented. This study provides a significant expansion of previous work and critical insight into coral acclimatization dynamics.

POTENTIAL ROLE OF LARVAL CONNECTIVITY IN CORAL TEMPERATURE THRESHOLDS (Abstract ID: 28407)

The sensitivity of corals to elevated temperature depends on their acclimation and adaptation to the local maximum temperature regime. Through larval dispersal, however, coral populations can receive larvae from regions that are significantly warmer or colder. If these exogenous larvae carry genetic- based tolerances to colder or warmer temperatures, then the thermal sensitivity of the receiving population may be lower or higher, respectively. Using a high-resolution Regional Ocean Modeling System (ROMS) configuration for the Coral Triangle region, we quantify the potential role of connectivity in determining the thermal stress threshold (TST) of a typical broadcast spawner. The model results suggest that even with a pelagic larval dispersal period of only 10 days, many reefs receive larvae from reefs that are significantly warmer or cooler than the local temperature. This has important implications for conservation planning, because connectivity may allow some reefs to have an inherited heat tolerance that is higher or lower than would be predicted based on local conditions alone.

INTEGRATING CELLULAR PHYSIOLOGY, RECIPROCAL TRANSPLANTS AND REEF BIOGEOCHEMISTRY TO DECIPHER THE MECHANISMS FOR CORAL CALCIFICATION AND PHOTOSYNTHESIS. (Abstract ID: 29977)

There is growing concern about the future of coral reefs and the impact of anthropogenic stressors including eutrophication, ocean acidification, and warming. However, the lack of knowledge of fundamental coral cellular mechanisms precludes our ability to understand and predict general and species-specific responses to stress. Conversely, results from controlled laboratory experiments are not necessarily relevant for corals in the field, where environmental conditions may change dramatically from one reef site to the next, limiting our ability to implement appropriate management decisions. Using an integrated set of field studies, including sampling of corals from different environments and reciprocal transplants between sites and depths, with manipulative single stressor aquarium studies, immunohistochemistry, and ecosystem level biogeochemical studies, we are trying to better understand mechanisms underlying coral calcification and photosynthesis. We will present results from studies in Bocas del Toro, Panama, with support from the NSF. The overall approach was to study recently discovered cellular mechanisms related to calcification and photosynthesis in three coral species, Orbicella franksi (Robusta), Acropora cervicornis (Complexa), and Porites furcata (Complexa) at two field sites with different environmental conditions, as well as in aquarium studies. The goal is to assess the relevance of these cellular mechanisms in nature and to identify biomarkers of coral physiology that can eventually be used to monitor and predict responses to stress.

ENVIRONMENTAL METABOLOMICS – A NEW DIAGNOSTIC TOOL FOR CORAL REEF ECOSYSTEM ASSESSMENT AND MONITORING? (Abstract ID: 30070)

Worldwide, coral reefs are under increasing pressure from a variety of environmental and anthropogenic stresses, creating a need to establish efficient and accurate methods to monitor reef health. Metabolomics, the comprehensive measurement of all metabolites and low-molecular-weight molecules in an organism, provides an opportunity to assess the effects of environmental change at an extremely fine scale. This should lead to the identification of suitable bio-indicators for use in coral reef ecosystem monitoring. Currently, we are in a developmental phase, where technologies are being refined, and baseline knowledge on a variety of metabolomes is being acquired. We characterized metabolic profiles of Stylopohora pistillata, collected from three geographically disjoined locations in the GBR that differ in water quality. Tissue was analyzed by preparing acetone/methanol extracts for Liquid Chromatography Mass Spectrometry. A Random Forest analysis indicated significant differentiation of metabolic profiles in relation to sampling location, and also identified diagnostic metabolites. Differences among regions were quantified via a hierarchical Bayesian model. This talk will summarize the results of a comprehensive environmental metabolomics approach and evaluate the effects of water quality on the metabolic profiles of S. pistillata. Using results and lessons learned in this study, we critically evaluate the potential of environmental metabolomics as a new monitoring technology for assessing the health of coral reefs. In particular, we highlight issues concerning sample collection, metabolite identification, and statistical analyses.

HOMOLOGS TO HUMAN CANCER GENES ASSOCIATED WITH CORAL GROWTH ANOMALIES (Abstract ID: 28448)

Scleractinian disease outbreaks can be hugely detrimental to coral reef ecosystems and are only predicted to increase in frequency and severity under long-term global climate change. Despite great advances in our knowledge of coral diseases since their discovery over 50 years ago, disease causation is still unknown or poorly understood for many diseases due to their complex multifactorial etiologies. It is also clear that not all individuals from the same species are afflicted when there is a disease outbreak, suggesting that both environmental and biological factors will determine the long-term outcome of a population. For the first time, next-generation technologies such as restriction site-

associated DNA sequencing (RAD-seq) provide the tools to examine the genome from non-model organisms, like scleractinian corals, relatively easily and cheaply. Here we use ezRAD and Seanome (a pipeline developed to analyze ezRAD data) to screen the single nucleotide polymorphisms (SNPs) between both healthy and diseased (growth anomalies) Acropora cytherea colonies from Palmyra Atoll, Central Pacific. We found consistent genetic differences between colonies with and without growth anomalies. In addition, gene ontology (GO) annotation of the enriched variants in the diseased colonies highlighted a number of regions that were linked to important functional components found in human cancers. This is the first instance genetically linking hyperplasias in humans to the more basal cnidarians, indicating that this process is potentially conserved and fundamental in metazoans.

PIGGYBACK-THE-WINNER: ECOSYSTEM AND EVOLUTIONARY EFFECTS OF VIRAL LYTIC TO LYSOGENIC SWITCHES ON CORAL REEFS (Abstract ID: 28882)

Viruses and protists can control microbial communities through density-dependent predation. This top-down dynamic inhibits microbial growth, at odds with increasing microbial densities observed on degraded coral reefs. Viral and microbial abundances on coral reefs show a decline in the ratio of viruses to hosts, consistent with suppressed viral predation at high host density. Bioinformatic analysis of viral communities explained this deviation from density-dependence, showing that high host densities are associated with lysogenic dynamics - where viruses integrate into host genomes - rather than lytic predation. Lysogenic viral communities carry increased levels of pathogenicity genes, possibly granting their hosts the ability to evade protist predators. Viruses therefore appear to become parasitic when predation is favored by density- and frequency-dependent Kill-the-Winner dynamics, a model we term Piggyback-the-Winner (PtW). PtW dynamics likely facilitate increasing microbial densities as non-lytic activity is favoured at high host density and by conferring on hosts broad-spectrum immunity to viral infection as well as viral-encoded functions. The resulting lineages with integrated viruses are ecologically and evolutionary divergent from their non-lysogen conspecifics and experience different selection pressures. This may explain how degraded ecosystems that have transitioned towards PtW rather than more resilient Kill-the-Winner dynamics are dominated by few, unstable, pathogenic bacterial lineages that can survive at high densities with protective integrated viruses.

CORAL REEF ECOSYSTEM PROPAGULE RETENTION AND EXPORT UNDER SCENARIOS OF CLIMATE CHANGE (2006-2100) (Abstract ID: 30060)

Propagule transport within and between a global circumtropical array of coral reef habitats (derived from the WRI Reefs at Risk Revisited global database) was investigated using flow-fields from CMIP5 Earth System Models ESM2G RCP4.5 and RCP8.5 developed by the USA NOAA Geophysical Fluid Dynamics Laboratory coupled with Lagrangian particle transport modeling. These models allowed long-term projection of planktonic egg and larval connectivity out to year 2100 using ocean currents realized under plausible scenarios of climate change. Temporal and spatial patterns of propagule connectivity were identified using generalized additive modeling (GAM). Connectivity components of retention and export were separately examined using GAM. The results indicate a positive trend in successful settlement; i.e., the magnitude of connectivity probabilities gradually increases over time. The increase in settlement success was primarily due to increased retention of natal propagules. Mechanistically this appears to be due to a general waning of current velocities over this temporal domain. Sensitivity of results to spawning seasonality and pelagic larval duration were also investigated.

USING PHOTOGRAMMETRY TO QUANTIFY THE CONTRIBUTION OF SIX MORPHOLOGIES OF SCLERACTINIAN CORALS TO THE HABITAT COMPLEXITY IN A REEF: A RUGOSITY INDEX. (Abstract ID: 28756)

Coral reef biodiversity is at risk of declining. The relationship between biodiversity and habitat structural complexity (through surface rugosity - SR) is key to understand, measure, and monitor this decline. Reef-building scleractinian corals enhance biodiversity by increasing the number of three-dimensional structures, influencing key ecological processes such as predation and foraging. However, a comprehensive value of SR for different types of coral morphologies or size classes is still lacking. This study provides a value of SR for six common morphologies of scleractinian corals (branching, corymbose, foliose, massive, tabulate, and staghorn) across two different size classes. We used novel photogrammetric techniques, which enabled the precise reconstruction and measurement of 3D computer models of 108 coral specimens from photographs taken underwater. The staghorn morphology presented the highest value of SR. Branching, corymbose, and foliose morphologies had a significantly lower SR than staghorn corals, however SR did not differ significantly between these three morphs. The lowest values of SR were attributed to massive and tabulate morphs. Additionally, significant differences between size classes were found only for branching, foliose, and tabulate morphologies. Close-range photogrammetry provided a useful non-invasive technique to calculate SR at a high resolution. If incorporated in monitoring programs, this SR index will aid in quantifying the change in habitat complexity in a reef as a result of the shifts in community composition caused by disturbances.

CARBONIC ANHYDRASE ACTIVITY IN THE SYMBIOTIC SEA ANEMONE*ANTHOPLEURA ELEGANTISSIMA* ACROSS A LATITUDINAL GRADIENT (Abstract ID: 29551)

The sea anemone Anthopleura elegantissima occurs in the intertidal zone from Mexico to Alaska. It is symbiotic with two genera of microalgae, the highly productive dinoflagellate Symbiodinium and the less productive chlorophyte Elliptochloris. The enzyme carbonic anhydrase (CA) catalyzes the interconversion of bicarbonate and CO2 and is known to play an important role in delivering CO2 to symbionts embedded deep in host tissues. Symbiont types in anemones are differentially distributed depending on latitude, tidal height, and light level. Anemones containing Symbiodinium are found at lower latitude, higher light environments compared to Elliptochloris-containing anemones that occur at higher latitude and lower light. Anemones in very low light lack symbionts. Previous research found aposymbiotic and Elliptochloris-containing anemones to have similar and low CA activity compared to Symbiodinium-containing anemones. We predicted that anemones collected from lower latitudes would have greater CA activity than anemones of the same symbiotic state at higher latitudes. To test the effect of light on CA, A. elegantissima from the Oregon coast were collected and split into three 30-day treatments: dark, low light, and high light. To test the effects of latitude A. elegantissima were collected from several locations ranging from central Oregon to the Puget Sound. Symbiont density counts and CA assays were performed in triplicate on each anemone. Our results suggest that latitude, symbiont type and density, and light interact to influence CA in A. elegantissima.

BRIDGING THE DIVIDE BETWEEN SYSTEMATIC CONSERVATION PLANNING AND COMMUNITY-BASED CONSERVATION: A PHILIPPINES CASE STUDY (Abstract ID: 30119 | Poster ID: 645)

Systematic conservation planning is playing an increasingly important role in developing marine protected area (MPA) networks that accommodate conflicting needs between conservation and fisheries. Yet, conservation planning continues to fail to inform conservation action in the Coral Triangle, a region of high ecological importance. Failure to implement conservation plans in this region has primarily resulted from inadequate consideration of governance and socioeconomic factors. More specifically, there is a need to develop and evaluate methodologies to accommodate small-scale MPA governance systems and resource access needs of local stakeholders. This case study focuses on Sogod Bay in the Philippines to examine the conservation and fisheries trade-offs of explicitly incorporating marine tenure boundaries and spatial use patterns of small-scale fishers in conservation planning within the context of the Coral Triangle Initiative. The decision-support tool, Marxan with Zones, was applied to develop and evaluate three planning scenarios with increasing levels of complexity, where additional zones and fisheries information were added. Remote sensing data was used to identify priority areas for conservation, while participatory mapping exercises with fishers were conducted in over 100 communities to document the spatial resource patterns and minimize conservation costs. The results of this research illustrates the importance of developing conservation planning approaches within the broader governance and social context of the Coral Triangle.

EFFECTS OF ALGAL OVERGROWTH ON WATER FLOW INTO AND OUT OF CORAL REEFS (Abstract ID: 28905)

Many coral reefs are being overgrown by algae. We studied how algae of different structure (branching vs. mat-forming) affected the flow of water into and out of the

spaces within Hawaiian reefs dominated by branching coral, *Porites compressa*. Such flow carries nutrients, oxygen, and prey to the organisms living in the reef, carries away wastes, and transports released larvae from and settling larvae into reefs. Transects across reefs since 2003 showed dominance in different years by living coral, mat-forming bubble algae, or branching algae on dead coral. Measurements of vertical water velocities into and out of reefs revealed that there was net flow into reefs in concave areas and net flow up out of reefs at convex areas when coral or branching algae dominated, but that flow was stopped when the cover of bubble algae was >60%. Field releases of larval mimics showed that fewer mimics contacted surfaces within reefs (where hydrodynamic forces on larvae are low enough that they can recruit) when there was algal cover, and that bubble algae stops more mimics than branching algae. Thus, algae not only compete with coral, but also can interfere with the recruitment of larvae and the transport of materials to and from the organisms living in the reef.

MOLECULAR PHYLOGENETIC ANALYSIS OF THE SOFT CORAL FAMILY XENIIDAE (OCTOCORALLIA, ALCYONACEA) IN JAPAN AND TAIWAN (Abstract ID: 28322 | Poster ID: 75)

Species in the family Xeniidae are classified by only a small number of morphological characters. Therefore, species identification is quite difficult in this family and the species diversity is still unknown in Asia. Around Oshima Island in Miyazaki, Japan, and Lyudao Island in Taiwan, many soft corals including the Xeniidae inhabit. This study aims to know the species richness and diversity of the Xeniidae there, using molecular phylogenetic analysis. In this study, we collected xeniids including 248 specimens from Oshima isl. and Lyudao Isl. Based on the taxonomic references, we identified 22 species from seven genera (*Anthelia, Cespitularia, Efflatounaria, Heteroxenia, Sansibia, Sympodium, and Xenia*) in the Xeniidae. Fourteen out of 22 species were first records in Asia. In addition, we found total four undescribed species in both islands. We analyzed these samples phylogenetically using a mitochondrial marker (ND2) and a nuclear marker (ITS), together with additional samples of other families which were collected in Oshima isl. Our results revealed that all the seven genera except*Xenia* were monophyletic, indicating that traditional taxonomy based on the morphology reflects the molecular phylogenetic relationships among genera in the Xeniidae. On the other hand, *Xenia* was paraphyletic. More detailed morphological analysis of *Xenia* would be needed. In total, this study revealed high species diversity of the Xeniidae in Japan and Taiwan, which is comparable to that of the Great Barrier Reefs.

THE BUTTERFLYFISHES (CHAETODONTIDAE) CONDITIONS IN RATATOTOK PENINSULA REEF, NORTH SULAWESI PROVINCE, INDONESIA (A MONITORING STUDY: 1996-2012) (Abstract ID: 28051 | Poster ID: 667)

Coral reef can be easily found along the coastline of the Ratatotok Peninsula which integrated in South-East Minahasa, North Sulawesi, Indonesia. For years this area was intensively used by villagers as fishing ground. In this area, a gold mining company PTNMR was operated in 1996 – 2004 and put it's tailing in the seabed of Buyat Bay. Since 1996 to 2012, an intensive monitoring establish by PT Newmont Minahasa Raya (PTNMR) to monitor closely the condition of butterfly fishes in the coastal areas of Ratatotok and Buyat bay, South-East Minahasa region, North Sulawesi, Indonesia. The objective of this study was to describe the butterfly fishes condition before, during, and after PTNMR operation. Butterfly fish can be use as an indicator of the health of coral reef. A Fish Visual Census method was applied for gathering butterfly fish data a long 50 m permanent transect established in four locations at the depth of 3 m and 10 m. All data were collected each year. There were several changes occurred during the monitoring period both on the number of genera and species of butterfly fishes on each study sites. The presences of butterfly fish were varied during the whole monitoring years. There are several factor were identified during this study that could be connected to the fluctuation of butterfly fish conditions. Unsustainable fishing practices (bomb fishing, cyaniding, anchoring, bottom gillnet), Crown of Thorn Starfish attacked, and coral disease weremajor factors that caused the changes in butterfly fish numbers. Keywords: butterfly fish, chaetodontidae, coral reef, ratatotok

SURVEY OF BOAT BASED RECREATIONAL FISHERS IN THE U.S. VIRGIN ISLANDS (Abstract ID: 29518)

Recreational fishing is important to the residents and economy of the United States Virgin Islands (USVI). Government management efforts primarily focus on commercial fisheries in the USVI, largely due to assumptions regarding the relative importance of the recreational fishery and the paucity of data. While recreational fishers fish from the shore as well as boats, data indicate that boat based recreational fishing predominates. This study, conducted in 2014, characterized boat-based recreational fisheries, compared phone and mail survey methods, and determined if the annual vessel registration list maintained by the USVI, Division of Environmental Enforcement, could be used as a frame to survey recreational fishers. Of the 769 boat owners who were randomly selected from the 2013 boat registration list, 378 responded to the surveys. Of these, 38% recreationally fished. More boaters responded to phone surveys (60%) than mail surveys (40%). They fished primarily from their own power boats (81%) with a much smaller percentage fishing from sailboats (16%). Seventy-five percent fished for food and 42% considered themselves subsistence fishers. The primary families of fish targeted were the Scombridae (54%), Lutjanidae (49%), Coryphaenidae (37%), and Serranidae (32%). The most common recreational fishing technique was trolling. Fishers took an average of 3.3 trips per month with an average length of 4.4 hrs. The USVI vessel registration database is an important tool for surveying recreational fishermen, but it can only be used effectively if the information is updated annually.

USING REGRESSION-BASED EFFECT SIZE META-ANALYSIS TO INVESTIGATE CORAL RESPONSES TO CLIMATE CHANGE (Abstract ID: 28422)

Attempts to quantify the effects of ocean acidification and warming (OAW) on scleractinian corals provide a growing body of response measurements. However, placing empirical results into an ecological context is difficult, owing to large variations that reflect both natural heterogeneity and scientific bias. This study addresses the heterogeneity of climate change induced changes in coral recruitment and calcification. To discern scientific bias and identify drivers of the remaining heterogeneity, 100 publications were analyzed using a combination of weighted mixed effects meta-regression and factorial effect size meta analysis. A linear model was applied to quantify the variation caused by differing stress levels across studies. The least squares predictions were then used to standardize individual study outcomes and weighted effect size meta-analysis was performed on original and standardized outcomes separately. Increased temperature significantly reduced larval survival, while ocean acidification hampered settlement and calcification. Differences were based on biological traits (genera and life cycle stage), environmental factors (climate and various characteristics of the collection site) and experimental design (presence of particulate food, filter size and experimental duration). Standardizing outcomes to linear model predictions proved useful in discerning strong sources of scientific bias. This approach can inform policy and management on changes in coral community structure associated with the expected future intensification of OAW.

ECOLOGICAL DYNAMICS OF REEF CORALS ACROSS THE MIDDLE PLEISTOCENE CLIMATE TRANSITION (Abstract ID: 28287)

The Middle – Late Pleistocene (~1.2 – 0.125 Ma) climate is characterized by the intensification of cyclic oscillations between glacial (cool, low sea level) and interglacial (warm, high sea level) intervals. The fossil record, preserving a long-term dataset of coral reef communities composed of extant species, reveals that reef corals have persisted throughout the Pleistocene despite these frequent and dramatic climate fluctuations, some of which are similar in magnitude to projected modern climate change. Although it provides a valuable ecologic resource, the Middle to Late Pleistocene history of coral reef ecology remains largely unexplored, particularly in relation to climate changes during this critical period of reef expansion, and persistence, into modern reef ecosystems. Using deep drill core records through modern and historical reef environments, our work integrates taxonomic and trait-based paleontological data with paleoclimate and sedimentological interpretations as well as extant reef ecology to quantitatively evaluate the temporal distribution of coral taxa and functional traits in relation to past climate and environmental transitions. The overarching goal is to highlight the effects of past global climate and environmental change on reef community taxonomic and trait composition during the Middle to Late Pleistocene, when modern reef systems developed. These

findings enhance our understanding of the range in response of coral community structure and functional traits to rapid climate change and biogeographic variability.

THE IMPORTANCE OF SOCIO-ECONOMIC INFORMATION FOR EFFECTIVE MANAGEMENT OF PROTECTED AREAS IN SIX STATES IN PALAU (Abstract ID: 28574)

Often, studies on the effectiveness and sustainability of protected areas focus heavily on biological and ecological information. While it is important to ascertain the progress of these protected areas according to such indicators, equally important is assessing progress towards socio-economic factors. Socio-economic information can provide resource managers essential information regarding perceived socio-economic trends and changes as they relate to these conservation areas. Globally, little information is known regarding the socio-economic impacts of conservation areas as well as the role of such areas in achieving human well-being outcomes. This study draws on a socio-economic study of communities living nearby to conservation areas in six States across Palau. Using a household questionnaire, a variety of socio-economic information was collected on: socio-demographics, livelihood activities and income, food and water security, and views of and support levels for the conservation areas. Overall, a number of indicators were also developed to assess the role of these conservation areas in improving livelihood outcomes in these States in Palau. Preliminary results of this study suggest that continuous socio-economic monitoring, educational outreach along with stricter law enforcement is necessary to ensure the success of these conservation areas in achieving human well-being management objectives. This study builds on a limited knowledge base of empirical socio-economic data the findings of which can be relevant to other small island developing states and elsewhere.

EFFECTS OF SEDIMENTATION ON REEF-BUILDING SCLERACTINIAN CORALS IN SOUTHEAST FLORIDA (Abstract ID: 28920 | Poster ID: 436)

Southeast Florida coral reefs can be characterized as marginal coral reefs. Close proximity to overdeveloped land causes significant biological effects on nearshore coral reefs and coral-containing hardbottom communities. Sedimentation is arguably the most significant adverse impact on coral communities; and although natural events such as major storms can lead to sedimentation impacts, monitoring data from coastal projects in southeast Florida indicate that sedimentation is much higher when enhanced by anthropogenic activities. Large amounts of sediments are introduced to coastal water in southeast Florida annually from fixed inlets, dredging, and nourishment. Amounts of material and validity of data are discussed. Anthropogenically introduced sediments also bring a considerable amount of nutrients to nearshore reefs and hardbottom communities. Sediments of different granulometric content have varying effects on coral reef biota. Sedimentation of fine material has more extended and inhibitive effects on corals than coarser sand, and the effect on benthic communities expressed in smothering, mortality, and partial mortality is also higher. Mechanisms and consequences of such sedimentation are discussed. Measuring effects of turbidity and sedimentation is a challenging task in coral reefs and nearshore hardbottom habitats. The currently used nephelometric measurements of turbidity in Florida and sediment traps for sedimentation do not correlate with sediment deposition on reef biota. Methods of monitoring and evaluations of impact are discussed.

ELECTROLYSIS, HALOGEN OXIDIZING AGENTS AND REEF RESTORATION (Abstract ID: 28902 | Poster ID: 469)

Applications for electrolysis of seawater include preventing fouling in piping systems and conditioning water for aquaculture. Electrolysis creates a variety of chlorine-produced oxidants that attack essential proteins of living tissues and react with organic materials, metals and other compounds (e.g., ammonia, nitrites, organic amines). The Biorock® process developed by Dr. T.J. Goreau and Dr. W. Hilbertz uses electrolysis for restoring reefs and enhancing growth and survival of corals. It is believed to act by elevating pH and alkalinity at the cathode and/or by reducing enzymatic costs for pumping cations and anions across cell membranes by providing an appropriate electrical gradient (Goreau, 2013). We hypothesize that a third mechanism for enhancing organisms may also be involved: inhibition of microorganisms by halogen oxidizing agents. Applying Faraday's laws of electrolysis for a system at 8.0 amperes and 90% efficiency gives an estimated ~230 grams of chlorine per day (equivalent to ~70 liters of gas at STP). In nature (i.e., an open system), diffuse follow-on reaction products (including hypochlorous acid, hypochlorite, hypobromous acid and hypobromite ion) may benefit macrobiota via inactivation of microbial pathogens and competitors, or by other improvements to water quality, as long as concentrations are too low to harm larger, ecotoxilogically less vulnerable organisms.

PHYSICAL PROCESSES CONTROLLING CONNECTIVITY AMONG SOUTH FLORIDA CORAL REEFS AND PATHWAYS OF UPSTREAM RIVER INFLUENCE (Abstract ID: 29587)

A combination of in situ and satellite measurements and high resolution modeling are combined to study the connectivity among South Florida coral reef systems and the influence of upstream nutrient sources on local water properties. The study area covers the mesophotic Pulley Ridge reef on the Southwest Florida Shelf and the Florida Keys shallow reef system, extending to the Dry Tortugas. An unprecedented 3-year time series of currents and temperature reveals dominant circulation modes and pathways that are influenced by both shelf dynamics and the proximity of the large scale Loop Current (LC) - Florida Current (FC) system. Modulations of the LC/FC system, changes in LC core (from extended to retracted position in the Gulf of Mexico) and eddy passages were key factors in the connectivity pathways. Moreover, two major episodes of Mississippi water offshore removal took place during the study period, with in situ data quantifying their low-salinity signal around Pulley Ridge and the Florida Keys. Such episodes directly influence water quality around coral reefs in the Northern Gulf of Mexico, but also have remote impacts. For the first time, thick lenses of low salinity and high in nutrient content waters of Mississippi River origin were traced hundreds of kilometers away from the Mississippi Delta to the South Florida reefs, under both flooding and below normal Mississippi discharge conditions. A targeted numerical study elucidated the related processes and revealed complex pathways connecting remote reef systems in the Gulf of Mexico.

A DECADE OF CORAL REEF BENTHIC COMMUNITY DYNAMICS FROM HIGH SPATIAL RESOLUTION SATELLITE IMAGERY AND FIELD SURVEY DATA (Abstract ID: 29054)

To develop, implement and evaluate management strategies coral reef scientists and managers require information to understand reefs and how they are changing. Maps showing the distribution of corals, algae, sand, rubble and rock are an essential component of this information. While annual point and plot based benthic community data have been collected over decades in long term ecological studies in marine environments, there has been limited work focussed on the creation and analysis of time series benthic community maps of coral reefs. This study presents a set of benthic community maps created from georeferenced field data in combination with high spatial resolution (< 2 m pixels) satellite imagery. Imagery and field data were collected annually over a 14 year period (2002-2015) for Heron Reef, Great Barrier Reef, Australia. A semi-automated object based classification was applied to pre-processed satellite imagery. Two thirds of the benthic field data was used as calibration data for the classification, while the remainder was used to validate the output maps. This method generated benthic community maps for each of the 14 years with overall accuracies ranging between 50-75%. Our output time series of coral reef benthic community maps provides the necessary information for assessment and understanding of the spatial and temporal dynamics of the reef environment at Heron reef. The methods developed provide the basis for building on existing field surveys at other locations to deliver long term benthic community maps for additional coastal and coral reef environments.

A RE-EVALUATION OF NET COMMUNITY CALCIFICATION SENSITIVITY TO CARBONATE SATURATION STATE (Abstract ID: 28383)

Ocean acidification-induced declines in carbonate mineral saturation are concerning for coral reefs due to their presumed effects on coral reef community calcification. To improve forecasts of coral reef trajectories in an acidifying ocean, an increasing number of studies aim to elucidate the sensitivity of coral reef community calcification to carbonate saturation states. Many of these studies employ a simple linear regression approach. However, recent studies have highlighted the complications of interpreting these simple linear regressions, including the dependence of saturation state on calcification, the abil-

ity of many corals to up-regulate their internal calcification environments, and calcification rate dependence on photosynthesis leading to collinearity with other environmental variables. Here we re-evaluate a globally distributed set of published coral reef studies using statistical approaches capable of handling multiple environmental predictors (light, temperature, saturation state) to better quantify net community calcification sensitivity to carbonate mineral saturation state. This approach better constrains the range of community-scale calcification sensitivities to carbonate mineral saturation state and improves our ability to forecast OA effects on coral reef communities.

A FUNCTIONAL MODEL OF BLACK BAND DISEASE BASED ON TRANSCRIPTOMICS (Abstract ID: 28353)

Black Band Disease is a persistent, pan geographic, coral disease. Despite its prevalence, the activities of the mat microbiota in the disease process remain unknown. We used metatranscriptomics to unravel the roles of the major mat constituents in the disease process in the coral Favia sp. from the Red Sea. We enriched and sequenced mRNA of the microbial consortium of the mat in BBD affected corals and compared with healthy tissues and healthy colonies. Identification of metabolically active bacteria of the disease front provides us with a glance at the microbial structure and function of the various constituents. Results showed a shift in bacterial composition and function in BBD affected colonies as compared with unaffected colonies. In the mat, members of Cyanobacteria, Bacteroidetes and Firmicutes bacterial phyla are numerous and are metabolically active. These groups are absent in healthy colonies of the same species. The Adenosylhomocysteinase enzyme produced by cyanobacteria and involved in cyanotoxin production, is the most transcribed gene in the band consortium. Members of the Bacilli class found in the mat transcribed high levels of Rhodanase, an enzyme responsible for cyanide detoxification. Vibrios are abundant in several pathogenic and non-pathogenic forms, and are highly active, most of them transcribing the thiamine ABC transporter. Desulfovibrio desulfuricans is the primary producer of sulfide in the band. These data offer a look at the varied functions of the microbiota in the disease mat enabling us to develop a functional model of this disease.

3D PRINTED REEFS AS AN ENRICHMENT FOR NATURAL HABITATS (Abstract ID: 28855)

Increased insight into the complexity of reef functioning calls for new reef restoration strategies including updated geometrical designs and materials. In a pilot project in the Larvotto marine protected area (MPA) in Monaco, the new technology of 3D printing is currently being tested. Artificial reef (AR) units are being installed to enhance the rocky reef system of the MPA by creating habitat for sessile organisms and fish. Early 2016, a series of preparatory tests on material characteristics were carried out using 3D printed reef units and samples to prepare for an AR installation in the Larvotto MPA in summer 2016. As part of these tests and long-term pilot, samples of the printed material have been installed in the MPA in 2015 which are being monitored for material and ecological development. Once the AR units are installed, they will be monitored for their ecological performance during at least a 2 year monitoring period, along with regular monitoring of printed material samples. 3D printing technology is a valuable addition to existing reef restoration strategies allowing for construction of complex, tailored designs, use of native material such as sand and facilitating easy development, testing and adaptation of prototypes, materials and design processes. In combination with thorough studies on reef building processes and assessment of cost-effective proven production methods, 3D printed reefs are expected to allow for successful up scaling in projects. This article describes the 3D printing technique, design process and monitoring schedule of the pilot program.

QUANTIFICATION OF CORAL BLEACHING AND CATASTROPHIC MORTALITY OF REEF-BUILDING CORALS ALONG WEST HAWAI'I ISLAND (Abstract ID: 29019)

In 2015, leeward reefs of Hawai'i Island suffered catastrophic coral mortality due to widespread and severe coral bleaching, resulting in more than 90% mortality for massive coral species, *Porites evermanni*, and 70% mortality for locally ubiquitous coral species, *Pocillopora meandrina*. The prevalence of coral bleaching and related health conditions (e.g. algal turf overgrowth) were quantified in October 2015 at 8 permanent monitoring transects and at 7 newly established shallow reef transects from South Kona to North Kohala. Benthic cover was compared from 2003 through 2016 for 24 permanent monitoring sites using standardized image analyses. Video transects during and after the bleaching event and citizen science reports from the local Eyes of the Reef Network provided supporting qualitative information. Survey results indicated unprecedented levels of coral bleaching for the majority of common coral species, resulting in a significant decline in total coral cover. Results from these surveys were used to inform state managers working to identify and apply effective management actions for reef recovery.

WHERE ARE THE CRUSTACEA ON CORAL REEFS, AND DOES IT MATTER? (Abstract ID: 28503)

Crustaceans are one of the most widespread and speciose marine groups, performing key ecological roles in many ecosystems. They are one of the most influential taxa in aquatic trophic networks, providing a major connection between primary production and higher consumers. To investigate the role of crustaceans in the trophic network of a coral reef, abundance and biomass of crustaceans within different coral reef microhabitats was examined. Dead coral was by far the most important microhabitat type in terms of crustacean abundance (mean of 7838 individuals 100 cm−2) and biomass (0.75 g m−2, wet weight), producing values up to 3 orders of magnitude greater than the least important microhabitats (the epilithic algal matrix and fine-branching live coral). The importance of crustaceans and dead reef substrates to the trophic structure of coral reefs was further investigated using wrasses (Family: Labridae), one of the most abundant and diverse fish families on coral reefs. Gut content analyses found crustaceans in the guts of 93 % of the 30 wrasse genera investigated, with a distinct division between micro- and macro-crustacean predators: wrasses <80 mm standard length (SL) were predominantly micro-crustacean feeders, while wrasses >90 mm SL displayed a predominantly macro-crustacean diet. Micro-crustacean predators tended to specialise on specific crustacean taxa, whereas macro-crustacean predators consumed mostly brachyurans. These findings highlight the value of complex dead coral microhabitats and the importance of crustaceans in coral reef trophic networks.

ENHANCING AND RESTORING CORAL REEFS FOR COASTAL DEFENCE: A SOFT SOLUTION CASE EXAMPLE FROM GRENADA (Abstract ID: 29853)

Coral reefs naturally protect coasts from erosion and flooding by attenuating wave energy and supplying sediment found on adjacent beaches. However, declines in their condition coupled with increasing rates of global sea level rise are jeopardizing communities and coastal infrastructure. The typical hard engineering solution to this problem is to construct breakwaters or groins is to protect high value shorelines even in places where shallow reef crests occur. Softer solutions such as coral restoration offer a cost effective alternative to traditional engineered solutions in some places. Degraded reefs can be structurally restored using both biological and physical techniques including the use of structural materials. However, few reef restoration projects have been designed with coastal protection as a primary objective and guidelines are lacking. Here we discuss the process of designing a low crested breakwater structure to restore the wave breaking properties of a degraded reef crest in Grenada. Structures were designed to withstand hurricane wave forces, have a minimum 30 year lifespan, and promote coralline algae and coral growth. A total of 30 meters of pilot structures were constructed in 2015 and installed on a high energy back reef environment using local materials, community labour, and a specially built shallow water barge. Monitoring results of the pilot structures suggest they perform similar to traditional submerged breakwaters but have significantly greater ecological benefits including the potential to enhance natural reef accretionary processes.

SCALING UP CONSERVATION AND MANAGEMENT OF SMALL ISLAND NATIONS THROUGH SCIENCE-BASED LEARNING NETWORKS AND DATA PLATFORMS (Abstract ID: 30076)

The Eastern Caribbean (EC) islands are linked through coral reef ecosystems, oceanic currents, and a rich cultural heritage. To safeguard the region's biodiversity, restore fishery stocks and address climate change concerns, ECMMAN (Climate-Resilient Eastern Caribbean Marine Managed Areas Network) developed a Learning Network of partners from 6 EC countries to collect and share data on biodiversity, socioeconomics and marine management effectiveness. Results are available on CaribNode - an open access, decision-support web platform with geospatial tools to map the status of the islands resources (caribnode.org) and as easily understood Coral Reef Report Cards, pioneered by Healthy Reefs Initiative. Results from a new analysis included data from 277 reef surveys, benthic habitat maps and 44 MMAs. Reef condition examined by geographic zones and in/outside MMAs varied but several common findings included: Acropora palmata corals are recovering since 2005; More fleshy seaweed is found on leeward reefs and near settlements; Diadema populations are high; few large fish occur; and reefs with complex structure or protection had higher fish abundance. Small island nations rely heavily on their coastal resources yet chronic local impacts and climate change impacts threaten their limited resources. The 44 MMAs protect 5% of the shelf area, highlighting the need to strategically increase protection to meet the Caribbean Challenge's 20% goal by 2020. The resilience of these ecosystems will depend on effective local management and adopting transboundary, adaptive management strategies.

THERMAL STRESS AGGRAVATES THE EFFECT OF OCEAN ACIDIFICATION ON FOUR CARIBBEAN REEF-BUILDING CORALS (Abstract ID: 28443)

Climate change leads to rising sea surface temperatures and changes in carbon chemistry that result in decreasing ocean pH and aragonite saturation state. Low pH has been shown to reduce calcification rates of symbiotic corals, but its impact under conditions of elevated light stress during thermal stress events is not known yet. Light absorbed in excess and increased photodamage is the main cause of the loss of photosynthetic activity during thermal stress, so the role of the light stress in this response should not be ignored. In this study we exposed four species of Caribbean reef-building corals Pseudodiploria strigosa, Orbicella faveolata, Montastraea cavernosa and O. annularis to heat stress conditions (pH8.1-32 °C); low pH (pH7.9-30 °C); and their combined effect (pH7.9-32 °C) for 10 days under natural light. Exposure to +2 °C in summer induced a loss of pigmentation, symbionts and photosynthetic activity and calcification due to increased accumulation of damage in Symbiodinium (decline in Fv/Fm). Low pH did not adversely affect coral photosynthesis and pigmentation, and only a slight decrease in the calcification rates was observed in P. strigosa. However, the combined effect of thermal stress and low pH significantly exacerbated the loss of calcification in P. strigosa and O. annularis, but not in the other two species. Considering the predicted changes for the ocean in the different global change scenarios, coral reefs are seriously threatened due to their adverse impact on the physiology of this symbiosis and carbon production, even prior to undergoing bleaching.

GENE EXPRESSION UNDER THERMAL STRESS AND THE POTENTIAL FOR THERMAL ACCLIMATION IN A SYMBIOTIC CNIDARIAN (Abstract ID: 28069)

Despite its central importance for coral-reef ecosystems, the cnidarian-dinoflagellate symbiosis remains poorly understood at the genetic, molecular, and cellular levels. To explore the mechanisms underlying this symbiosis and their responses to stress, we used RNA-Seq to identify genes that are differentially expressed under thermal stress in the sea-anemone model system Aiptasia. The clonal line CC7 (containing its endogenous Clade A Symbiodinium symbiont), an aposymbiotic line derived from CC7, and the line CC7-SSB01 (aposymbiotic CC7 reinfected with a clonal Clade B Symbiodinium strain) were thermally stressed at 34°C and sampled at intervals for 10 d. We observed a strong upregulation in the mRNAs for heat-shock and other stress-response proteins at early time points (0-12 h) but distinct expression patterns when the symbiotic anemones began to bleach (≥48 h). The expression patterns were similar in all three lines, indicating that most, at least, are not related specifically to the presence of the endosymbionts. When we compared differentially expressed genes in Aiptasia to those identified by others in corals, up to 70% were found to be concordantly expressed in both hosts in response to thermal stress. We are also examining how prior thermal history influences the tolerance of symbiotic Aiptasia to subsequent thermal stress, finding that acclimation at elevated but sub-bleaching temperatures (30-32°C) decreases the rate and severity of bleaching during subsequent thermal stress at 34°C. Future studies will analyze gene expression in thermally acclimated animals.

TOWARDS PROTECTING THE GREAT BARRIER REEF FROM LAND-BASED POLLUTION (Abstract ID: 28280)

The Great Barrier Reef (GBR) is an iconic coral reef system extending over 2,000 km along the north-east coast of Australia. Global recognition of its Outstanding Universal Value resulted in the listing of the 348,000 km2 GBR World Heritage Area (WHA) by UNESCO in 1981. Despite various levels of national and international protection, the condition of GBR ecosystems has deteriorated over the past decades, with land-based pollution from the adjacent watershed being a major cause for this decline. Moreover, poor water quality from land-based runoff remains a major threat to the future condition of the GBR WHA. To address land-based pollution, the Australian and Queensland Governments have implemented a range of policy initiatives since 2003. Here, we discuss the evidence on (i) the decline in GBR water quality and ecosystem condition, and (ii) the effectiveness of the existing initiatives to reduce discharge of land-based pollutants into GBR waters. We conclude that recent efforts in the GBR watershed to reduce land-based pollution are not sufficient to protect the GBR ecosystems from declining water quality within the aspired timeframes. To increase the likelihood of protecting GBR ecosystems from land-based pollution into the future, we identify incremental improvements that can be made to current approaches, and highlight potential transformational changes to current agricultural land uses, that may also provide guidance for the management of other marine ecosystems around the world.

GLOBAL TARGETS FOR MARINE RESERVE COVERAGE ON UNREGULATED CORAL REEFS (Abstract ID: 27886)

Marine reserves are the primary tool for biodiversity conservation, but increasingly relied upon also to manage fisheries, particularly in complex and over-exploited tropical systems. While global agreements define a minimum percentage of habitats to be protected for more effective conservation, associated impacts on fisheries are unclear and could weaken food security if over-exploitation increases outside reserves. Here, we present a systematic analysis of the ability of reserves to rebuild complex and unregulated fisheries, and we identify maximum reserve coverages for biodiversity conservation that are unlikely to impair long-term fishery performance. We find that large reserves, exporting less than 30% of larvae, might impair fishery performance, but that realistic reserve network designs should benefit most complex fisheries. Specifically on coral reefs, where larval dispersal distances of many target species are likely to exceed their home ranges as adults, negative fishery impacts are unlikely. Even the modest UN Aichi target of 10% reserve coverage can then help rebuild depleted catch. However, 20-30% reserve coverage will likely deliver better biodiversity outcomes while not harming healthy fisheries and allowing for more efficient rebuilding of substantially depleted fish populations and catch.

IS THE RED SEA CORAL *STYLOPHORA PISTILLATA* ALREADY PREPARED FOR FUTURE OCEAN CONDITIONS? (Abstract ID: 28629)

Migration of corals through a hot water bottleneck in the Southern Red Sea, following the last glacial period, has led to a situation where corals in the Northern Red Sea now

express high thermal thresholds while living at suboptimal lower temperatures. We tested to what extent the coral*Stylophora pistillata* is capable of resisting future ocean conditions as a result of this selection. We combined chlorophyll fluorescence analysis, biochemical markers, and respirometry with state of the art correlative TEM and NanoSIMS techniques to obtain a holistic picture on the physiological impact of the isolated and combined effects of temperature (+5°C) and pH (-0.3 units relative to ambient). After 2 months, most physiological variables were either unaffected or improved by the combined effect of high temperature and low pH. Net oxygen production effectively doubled due to changes in photochemistry and higher symbiont pigmentation, and we observed higher values for holobiont productivity with P:R ratios of up to 1.72. No significant change in the activity of enzymatic antioxidants or daily calcification was detected. NanoSIMS data revealed that carbon and nitrogen assimilation in the symbiont and host gastrodermis are negatively affected by isolated temperature stress. However, no difference in the proportion of symbiont-derived carbon in the host lipids was observed and neither protein nor overall carbohydrate content was affected in either partner. Our data point to a high degree of physiological resistance of this coral to the expected global trends in ocean conditions and emphasize the urgency of reducing local stressors in this region.

TRANSGENERATIONAL EFFECTS OF TEMPERATURE STRESS: IMPACTS ON AND BEYOND CORAL REPRODUCTION (Abstract ID: 28172)

As oceans warm, corals are exposed to temperatures outside their normal range, causing stress to the organism. Previous studies demonstrate that temperature stress negatively impacts the reproductive output of corals. However, the transgenerational impacts of temperature stress on corals are unknown. Additionally, corals are expected to experience warmer temperatures months before the spawning season, when their gametes are still developing. To assess transgenerational effects of temperature stress during gametogenesis, colonies of *Montastraea cavernosa* were exposed to elevated temperature for two weeks four months prior to spawning, and then returned to the reef. At spawning, gametes from temperature stressed and unstressed corals were combined to create four fertilization crosses: unstressed eggs and sperm, unstressed eggs with stressed sperm, stressed eggs with unstressed sperm, and stressed eggs and sperm. Larvae and juveniles from each cross were kept at ambient (29°C) and elevated (31°C) temperatures. Larvae and juveniles originating from stressed gametes had lower survival. When temperature stress occurred during both gametogenesis and larval or juvenile development, the decrease in larval and juvenile survival was exacerbated. These results demonstrate that temperature stress during gametogenesis has latent effects on larval and juvenile survival.

HOW TIME AND SPACE INFLUENCE LIFE-HISTORY TRAITS IN CORAL COMMUNITIES (Abstract ID: 29230)

Scleractinian corals have persisted under environmental shifts that have occurred over tens of thousands of years, and meanwhile evolved a vast array of life history traits. Today's rates of change, however, are much higher and organisms have to be able to adapt a lot faster. In the first example we use a spatially explicit, individual-based model to explore three important life history traits of corals (i.e. heat resistance, competitiveness and growth performance) under various environmental settings. Additionally, we estimate the required adaptation potential for a coral community in order to survive this century under different IPCC climate scenarios. Our findings show that (i) direct competition among corals seems to become a subordinate trait, and (ii) under the RCP4.5 scenario (2 °C temperature increase) a a simulated coral community would only maintain 5-15 % cover if it could adapt to Climate Change within 20-30 years, which is highly unlikely. The resulting community would then mainly consist of temperature-tolerant and some fast-growing species. In the current project we monitor environmental conditions of distinct habitat types at 7 stations along Heron Island Reef continuously for two years, and respiration rates of typical benthic communities at two stations seasonally. Based on these data we will use a variation of the individual-based modelling approach above to analyze the importance of particular life history traits in benthic communities at distinct locations, measure their productivity rates and estimate their trajectories under Climate Change scenarios.

INCIDENCE AND CAUSE OF PINK/PURPLE PIGMENTATION SYNDROME IN GENUS *PORITES* IN OKINAWA ISLAND. (Abstract ID: 28549 | Poster ID: 158)

Specific pink color abnormality in genus *Porites* has been reported from many regions in recent years. Pink color abnormality has various types; such as pink lines, pink spots, pink patches, pink bands. Together, these are called pink pigmentation syndrome (PPS), and a pink fluorescent color is seen in all types. However, there has been little research from Okinawa on PPS. Moreover, not only PPS but also purple pigmentation is seen in Okinawan Porites (combined PPuPS). In this study, we investigated the frequency of PPuPS in Okinawa, and focused on defining a cause(s) for this syndrome. We examined 17 sites around Okinawa Island by taking images of more than 30 Porites colonies per site. PPuPS level, presence of epibionts, and presence of macroalgae were checked from photographs. Also, we calculated PPuPS incidence and examined relationships of PPuPS to epibionts and algae by multi-dimensional scaling (MDS) and principal component analysis (PCA). Most sites showed approximately 80% incidence of PPS and approximately 50% incidence of purple pigmentation syndrome (PuPS). However, sites at southern Okinawa (Odo, Oujima) uniquely showed a very lowly incidence of PPuPS (PPS: 37.5-48.6%, PuPS: 9.4-13.5%). Both sites also showed a relatively low quantity of epibionts and macroalgae, but we could not statistically determine the possible causes of color abnormality to epibionts or macroalgae. It may be possible clarify a cause of PPuPS by investigating these two sites in more detail.

BALANCING AREA AND EFFECTIVENESS: MPA EXPANSION VS. MANAGEMENT ENFORCEMENT IN MEETING GLOBAL CONSERVATION TARGETS (Abstract ID: 27800)

Protected area coverage has expanded rapidly in recent decades, yet there has been considerable debate surrounding the ability of protected areas to conserve biodiversity through establishment alone. While protected areas set geographical boundaries, enforcement of the laws and regulations within them is a fundamental driver of user compliance and reserve success, which highlights the importance of active management. However, non-compliance is widespread and threatens the objectives and benefits which protected areas are intended to provide. This is particularly true in marine environments, which have experienced an estimated 513% expansion since 1990 but have documented continued shortfalls in management and illegal resource extraction. With international targets (i.e. Aichi Target 11) calling for large increases in marine protected area (MPA) coverage, a critical question arises: to achieve maximum conservation benefits are limited funds best spent on expanding the current MPA network or managing existing MPAs to a higher degree? Here, we explore this question in no-take MPAs by modelling fisheries and conservation benefits in a non-spatially distributed, unconstrained system. We then apply this model to the Great Barrier Reef Marine Park to retrospectively analyse the 2004 re-zoning expansion and its effectiveness in protecting the commercially and ecologically valuable species, the coral trout (Plectropomus leopardus).

REEF CONSTRUCTION AND DECONSTRUCTION IN THE FLORIDA KEYS, U.S.A. (Abstract ID: 28170)

Mirroring global trends, coral reefs in the Florida Keys have lost significant coral cover since the 1970s. The main reef-building process, coral calcification, has undoubtedly slowed on a region-wide scale resulting from declines in cover of massive head corals and the large, branching *Acropora* spp. In examining the coral record, however, it remains to be determined whether coral growth rates (linear extension or calcification) have systematically changed over the past two centuries. We present spatial and temporal patterns in existing and new data on coral growth rates for four reef-building species in the Florida Keys. We also examine the deconstruction side of the equation by quantifying decadal-scale rates of reef erosion by completing a study started in 1998 wherein dead coral heads were fitted with erosion-resistant cement and stainless-steel markers. In 2015, we revisited the site and found an average of 94 mm (std dev: 56) of reef elevation loss at 28 stations during the 17.3 year period. With the estimated rate of reef erosion at 5.4 mm per year, reefs that are presently devoid of coral cover in the Florida Keys are rapidly being eaten away by grazers and bioeroders. Conservation efforts intended to increase the abundance of parrotfish may, therefore, have adverse results in the Florida Keys and in other areas where herbivores are not targeted fisheries. Managing reefs with respect to physical resilience, in addition to ecological resilience, could optimize the expenditure of resources in conserving reefs and the services they provide.

QUANTIFYING THE ACCUMULATION OF MARINE DEBRIS NEAR CORAL REEFS USING AERIAL IMAGERY AND GIS ANALYSIS (Abstract ID: 28822 | Poster ID: 411)

Hawaii's coral reef ecosystem is a valuable natural resource that supports a unique and diverse host of marine life, providing sustenance to Hawaii and its inhabitants. The Great Tsunami of 2011 had devastating effects on Japan, dispersing millions of tons of debris, some of which drifted great distances across the Pacific Ocean via wind and current. This Japanese tsunami marine debris (JTMD), which includes an assortment of plastics, buoys, vessels and large docks, continues to make its way into Hawaiian waters. Debris poses serious risk to Hawaii's fragile reefs, including entanglement of reef dwelling organisms, introduction of aquatic invasive species, and physical breakage, particularly from large debris like vessels. In order to characterize the ecological consequences of JTMD, it is important to understand and quantify where and what debris is accumulating. Given the remoteness of coastlines in the Hawaiian Islands, large scale surveillance efforts are needed to identify these "hotspots" of marine debris. This project collected high-resolution aerial imagery and then, using ArcGIS software, identified and characterized marine debris densities along Hawaiian shores. This innovative technique allows analysts to identify hotspots across the state and their association with coral reefs. The project method could also prove useful in other sites or to quantify different targets, such as sedimentation or coastal wildlife. The study's findings will inform resource management on the part of federal and state government and local nonprofit and community groups.

THE GENUS WAMINOA ASSOCIATED WITH PALYTHOA HELIODISCUS (Abstract ID: 29253 | Poster ID: 62)

*Waminoa* species live on soft and stony corals, and can increase in number until they cover the entire host, disturbing the host's photosynthesis. Furthermore, *Waminoa* species feed on coral mucus and steal food from host corals. Therefore the study *Waminoa* species can be considered important in understanding coral reef ecosystems. There are two genera of symbiotic dinoflagellates within *Waminoa* species, *Symbiodinium* and *Amphidinium*. Previous studies have considered that *Symbiodinium* is acquired from host corals but phylogenetic analyses have revealed that the *Symbiodinium* of*Waminoa* spp. are different from the *Symbiodinium* of the host corals. Instead, the *Symbiodinium* and *Amphidinium* of *Waminoa* species are acquired via vertical transmission. In this study in Okinawa, Japan, we found a *Waminoa* species on the zoantharian *Palythoa heliodiscus* with a white line on the dorsal side, different from described species. Additionally, to understand if the *Symbiodinium* within *Waminoa* sp. are from the host *P. heliodiscus* or not, the internal transcribed spacer region of ribosomal DNA (ITS-rDNA) sequences of *Symbiodinium* from *Waminoa* sp. and *P. heliodiscus*were compared. These results represent the first described report of*Waminoa* sp. on *Palythoa*.

ADAPTIVE STRATEGIES OF SCLERACTINIAN CORALS (Abstract ID: 29093)

One of the major goals of ecology is to identify the way organisms meet the challenge of existence in different environments. One approach, termed the Universal Adaptive Strategy Theory (UAST), has been hypothesised to apply to all creatures on the tree of life, including corals. The UAST reflects the means by which an organism allocates resources between acquisition, maintenance or regeneration. However, previous attempts to classify scleractinian corals according to UAST have been inconclusive, perhaps because the traits used in these analyses were not chosen following the principles set out in the theory. Here, we test the ubiquity of UAST theory using a recently compiled online database of coral traits. The application of UAST will lead to improved insight into the variation of responses in coral assemblages. Subsequently, this will facilitate better informed management decision-making by allowing predicting the response of dynamic reef systems to different environmental conditions.

USING POLICY AND CORAL RESTORATION ACTION TO MITIGATE AND PREVENT INVASIONS BY AQUATIC ALIENS ON HAWAI'I'S CORAL REEFS (Abstract ID: 28949 | Poster ID: 621)

The introduction of aquatic invasive species (AIS) threatens Hawai'i's coral species diversity and existence, especially through vectors of transfer such as biofouling of ballast water and ship hulls. A single AIS can have the ability to monopolize food, space resources, and cause the endangerment or extinction of endemic coral. The Hawaiian Islands are the most isolated archipelago in the world as they are 2500 miles away from the nearest continent and 1000 miles from the nearest islands. This allows for spectacular speciation that occurs nowhere else. For example, more than 20% of coral species are endemic to Hawai'i. Not only do corals provide food and refuge for other organisms inhabiting coral reefs, they also provide important recreational, scenic, and in turn, economic opportunities. Presently, around 350 AIS have been found in the Hawaiian Islands, and the majority have been unintentionally brought over through the maritime industry. For example, 80% of consumable goods in Hawai'i are imported by ships. As a result, the frequency at which a single species of AIS may visit the state is relatively high thus constantly posing the threat of invasion. Though Hawai'i coral reefs are at a severe disadvantage because of AIS introductions, hope is not lost. This presentation will focus on the current state of affairs with regards to coral-reef-associated AIS preventative and reactive measures including coral restoration projects and biofouling regulation development/implementation for the State of Hawai'i.

SOCIO-ECOLOGICAL IMPLICATION OF HUMAN MULTI-IMPACTS ON CORAL REEF ECOSYSTEM AND ~ PALAU AS A CASE STUDY~ (Abstract ID: 28985)

Coral reef ecosystem supplies a number of ecosystem services that sustain human society. However, the ongoing rapid and multiple environmental changes caused by human activities are suspected to disturb the dynamic equilibrium and result in the loss of present reef ecosystem. The loss of reef ecosystems will have a critical impact in island society where socio-ecological interactions are highly linked. This study focus on the reef ecosystem in Palau. We first conducted surveys around coral reefs on different environment parameters including nutrient, chla, POC/N, carbonate chemistry and evaluated the correlation with the coral community structure. We found that aragonite saturation, nutrient condition and turbidity are the 3 main factors that define coral community structure. Then, we focus on the two stress, waste water discharge and ocean acidification (OA), and evaluate the potential ongoing impacts on Palau reef ecosystem. Results demonstrated that both OA and excess nutrient discharge is already causing degradation to the coral community, which may lead to the decrease of benefit such as coastal protection and tourism. These results suggest local management such as sewage treatment, together with the consideration of climate change, will be essential for management of Palau coral reef ecosystem.

PHYLOGENY AND DIVERSITY OF SEA PENS IN SOUTHERN JAPAN (Abstract ID: 29358 | Poster ID: 64)

Sea pens are important components of sandy and muddy marine ecosystems from shallow to deep waters around the world. However, our understanding of the phylogenetic relationships of sea pens is very poor and classification is confused and difficult. Despite

high biodiversity in the Ryukyu Islands (southern Japan), records of sea pens are very few. In this study, we collected sea pen specimens from the Ryukyu Islands and Sagami Bay and analyzed the phylogenies of two mitochondorial protein coding genes, MutS and the ND2 region. Consequently, family Virgulariidae was not a monophyetic group, nor was Pennatulidae or Kophobelemnidae. As well,*Pteroeides* with acrozooids formed a monophyly sister to a clade of*Pteroeides* without acrozooids and these two groups were separated by high genetic distance. As *Sclerobelemnon* (Kophobelemnidae) formed a paraphyletic group including *Cavernulina* (Veretillidae), this suggests that*Cavernulina* is derived from *Sclerobelemnon*. The traditional classification scheme is not reflected in phylogenetic relationships and therefore requires revisions. Additionally, from this research, we report the first records of*Scytalium* (Virgulariidae) and *Echinoptilum* (Echinoptilidae) in the Ryukyu Islands. Overall, we have confirmed at least 12 species-groups in Okinawa . It is clear more research is needed on this understudied group in Okinawa.

MANIPULATING CORAL-ALGAL SYMBIOSES TO ASSESS THE RELATIVE CONTRIBUTION OF SYMBIONT IDENTITY VS. HOST ACCLIMATIZATION IN DETERMINING HOLOBIONT THERMOTOLERANCE. (Abstract ID: 29607)

Reef corals that have recovered from thermal bleaching often show increased tolerance to thermal stress, but it is not clear how much of this increased thermotolerance is due to changes in algal symbiont communities vs. acclimatization of the coral host. This question can be addressed by manipulating corals to host different symbiont assemblages. Replicate cores from 4 colonies of the Caribbean coral Siderastrea siderea were heat-bleached (by exposure to 32 C for 10 days), or herbicide-bleached (by exposure to DCMU for 10 days) and allowed to recover under high or low light at 26 C (resulting in recovery with symbiont assemblages that varied in their abundance of Symbiodinium D1a). This gave replicate corals of the same genotype that either had or had not undergone thermal acclimatization (as measured by tag-based RNA seq) and either had or had not changed their algal symbiont communities (as measured by an actin-based qPCR assay). Corals were common-gardened under ambient light conditions for 1 month before being exposed to a second period of thermal stress (32 C for 10 days). Thermotolerance was measured as a combination of photochemical efficiency (using chlorophyll fluorometry) and symbiont loss (using qPCR). This approach allows us to tease apart the contribution of host acclimatization and shifts in symbiont assemblage to holobiont thermotolerance. As reefs continue to warm over the coming decades, understanding the relative importance of different mechanisms in changing coral thermotolerance is critical to managing reefs to maximize coral survival trajectories.

HYPERSPECTRAL IMAGING OF CORALS IN LABORATORY CONDITIONS (Abstract ID: 28678 | Poster ID: 546)

Spectral signatures of corals, seagrasses, macroalgae and other coral reef habitats are needed for remote sensing as well as for physiological and ecological studies. The necessary reflectance spectra have been collected both in situ and in laboratory conditions. Fiber optics probes were used to collect the data. However, coloration of corals may vary significantly within a coral colony. Such variability is common also in the case of macroalgae. Collecting spectral data from all these differently colored parts with a fiber optics is a tedious task and the total studied area still covers just a small fraction of the colony. We designed a scanning bench for hyperspectral imaging spectrometer HySpex that allows to collect high resolution imagery in laboratory and outdoors (not in marine environment). Spectral range of HySpex is 410.6-989.2 nm, spectral resolution 2.5 nm and the imagery is collected with high spatial resolution. For example, with the 30 cm lens the spatial resolution is around 0.1 mm. Also a 100 cm lens is available and the altitude of the spectrometer above the study object is adjustable. We tested performance of the system by collecting imagery of live (fluorescent and non-fluorescent species) and dead corals in an shallow water aquarium which was placed under the imaging spectrometer. The imagery revealed remarkable variability in coral reflectance at subcentimeter scale. This instrument can be used in multitude of coral reef studies, but the potential range of applications is wide.

SHELL AND PEARL CHROMATIC VARIATION IN PINCTADA MARGARITIFERA AMONG CORAL REEF ENVIRONMENTS IN FRENCH POLYNESIA (Abstract ID: 27862)

The black-lipped pearl oyster Pinctada margaritifera inhabits subtropical and tropical coral reefs, and is particularly abundant in the lagoons of French Polynesia. Its aquaculture is developed in lagoons of 25 atolls and islands widely geographically spread over 14° longitude and therefore subject to disparate environmental regimes. This species exhibits a remarkable wide range of colors of the shell and cultured pearls. The factors that contribute to the color determination include the oyster phenotype (genetic), the culture zone (environment) and their interactions. To understand the origin of the phenotypic color variations, several approaches have been approached, both at a genetic and a macro-environmental level. Specific crosses are set up to show the clear pattern of phenotypic inheritance of flesh and shell color mutation consistent with Mendelian inheritance and expression of a single-locus, dominant trait. Relations to environmental variation were studied using first generation P. margaritifera families, produced through hatchery system, to test in field for their potential. For pearl color, classification tree model could be built to predict, according to shell phenotype and culture location, the color and darkness level of harvested pearls. Lustre was shown to be more influenced by the environment than by phenotype. All these preliminary results have implications for a better understanding of P. margaritifera adaptation to the environment, associated with its phenotypic plasticity.

GROUNDWATER-ASSOCIATED NUTRIENTS IMPACT BENTHIC PRODCUTIVITY AND NUTRIENT UPTAKE ACROSS A REEF FLAT IN MAUNALUA BAY, HAWAI'I (Abstract ID: 28765)

Submarine groundwater discharge (SGD) can contain high nutrient concentrations from sources that include agricultural activities, urbanization, and leaky septic systems. Coral reef systems are especially sensitive to increases in nutrient concentrations which can change community composition, productivity, and nutrient uptake by the benthos. In this study we used salinity as a proxy to map groundwater-derived nutrients, across a coastal reef in Maunalua Bay, Oahu over time. Nutrient relationships were derived by sampling synoptically along an onshore to offshore transect from the SGD seeps. Using in situ benthic chambers, we mapped the C-uptake and dissolved inorganic nitrogen (DIN) uptake by different species across the reef. We also mapped algal species distributions, and quantified the contribution of different species to benthic productivity and DIN uptake across the reef. Results indicate that DIN uptake and productivity vary among species and vary spatially across the reef. This spatial pattern of nutrient uptake and productivity in turn affects the concentration of important chemical constituents of the water transiting the reef system, which has implications for reef resilience and health.

COMPETITION AND ITS CONSEQUENCES ON CHANGING CARIBBEAN CORAL REEFS (Abstract ID: 29817)

Coral cover on Caribbean coral reefs has dramatically declined over the last several decades accompanied by an increase in "weedy" coral species, gorgonians and sponges. Loss of coral cover and diversity can lead to decreased structural complexity, fish populations and decreased coral recruitment, ultimately reducing productivity, ecosystem function and the recreational value of reefs. Thus, understanding the outcomes of competitive interactions between corals and other benthic species in the context of changing community structure on Caribbean coral reefs is critical. We combined observational field surveys and a common garden experiment to understand the frequency, outcome, and consequences of competition between corals, sponges, encrusting gorgonians and zoanthids. We found consistent competitive outcomes between species. Interestingly, we observed that multiple species grew most when paired with a conspecific competitor. Importantly, we found that several increasingly common benthic species are able to rapidly outcompete key reef building corals. Our data provide insights regarding the mechanisms driving observed shifts in benthic community structure on Caribbean reefs. Further, these results provide some of the first contemporary empirical data that can be used to develop competitive models to predict shifts in coral reef community composition and reef function.

DIRECT FINANCING OF CONSERVAITON ON THE GROUND: A MODEL FOR PALAU AND BEYOND (Abstract ID: 29694)

Local managers and conservation leaders – the cornerstone of marine management success – must have dependable and adequate resources, and freedom from political interference. We report out on a public/private partnership model that directly finances ground-level efforts by these key actors. The model incorporates simple incentives and the checks and balances necessary to effectively implement programs. It also aligns

user fee sources with private funds, risk capital sources, and technologies that reduce costs and increase management efficacy. Palau has a network of marine protected areas (MPAs) and conservation programs that rely on bottom-up implementation. Our model caters to local managers, who must juggle a suite of challenges related to enforcement of no-take zones and ever-changing local politics. These conservation leaders also require financing to develop local capacity, engage community outreach, and use technology effectively. We seek to reduce their time spent navigating political landscapes and securing adequate funding and related resources, allowing more time for key management operations. Moreover, our approach rewards effective management and leadership. Model implementation is proceeding under a formal Memorandum of Understanding (MoU) with the Republic of Palau. The effort is aligned with overarching regional initiatives, including the Micronesia Challenge, Protected Area Networks, and Palau's emerging National Marine Sanctuary.

IMPACTS OF NEAR SHORE STRESSORS ON FERTILIZATION SUCCESS IN THE STONY CORAL, *MONTIPORA CAPITATA* (Abstract ID: 28818 | Poster ID: 171)

In Hawaii, runoff and thermal stress are some of the main physical stressors on coral reef communities. Successful reproduction and recruitment is important in promoting reef resilience and recovery. While the impacts of sediment, salinity, and temperature on adult corals have been extensively studied, their effects on fertilization of Hawaiian corals remain poorly understood. In this study, we tested the hypotheses that fertilization would be negatively affected by high sediment concentrations, low salinity, and high temperature. In June and July 2015, we collected bundles of sperm and eggs from the dominant Hawaiian coral, *Montipora capitata*, and determined fertilization success in various treatments and found that fertilization success differed among treatments. Fertilization success significantly decreased in both the low salinity and high temperature treatments, however, it did not differ with high sediment loads. These results suggest that fertilization of *Montipora capitata* can be successful under high sediment concentrations, but is negatively affected under anomalously high temperature or low salinity. Kaneohe Bay has a long environmental history of high sediment loads and further studies are needed to ascertain if these corals are locally adapted to suspended sediment and are better able to successfully reproduce under such harsh conditions.

AGENT BASED MODELLING AS A TOOL TO MANAGE DREDGING IMAPCT ON CORAL SPAWNING (Abstract ID: 28614)

Turbidity and sedimentation generated by dredging and dredge material disposal can seriously affect coral reproduction during spawning periods. Numerical modelling can be used as a powerful tool to predict and manage the risk of impacts. Dredge plume modelling predicts the plume dispersion and associated turbidity and sedimentation rates, and simultaneous agent based modelling is used to predict the pathways of released gametes and connectivity between reefs on a regional scale. Combined with set tolerance limits, the modelling can be used to predict the level of impacts from a given programme, and scenario type modelling can be used to optimise the dredging plan to minimise impacts. Taking this a step further, a reliable forecast model provides the opportunity to make informed proactive and adaptive management decisions of the dredging during a spawning period to minimise the impact on the coral gametes. The presentation will show examples of dredge plume and coral spawn modelling in Western Australia and discuss how this can be used to proactively manage the risks of impacts. The study was carried out using DHI MIKE Agent Based Modelling (ABM) tool. This integrates hydrodynamic, wave, sediment transport and the ABM models to define the dredge plume dispersion and concurrent behaviour of coral larvae in response to the environment. Examples of management measures will be provided and discussed.

A SYSTEMATIC REVISION OF *SYMBIODINIUM*: "CLADES" ARE GENERA (Abstract ID: 29647)

Twenty-five years have passed since the first phylogenetic data revealed that members of the dinoflagellate 'genus' Symbiodinium comprised highly divergent lineages. Hundreds of published papers on cnidarian-dinoflagellate symbioses confirm genetic variation within this microalgal group is both evolutionarily broad and highly diverse. Traditionally, these divergent lineages have been referred to in the literature as "Clades." Although many researchers recognize the extent of diversity within each Clade, all too often these designations are still used and discussed in ways that suggest they are equivalent to species. However, various lines of evidence indicate that most Clades contain numerous ecologically and physiologically distinct entities ('types' or 'sub-clades'), many of which represent reproductively isolated species. Recent efforts have begun to populate each Clade with formally described taxa, but there remain hundreds of entities that merit unique binomials. As the community moves forward revising Symbiodinium systematics, the imperative question is whether the informal Clade structure effectively organizes this species diversity in a hierarchical framework. Do Clade designations promote or rather hinder scientific discourse and the advancement of knowledge? As emerging evidence from comparative genomics further clarifies the phylogenetic relationships among Symbiodinium, we argue that Clades have outlived their usefulness and should be replaced with generic designations that more accurately reflect their taxonomic rank.

RELATIONSHIPS BETWEEN THE ABUNDANCE OF BUTTERFLYFISHES AND CORAL COMMUNITIES IN THE REEF AREAS OF TUTICORIN REGION, GULF OF MANNAR, INDIA (Abstract ID: 28744)

Reef fishes play a vital role in any reef ecosystem and butterflyfishes are in close association with corals. Despite their ecological importance, butterflyfishes are poorly studied and documented in Gulf of Mannar, India. Here we report the relationship between the coral growth forms and abundance of butterflyfishes in four islands of Tuticorin region of Gulf of Mannar namely Vaan, Koswari, Kariyachalli and Vilanguchalli islands. Live coral cover, coral diversity, coral growth form, butterfish abundance and diversity were assessed during 2014. Live coral cover was found to be between 17.7±1.45 and 37.24±2.54%. Visual census using belt transects was done to assess the fish communities and 5 butterflyfish species belonging to the genus Chaetodon were noticed. Among the 5 species, Chaetodon collare and C.octofasciatus were found to be dominant. Highest abundance of butterflyfishes was recorded in Kariyachalli Island with 117 50/m2 where the percentage of live coral was also highest (37.24%). The abundance of C.octofasciatus and C.collare showed significant correlation with live coral cover. The total Chaetodontidae density strongly correlated with the scleractinian coral cover and with the cover of branching corals .The results suggest the existence of strong links between chaetodontids and the cover of scleractinian corals. Further studies are needed to assess the behavioural and spatial distribution of these fishes in Gulf of mannar to get the baseline information for the better management.

CORAL SETTLEMENT, SURVIVABILITY, AND DIVERSITY IN A HEAVILY STRESSED SUB-OPTIMAL URBAN REEF ENVIRONMENT IN THE FIJI ISLANDS (Abstract ID: 27793)

A relic inshore reef ecosystem located 400 meters from the Fijian capital City of Suva and adjacent industrial area was monitored monthly from July 2014 to July 2015 for coral cover, recruitment rates, sedimentation rates, light intensity, temperature, salinity, and dissolved oxygen magnitudes. Five permanent quadrats, five settlement tile racks, five sediment traps, and two light and temperature loggers were deployed in this site, and in a control site with a similar depth profile and located offshore. Despite a major sewage spill disaster in Suva Harbour in December 2014, the stressed inshore site recorded higher coral species diversity and similar species abundances in comparison to the offshore site. A significant decrease in coral cover was observed between July 2014 (27.10%) to January 2015 (20.33%) in this site, however, no significant decrease was seen in July 2015 (18.47%). Coral spat abundance on artificial substrata (6720 cm2 per site) was similar for both sites except for Family Poritidae; with relatively similar total yearly spat abundance between sites: 106 spat inshore, 132 spat offshore. Annual sedimentation was significantly higher in the inshore site (657.14 grams), compared to the offshore site (371.52 grams). Particulate Organic Matter (POM) was also significantly higher in the inshore location (107.51 grams), and (43.37 grams) for the offshore site. Mean light Intensity was significantly lower for the inshore site (69.81 lum/ft2) compared to the offshore site (239.26 lum/ft2). Mean ambient site temperature was consistently similar for the inshore and offshore sites; 26.87 and 26.86 degrees Celsius respectively.

CORAL COLONIZATION ON REEF BALLS AT RATATOTOK COASTAL ZONE IN NORTH SULAWESI PROVINCE OF INDONESIA (Abstract ID: 27981 | Poster ID: 668)

Enhancing the produtivity of reef area by using artificial reef methods has been recently used by coral reef aurthorities throughout the world. Such program is also adopted by Indonesian reef communities. Reef Balls deployment was one of some coral reef management activities that being used in Indonesia. Ratatotok coastal area at North Sulawesi Province of Indonesia had been chosen for this program. During 1999 to 2001 a total of 2500 reef balls were laid at the bottom of Ratatotok coastal area. Reef Ball is an artificial reef which was made to closely mimicked the natural hard coral substrate. It was originate by PT Newmont Minahasa Raya to use reef balls to increase the productivity of Ratatotok coastal area. After 15 years, various hard corals were found to attach on reef balls. More then 20 genera of hard corals colonized the reef balls. The diameter of these corals were varied between 10 to more 40 cm. Dominant genera found to dominate in the reef balls were Acropora spp, Porites spp, Gardineroseris sp and Favites spp. Base on the result of this study, it seems that reef balls can be adopted as one of promising artifial reefs chich could be used to recover a damaged reef. Keywords : hard coral, colonization, reef ball

HARD CORAL CONDITIONS IN RATATOTOK PENINSULA REEF, SOUTH-EAST MINAHASA, NORTH SULAWESI PROVINCE, INDONESIA. (A MONITORING STUDY: 1996-2012) (Abstract ID: 28049)

Since 1996-2012, an intensive monitoring esthablish by PT Newmont Minahasa Raya (PTNMR) to closely monitor the condition of coral reef in the coastal areas of Ratatotok and Buyat bay, South-East Minahasa region, North Sulawesi, Indonesia. In this area, PTNMR a gold mining company was operated in 1996 – 2004 and put its tailing in the seabed of Buyat Bay. One of coral reef monitoring programs is to monitor of hard coral condition. The objective of this study was to describe the hard coral condition before, during, and after PTNMR operation. A Line Intercept Transect (LIT) method was applied for gathering the hard coral data. Fix permanent transects were established in four location at the depth of 3 m and 10 m. All data were collected each year. There were several changes occurred during the monitoring period both on the number of genera of hard coral and the total coverage of hard coral on each study sites. The percentages of hard coral coverage were varied during the whole monitoring years. There are several factor were identified during this study that could be connected to the fluctuation of hard coral conditions. Fish bombing, bleaching (1997, 2010), Crown of Thorn Starfish attacked (1998), bottom gillnetting, and coral disease were major factors that caused the changes in hard coral. However, it can be concluded that beside such destructive factors mentioned above, the hard coral conditions were stable during the whole monitoring years. Moreover, there were no sign that the sediment from the PTNMR operation have influenced the coral condition these areas. Keywords: coral reef, hard coral, ratatotok

CORAL TRANSPLANTATION ON REEF BALLS AT PUTUS-PUTUS ISLAND COASTAL ZONE, NORTH SULAWESI, INDONESIA (Abstract ID: 29249 | Poster ID: 663)

In 2000 around twenty reef balls were laid at the depth of 8 – 10 m in Putus-pitus Island coastal area. Several little holes were made at each reef ball. Hard coral transplants were attached to these holes. Acropora and Pocilloporids were chosen as transplant considering to their faster growing capabilities compared to other hard corals. Transplants were taken at almost same depths where the reef balls were. The transplant lengths were varied from 5 to 8 cm. At the first ten years 75 % of transplants seemed to grow well. After 11 years the transplants started to die for unknown reason. The Pocilloporids were no more after 12 years. Some table-like Acropora were also started to die and covered by turf algae. After 15 years only three Acropora transplants left. However, these three transplant were succesfully grew. Each of them attained more than 2 m in colony length. All of these Acropora had irregular branch type of growth. As a conclusion, it can be said that Acropora with irregular branch type would adapt perfectly to the reef ball construction. Keywords : reef ball, transpant, Acropora

CORAL BLEACHING IN RATATOTOK PENINSULA AND ITS SURROUNDINGS AREA, SOUTH-EAST MINAHASA, NORTH SULAWESI PROVINCE, INDONESIA (A 15 YEARS MONITORING DATA) (Abstract ID: 28043)

Ratatotok Peninsula and its surrounding areas are integrated to South-East Minahasa District of North Sulawesi Province, Indonesia. 15 years hard coral and sea surface temperature data were collected respectively. In 1997, 2000 and 2010 the surface temperature was noted to rise about 2 – 3 degree of Celsius. The total coverage of hard corals was declined or tent to decline during those years. Although several other causes, i.e. bombing, poisoning, netting and Acanthaster plancii predation, were found also as reasons for coral destruction, bleaching events that occurred in 1997, 2000 and the latest one was occurred in 2010 could be blame as major factor that ruined the reefs in these area. Nevertheless, not all hard corals were affected. Compared to other Indonesian reef which were also affected by coral bleaching, most of coral genera attacked in this study area was the dominant genera, such as Acropora (at Ratatotok Peninsula and Hogow Island) and Galaxea (at Ratatotok Peninsula). It was very obvious that the bleaching events in those years were corresponded by increasing sea temperature. Sea temperature data were collected by using CTD (Conductivity, Temperature, Depth) data logger. However, after several months, it seemed that almost all of coral suffered from bleaching were survived. Strong current was probably the main key for the corals to survive from those bleaching events. Keywords: coral, bleaching, temperature.

EFFECT OF MANGROVE FOREST DISTANCE AND FISHING ON THE ASSEMBLAGE OF TARGETED NURSERY REEF FISHES (Abstract ID: 29287)

Expansion in fishing effort and reduction of adjacent habitats, such as mangrove forests, seriously affects fishery catch in the Philippines. As a consequence, catch and abundance of fishes are reduced significantly. This alarming situation prompts initiatives to explore new insights for fisheries management. Small scale fishing gears in the Philippines heavily target fishes at nearshore habitats. Some of these fishes are nursery species, i.e., juvenile fish growing at mangroves to adult size subsequently move to seaward deeper reef habitats. This study examines the effect of fishing and nursery habitat distance on the assemblage of targeted nursery reef fishes in selected Philippine reefs with varying distances from mangrove forests and subjected to various levels of fishing pressure. Both fishery dependent and fishery independent methods were utilized for this study such as survey interview with fishers and fish visual census, respectively. Initial results of the study stress the importance of gear regulation as a simple yet sound basis for sustainable fisheries together with other synergistic management strategy such as protection of the reef-mangrove continuum and considering the presence and proximity of nursery habitats, such as mangrove forests, in designing Marine Protected Areas (MPAs).

STATE-SPACE MODELLING TO QUANTIFY THE DRIVERS OF CORAL COMMUNITY DYNAMICS OF THE INSHORE GREAT BARRIER REEF (Abstract ID: 28436)

Knowing how different environmental and biological drivers interact to affect coral population abundance trends is critical to understanding the resilience of reefs exposed to multiple pressures. Here, we use a multivariate autoregressive state-space (MARSS) modelling approach based on a density-dependent Gompertz population to model the spatio-temporal trends in coral dynamics for 32 sites sampled over 9 years and spanning ca. 800 km of latitude within the inshore Great Barrier Reef (GBR). The MARSS approach accounts for observational error and environmental stochasticity (process error), while also handling missing values, irregular spaced and autocorrelated data and the high spatial and temporal variation typically encountered in coral community time-series.

A range of MARSS models were fitted, and water clarity and storm history emerged as key drivers of the expected underlying coral cover. The best-fit model also suggested that the dynamics of the 32 reefs was best explained using a spatial population structure of 4 distinct Natural Resource Management regions (NRMs). The underlying NRM-specific coral cover trends revealed 3 distinct spatio-temporal patterns over the 9 year period: high and stable in Mackay, low and stable in Burdekin; and decrease in both the Wet Tropics and Fitzroy regions. The MARSS approach helped to identify the key environmental drivers of coral reef dynamics of the ecologically distinct regions: information crucial for the prioritisation of cost-effective management actions for reefs exposed to regional-specific anthropogenic pressures.

## USING COASTAL ECOSYSTEM SERVICES TO MITIGATE HUMAN AND CORAL REEF PATHOGENS (Abstract ID: 28411)

Diseases that impact both human and coral reef health represent critical management challenges in rapidly developing coastal environments. To date, natural filtration services provided by seagrass, mangrove and bivalve ecosystems have not been examined as practical management tools for moderating runoff containing pathogens or disease-causing pollutants. Using next-generation sequencing, we present a series of recent studies suggesting seagrass meadows in a densely populated archipelago of Indonesia regulate seawater microbial communities and significantly reduce microbial pathogens implicated in disease causation in humans and numerous coral reef organisms. Parallel field surveys reveal that globally devastating diseases affecting reef-building corals are significantly lower on reefs adjacent to seagrass meadows compared to reefs without seagrass meadows. These results underscore conceivable strategies for mitigating waterborne marine diseases and highlight novel services provided to humans and coral reefs by intact coastal ecosystems.
